In 81 of 82 patients at risk for a neural tube defect the diagnosis of spina bifida was excluded with ultrasound and thus far normal babies have been born. Amniotic fluid AFP levels were also normal in these pregnancies. The other patient at risk, who had previously been delivered of an infant with anencephaly, was studied because the amniotic fluid AFP was 9 standard deviations above the mean for 16 weeks' gestation. Ultrasound evaluation revealed a small spinal defect in the upper lumbar area (Fig. 6). The defect was delineated with fetoscopy just prior to termination and at abortion an open spinal defect involving the eleventh thoracic vertebra through the second lumbar vertebra was found. It is of interest that the fetus actively moved

both legs during real-time examination, yet this defect most likely would have resulted in paralysis of the lower extremities after birth. Another investigator[4] has recorded active fetal leg movement in a fetus with a neurologically significant spinal defect. This phenomenon is difficult to explain.

Meningoceles, encephaloceles, and myeloceles present ultrasonically as saccular protrusions from the fetal cranium and/or spine.[16, 30] In the presence of oligohydramnios these conditions can be difficult to identify.

Chest. Investigators are beginning to evaluate fetal heart function with echocardiography.[17] We have been able to identify all four valves, observe the interventricular septum, measure chamber size, and calculate various echocardiographic indices.[19] Recently it has been possible retrospectively to diagnose tricuspid atresia and a hypoplastic right ventricle with echocardiographic studies.[19] There is little doubt that soon it will be possible consistently to measure systolic time intervals and also to identify some cardiac anomalies in utero such as hypoplastic ventricles, atretic valves, and ventricular septal defects.

Certain surgically correctable intrathoracic defects can be identified in late pregnancy with ultrasound. For instance, a large diaphragmatic hernia will present

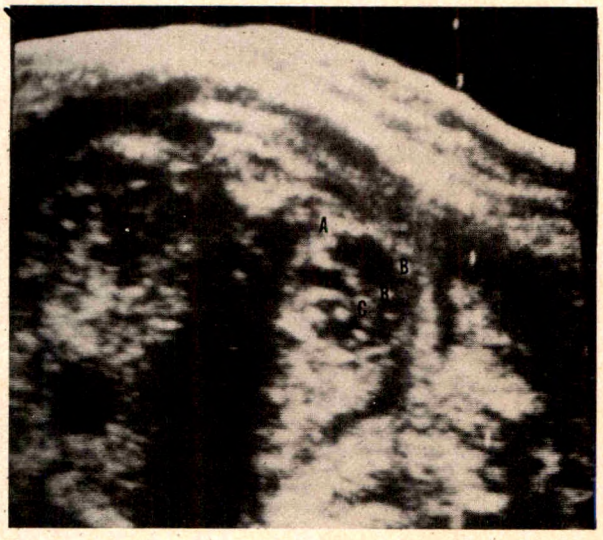

Fig. 12. Normal fetal kidneys. Internal structure is well demonstrated. *A:* Cortex; *B:* arcuate arteries; *C:* columns.

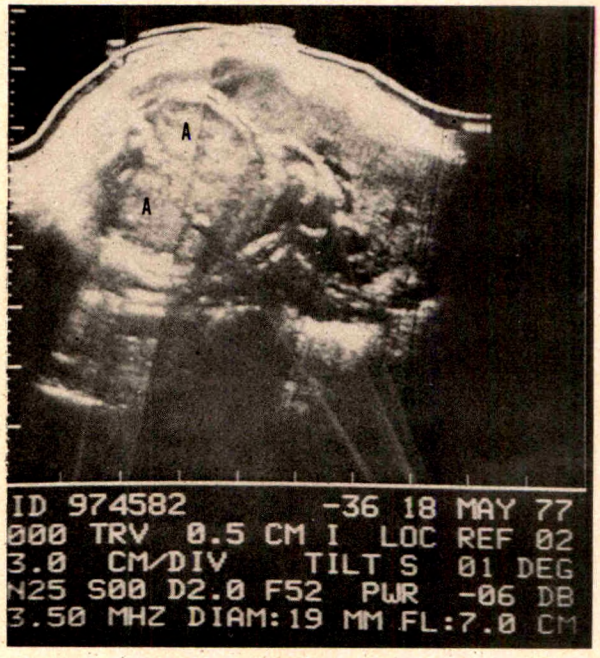

Fig. 13. Enlarged kidneys in 28 week fetus who had classic infantile polycystic kidneys *(A)* at birth.

as an echo-spared area within the chest next to the heart (Fig. 7). A transverse scan (Fig. 8) at the level of the diaphragm can reveal the defect. Since the mortality rate is high if this condition is unsuspected, prenatal diagnosis can be lifesaving to an affected infant because surgical correction of the defect can be instituted immediately after birth. We have diagnosed diaphragmatic hernia in a diabetic patient referred for evaluation of clinical polyhydramnios.[33] In another patient a posterior thoracic cyst was identified in a fetus prior to intrauterine death. At postmortem examination the cyst was of enteric origin.

The configuration and capacity of the chest can be evaluated with ultrasound. Real-time ultrasound offers the viewer a dynamic two-dimensional picture of fetal chest movement, a parameter which may have prognostic significance in high-risk pregnancies.[23] Real-time examination of the chest wall may also be useful in anomalous conditions resulting in pulmonary hypoplasia. We have examined nine second-trimester patients who previously had been delivered of infants with abnormal thoracic findings. Three fetuses were at 25% risk for either thoracochondrodystrophy (Charcot-Levin syndrome) (one case), or asphyxiant thoracic dysplasia (two cases). The other six patients had been delivered of fetuses with pulmonary hypoplasia. In each case the thoracic configuration was normal and the diameters appropriate for gestational age. Each woman gave birth to a normal infant.

In a patient referred because of polyhydramnios in the third trimester, the chest was found to be small in circumference when compared with the abdomen. During real-time evaluation, the fetus appeared to be making thoracic movements, but the excursions were of very small amplitude. Significant limb reduction was also noted. An infant with thanatophoric dysplasia (dwarfism) was born near term and died within a few hours following birth of respiratory distress.

Abdomen. The measurement of abdominal circumference at the level of the umbilical vein is an invaluable indicator of fetal mass,[6, 35] and the configuration of the abdomen may be an important clue to intra-abdominal pathology. In the presence of a normal volume of amniotic fluid it is generally easy to identify the umbilical cord insertion, therefore enabling the diagnosis of omphalocele and gastroschisis.[24] In patients with high serum or amniotic fluid AFP levels, the cord insertion site requires ultrasonic scrutiny since an omphalocele is often associated with elevated AFP.

Gastrointestinal tract. Ultrasonic findings in fetal gastrointestinal obstruction will depend upon the site of obstruction.[9] Under normal circumstances the fetal stomach appears as a circular echo-spared area in the left upper quadrant of the abdomen (Fig. 9). The intestines are represented by scattered echoes.

Theoretically, in esophageal atresia the stomach may or may not be visible, depending upon whether there is a communication between the trachea and esophagus distal to the obstruction. Also it is feasible that the stomach can secrete enough fluid in the presence of esophageal atresia to distend itself to ultrasonically definable proportions. However, since ultrasound

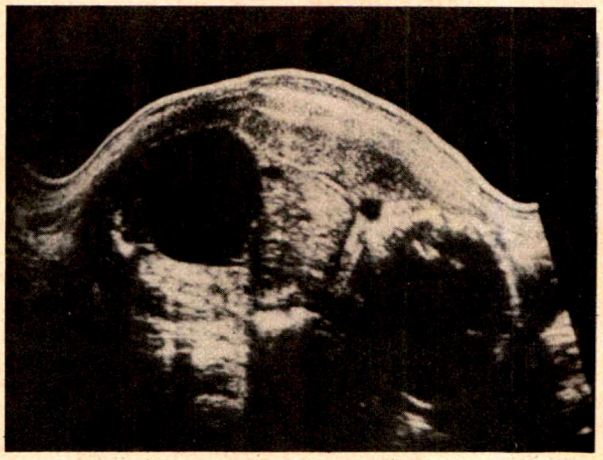

Fig. 14. Large cystic dysplastic kidney.

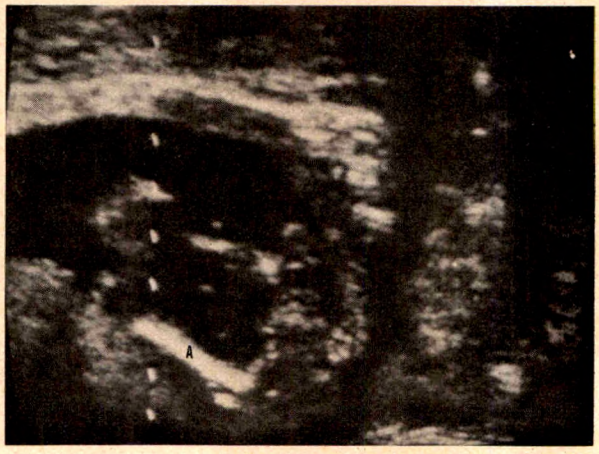

Fig. 15. Left femur *(A)* in normal 18 week fetus.

diagnosis of this condition has yet to be reported, the potential to diagnose esophageal atresia remains in question.

Duodenal atresia results in a markedly distending stomach and duodenum.[21] We have diagnosed this anomaly twice during the study period. In one patient a classic double area of echo sparing was noted (Fig. 10) and in the other a markedly dilated stomach was appreciated.

If multiple distended loops of bowel are noted, the diagnosis of ileus should be considered. One such infant was recently referred to our institution. The in utero ultrasound examination was compatible with the diagnosis of meconium ileus and the subsequent diagnosis of cystic fibrosis. Similar ultrasonic findings have been reported in association with anal atresia.[1]

We have noted dilated loops of bowel in an occasional patient in whom repeat scans did not confirm the original impression. It is suspected that in normal

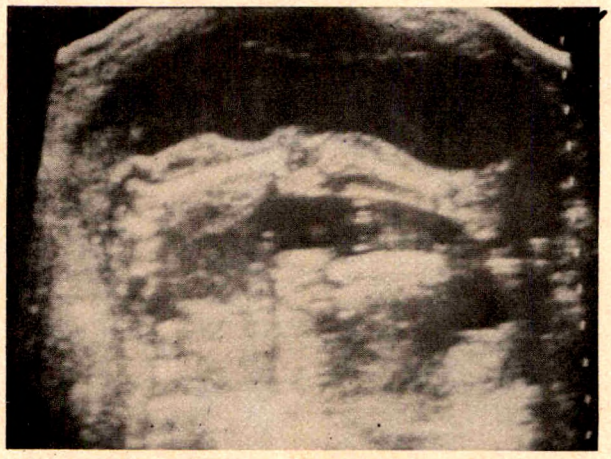

Fig. 16. Entire leg in 32 week fetus.

pregnancies transient dilation of the fetal bowel may be a normal phenomenon. Therefore, diagnosis of gastrointestinal pathology requires demonstration of ultrasonic findings on repeated scans made at least one week apart.

When dealing with an anomaly affecting gross body configuration, it is useful to compare the abdominal circumference with that of the thorax and head. A nomogram (Fig. 11) is presented from data generated in a previous study[35] in which abdominal circumferences were measured at different times in gestation. By using these measurements for reference, the visual impression of abdominal protuberance can be confirmed quantitatively.

Urinary tract. Fetal kidney size and composition can be determined with high-resolution ultrasound equipment (Fig. 12). On a transverse scan at the umbilicus the kidneys will appear as two circular structures on either side of the spine. The size of these kidneys, relative to the size of the fetal abdomen, can be quantitated (Table III). A recently constructed nomogram[15] comparing abdominal circumference with the mean kidney circumference (KC/AC ratio) is presented for reference.

The fetal bladder is frequently identified at 18 weeks and should be visualized in almost all cases after the twentieth week of gestation. Identification of the bladder precludes the diagnosis of nonfunctioning polycystic kidneys or renal agenesis. Failure to visualize the bladder could simply mean the fetus has recently voided. However, if the bladder is not identified by an experienced ultrasonographer after the twentieth week of gestation during scanning sessions spaced over a period of an hour and a half, inadequate renal function should be strongly considered.

We have examined two patients who had previously

Table IV. Postmortem external measurements (in centimeters) in control fetuses and ultrasound measurements in Cases 1 and 2

Measurement	*Controls**	*Case 1*	*Case 2*

†Measured from shoulder to end of third finger.

been delivered of infants with Potter's syndrome due to renal agenesis. There was a 5% risk of recurrence. Normal-sized kidneys and bladder were demonstrated in each fetus at 18 and 20 weeks' gestation, respectively.

Another cause of Potter's phenotype in a stillborn or newborn infant is infantile polycystic kidney disease, an autosomal recessive disorder with a 25% recurrence rate. If the kidney disease process is advanced at birth, the kidneys are large and show innumerable small cysts on the cut surface. These cysts measure about 1 mm in diameter and represent cystic dilatation of the tubules. The expected ultrasound findings are enlarged, solid-appearing kidneys rather than kidneys with many echo-spared areas typical of larger cysts. Some infants with this disease show prolonged survival. In these instances, the kidneys might not show the enlargement typical of the more severe cases.

We have studied with ultrasound four pregnancies in two patients at risk for infantile polycystic kidney disease. One patient was referred at 28 weeks for sonography. Oligohydramnios and markedly enlarged, solid-appearing kidneys (Fig. 13) were noted. KC/AC ratio was 0.48 (control mean, 0.29 ± 0.02 SD). A stillborn infant was delivered at term with nonfunctioning polycystic kidneys (by histology) and pulmonary hypoplasia. Sonography was performed at 18 and 22 weeks of gestation in the patient's following pregnancy. The KC/AC ratios were 0.28 and 0.29. The TIUV was within 1 SD of the mean for gestation and a bladder was seen. The diagnosis of nonfunctioning kidneys was excluded and the pregnancy continued. At term the infant encountered no problems and an intravenous pyelogram appeared normal.

Another patient was delivered of two stillborn infants with the autopsy diagnosis of infantile polycystic disease. Ultrasound evaluation in the twenty-eighth week of gestation revealed bilaterally enlarged solid kidneys (KC/AC ratio = 0.44). The 36 week infant was stillborn with classic Potter's phenotype and kidney pathology. The patient's last pregnancy was interrupted at 24 weeks. The KC/AC ratio at 20 weeks was 0.40 (four standard deviations above the mean). The bladder was not seen; marked oligohydramnios was present, and TIUV measurements were more than three standard deviations below the mean for gestation. Amniotic fluid protein concentration was elevated

to 4.1 g/dl (four to eight times normal). At autopsy, amnion nodosum, Potter's facies, and a contracted bladder were noted. The kidneys were slightly larger than normal but did not show the classic histologic dilation of tubules which is associated with the disease. A cause other than polycystic kidney disease may have led to oligohydramnios in the second trimester (a rare finding). Alternatively, it is possible that dilatation of the tubules had not yet progressed to a stage of histologically recognizable disease although renal function was severely impaired.

Fetal kidney pathology can also occur in patients without a history of fetal anomalies. In a patient scanned at 23 weeks to determine gestational age, enlarged kidneys were noted (KC/AC ratio of 0.45). Multiple large cysts measuring 5 to 15 mm were present within the kidneys and marked oligohydramnios was noted. A stillborn infant was born at 37 weeks with multicystic kidney disease.

Obstruction of the urinary tract will produce ultrasound findings which vary according to the level of obstruction.[27] Urethral strictures, for example, will result in a massively enlarged bladder and hydronephrotic kidneys. In one case in the study urethral stricture was also associated with bilateral dysplastic kidneys, one of which contained a single 10 cm cyst (Fig. 14). It is conceivable that by continuously draining the fetal bladder in cases of posterior urethral valve anomalies the kidneys could be protected from significant hydronephrosis.

Extremities. There are a variety of congenital and acquired conditions which affect the fetal limbs. These include certain forms of short-limbed dysplasia such as Ellis-van Creveld syndrome (chondroectodermal dysplasia) associated with a 25% recurrence rate, thanatophoric dysplasia recurring in 2% of cases, and phocomelia syndromes.

Recent attention has been drawn to the association between ingestion of progestogens in the first trimester of pregnancy and limb reduction defects,[18] although prospective data are lacking.[7] Abnormal limb anatomy may accompany congenital syndromes involving other organ systems. For instance, 12% of infants with Fanconi's anemia (with a 25% recurrence rate) have an absent or hypoplastic radius. This finding in a fetus at risk would strongly suggest the fetus was affected.

It is distinctly feasible to measure limb length and individual bone length in the fetus at risk. Measurement of limb length requires significant operator experience, because tangential sections through the limb will produce measurements that are spuriously short. Real-time ultrasound is useful to quickly delineate the proper plane in which to scan with compound contact equipment. The most accessible bone in the very active second-trimester fetus is the femur (Fig. 15). The humerus also can be outlined, but with more difficulty. Since in most cases the fetal limbs are flexed, measurement of an entire limb is possible only if the fetus is

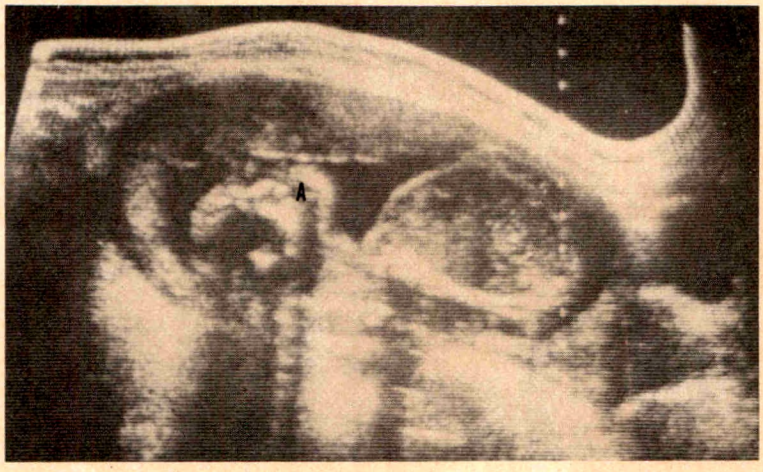

Fig. 21. Roberts syndrome. Premaxillary protuberance *(A)*.

caught by chance with a limb extended (Fig. 16) or when a drug, such as diazepam, is used to diminish fetal movement.

We have obtained control measurements of several limb and individual bone lengths from autopsy data (Table IV). In two of three cases at risk for Ellis-van Creveld syndrome,[22] femoral and humeral lengths were within one standard deviation of the mean. These fetuses were normal at birth. In the other patient the right humerus length and left shoulder-to-hand length were four standard deviations below the mean for gestation. The diagnosis of Ellis-van Creveld syndrome was confirmed on the abortus. In another patient (Fig. 17) who had previously been delivered of a fetus with a poorly defined type of skeletal dysplasia, fetal femur length and arm length were more than four standard deviations below the mean at 23 weeks' gestation. An infant with compomelic dysplasia was born at term. Five other patients were examined who were carriers of other forms of short-limbed dysplasia. Normal limb measurements were obtained (Fig. 18) and the infants were normal at birth. A fetus at risk for Fanconi's anemia was scanned and arm anatomy was found to be normal. This was also confirmed at birth.

Multisystem anomalies. A variety of unclassified multiple anomaly patterns can be diagnosed by ultrasound in the second and third trimesters. Often ascites is a consistent feature. In some cases a scan will demonstrate obvious definable abnormalities, but a definitive diagnosis cannot be made because of similarities to other disease entities. For example, we identified a sac behind the fetal head (Fig. 19) in one second-trimester patient. This finding was compatible with meningocele. However, the stillborn fetus was born with a rare condition, lymphangiectasia, in which the integument is dissected away from the underlying fascia by lymphatic accumulation.

We have also examined four pregnancies at risk for Roberts syndrome, a condition with multiple anomalies including tetraphocomelia, cleft lip and palate, genital hypertrophy, and nonfunctioning kidneys. There is a 25% chance of recurrence. One patient was studied in two successive pregnancies. She had previously been delivered of a stillborn infant with Roberts syndrome. In the next pregnancy she was referred for ultrasound evaluation at 20 weeks. The TIUV was more than four standard deviations below the mean for gestation, marked oligohydramnios was noted, and premaxillary swelling and a protuberant abdomen were noted. The bladder was not visualized and the extremities could not be well evaluated because of the oligohydramnios. Abortion was induced and the fetus was found to have Roberts syndrome with nonfunctioning dysplastic kidneys. In the next pregnancy the TIUV was within normal limits and normal-sized kidneys and bladder were demonstrated. However, markedly shortened femurs were noted along with a virtual absence of the radius and ulna bilaterally (Fig. 20). A protuberant maxilla was also delineated ultrasonically (Fig. 21). All of the above findings were found in the aborted fetus.

Osteogenesis imperfecta congenita is an inherited disease in which pathologic fractures of the long bones, ribs, and cranium are seen in infants born with the condition. Although it was postulated that these fractures could be present in the second trimester, confirmation of this hypothesis was only recently established.[32] They were able to diagnose two cases in 16

fetuses at risk by ultrasound identification of fetal fractures at 19 weeks in conjunction with elevated amniotic fluid pyrophosphate levels.

Comment

The experience with fetal ultrasonography reported here demonstrates the wide range of fetal morphology and function that can now be assessed. By outlining surface anatomy and identifying internal organ anatomy in the fetus, it is possible for the ultrasonographer to diagnose anomalies of the cranium, spine, gastrointestinal tract, urinary tract, and extremities. The predictive capacity of ultrasound is often enhanced when other diagnostic tests such as x-ray examination or serum and amniotic fluid fetospecific protein analysis are used.

This diagnostic capability is greatly enhanced by complete and accurate family and genetic history taking, including detailed information about previous stillborn or aborted fetuses. Many congenital anomalies have recognized modes of inheritance or empiric data for recurrence risks, and information from patient history will identify women who are candidates for early ultrasound examination. Patients exposed to potential teratogens whose effects are known may also benefit from sonographic diagnosis. Furthermore, a discrepancy between uterine size and dates should alert the physician to conditions which have the potential of diagnosis with ultrasound examination.

It must be stressed here that many of the diagnoses described in this review require significant operator experience and that some unusual ultrasonic findings are not necessarily associated with fetal pathology. Fluid-filled loops of bowel can mimic a distended urinary tract, and the fetal abdomen can contain other echo-spared areas which are unassociated with intra-abdominal abnormalities. Every effort must be made to define normal variations in fetal morphology and rule out sources of artifact.

In the future ultrasound technology will progress to a point where three-dimensional imagery will become a reality. With this enhanced capability to delineate entire organs and to measure volumes, it will then be possible more precisely to diagnose specific fetal anomalies.

COMMUNICATIONS IN BRIEF

This section is suitable for reporting results of therapeutic trials, descriptions of new procedures or instruments, and case reports which illustrate a principle. Reports should be limited to seven hundred words and two references. Use of an illustration or table requires a proportionate reduction in total words.

An unusual case of ovarian tumor

E. A. BAMBIRRA
C. P. TAFURI

Department of Pathology, Federal University of Minas Gerais, Belo Horizonte, Brazil

SEVERAL ovarian tumors have been associated with calcification, with or without systemic hypercalcemia: gonadoblastoma, teratoma/dermoid, dysgerminoma.[1] The calcification in these tumors had irregular, confluent, or rounded pattern. In mature cystic teratoma we frequently have bone well formed, but this fact occurred in a focal area.[2] We report a case in which an ovarian osseous cyst was diagnosed at the pathologic examination.

A 42-year-old woman was admitted to the hospital with a pelvic calcified mass. She complained of abdominal pain, especially during sexual intercourse.

An operation was performed and a right ovarian tumor, rounded, with no adhesiveness to neighboring structures, was excised. Pathologic examination of the specimen demonstrated a nodular tumor, 6.0 by 6.0 by 5.0 cm. In cut-surface view this tumor was a cyst with osseous wall and yellow and limpid fluid (Fig. 1). A roentgenographic view demonstrated a consistent osseous matrix in the walls of the cyst (Fig. 2). Routine histologic examination, after decalcification, revealed compact and trabecular mature osseous tissue in lamellar pattern (Fig. 3). Focal hematopoietic marrow tissue within osseous trabeculas was observed. No epithelial cells were identified in the tumor.

The patient was well postoperatively.

In the case reported here we have an unusual ovarian cystic tumor. No similar cases could be found in the literature and we have no histologic elements to determine the pathogenesis of this tumor.

Reprint requests: Eduardo Alves Bambirra, M.D., Rua Turmalina 274, 30.000 Belo Horizonte MG, Brazil.

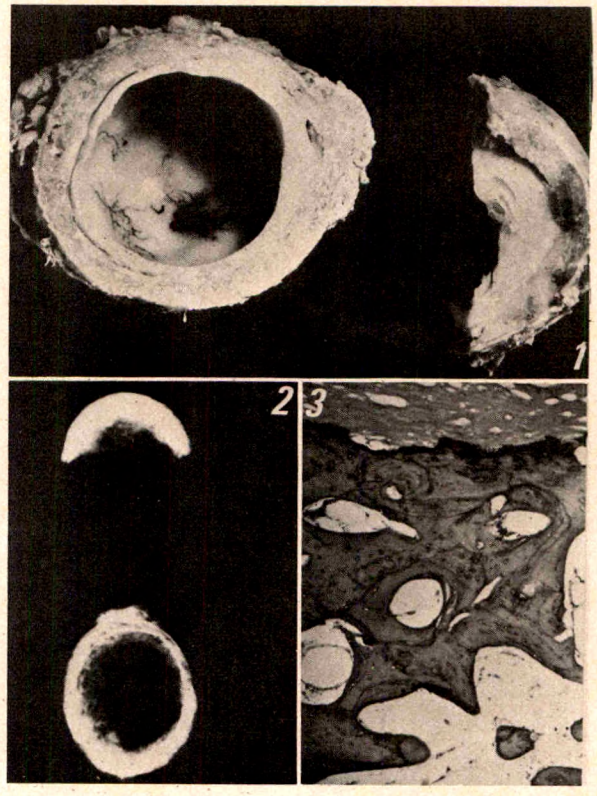

Fig. 1. A macroscopic cut-surface view of the tumor with a large osseous wall. The vascularization in the internal surface is evident.
Fig. 2. Roentgenographic view of the specimen; dense osseous matrix in the walls.

Fetal tachycardia prior to the development of hydrops—Attempted pharmacologic cardioversion: Case report

ALAN M. KLEIN, M.D.
IAN R. HOLZMAN, M.D.
EDWARD M. AUSTIN, M.D.

Departments of Pediatrics and Obstetrics and Gynecology of the University of Pittsburgh School of Medicine, Magee-Women's Hospital, Pittsburgh, Pennsylvania

ALTHOUGH FETAL tachyarrhythmia is now a recognized cause of hydrops, previous case reports have not documented the appearance of the tachycardia prior to the development of hydrops. We report a case of fetal supraventricular tachycardia in which prenatal administration of digoxin and propranolol to the mother failed to convert the arrhythmia or prevent the development of hydrops.

A 30-year-old white woman, gravida 3, para 2, presented at $28^{1}/_{7}$ weeks' gestation complaining of abdominal cramping of 12 hours' duration. Both the physical examination and sonographic examination revealed an active fetus with a heart rate of greater than 240 bpm.

The diagnosis of fetal tachyarrhythmia was made, and the mother was given an intravenous loading dose of digoxin 1.25 mg, followed by maintenance digoxin 0.25 mg by mouth four times a day. Propranolol at a dose of 20 mg, by mouth four times a day, was started 8 hours after the digoxin. Two days later the propranolol dose was increased to 40 mg by mouth four times a day.

After 4½ days with no change in the fetal heart rate, and the mother having physical signs of digoxin toxicity, the digoxin was discontinued and the propranolol tapered. Her fundal height rapidly increased over the next 2 days and polyhydramnios was suspected. Fetal ascites was present on sonographic examination. Because of the immaturity of the fetus, it was decided to continue observation without any active intervention.

At $31^{3}/_{7}$ weeks' gestation, 23 days after the fetal tachycardia was first discovered, the mother was delivered of a 2,250 gram hydropic male infant.

The infant had Apgar scores of 3 and 6 and required tracheal intubation and mechanical ventilation. At birth, the heart rate was 120 bpm but increased to more than 200 bpm on admission to the nursery. Physical examination revealed a hydropic male infant with a single umbilical artery but no other anomalies. The infant was not clearly in congestive heart failure.

Attempts to convert the arrhythmia with digoxin and edrophonium chloride (Tensilon, Roche Laboratories) were unsuccessful. Despite our initial inability to successfully convert the tachyarrhythmia, the infant slowly improved. By the fourth day of life, the infant's weight had decreased to 1,700 grams (the fiftieth percentile for a 31 to 32 week infant). The tachyarrhythmia persisted until oral propranolol was administered, with rapid successful pharmacologic cardioversion. The electrocardiogram was consistent with a Wolf-Parkinson-White type A pattern. At 39 days of life, the infant was discharged with a normal sinus rhythm and in apparent good health.

More than 50 cases of probable fetal tachyarrhythmia have now been reported. Levkoff,[1] from a review of 17 cases, concluded that the tachyarrhythmia is benign and should not be a cause for delivery.

A review of recent case reports, however, does not support the observation that fetal tachyarrhythmia is always benign. A fetal death has been noted in association with a heart rate of 350 bpm.[2] Morbidity has included hydrops and lesser degrees of fetal-maternal water imbalance, early-onset heart failure, hypoglycemia, and prematurity. While no neonatal deaths have been reported, mechanical ventilation and direct current cardioversion have occasionally been necessary for the management of these infants. Digitalis toxicity in the infants has been frequently reported.

Because of the potential fetal and neonatal complications, we attempted to pharmacologically convert the arrhythmia in utero. Digoxin is known to cross the placenta, but there is no information concerning the length of time needed to achieve therapeutic digoxin concentrations in the fetus. The arrhythmia in our patient did not respond to established therapeutic concentrations of digoxin in the neonatal period; thus it is not surprising that we could not convert the arrhythmia in utero.

Propranolol, a β blocker used for the treatment of paroxysmal supraventricular tachycardia, is also known to cross the human placenta. Since propranolol has been reported to adversely affect the fetus at birth, our intent was to withdraw this drug prior to the onset of labor. Why our patient responded quite rapidly to propranolol in the neonatal period but not in utero is unclear. With the known large variation in plasma concentrations following oral administration, it is quite possible that therapeutic concentrations were not achieved in the mother. As with digoxin, there is inadequate knowledge concerning the length of time necessary to achieve a therapeutic fetal tissue concentration.

The fetus in the present case report developed sonographic evidence of ascites within 1 week of admission. At 28 weeks, the risk of neonatal death led us to feel that termination of the pregnancy would be unwise. Weekly sonographic examinations and careful collection of fetal activity data would appear to be a reasonable approach to management in those infants too immature to be delivered. Despite our negative results, we feel that in those cases where termination of

pregnancy is not justified, pharmacologic intervention should be attempted in order to avoid the complication of fetal hydrops.

Uterine rupture with the use of vaginal prostaglandin E_2 suppositories

RAYMOND Z. SANDLER, M.D.
VICTOR K. KNUTZEN, M.D.
CHARLES M. MILANO, M.D.
NORBERT GLEICHER, M.D.

Department of Obstetrics and Gynecology, The Mount Sinai School of Medicine of the City University of New York, New York, New York

THE USE OF prostaglandin E_2 (PGE_2) vaginal suppositories for the termination of pregnancy in the mid trimester, induction of labor in cases of death in utero up to 28 weeks' gestation, and termination of benign molar pregnancy have recently been approved by the Food and Drug Administration (FDA).

A case of spontaneous rupture of the uterus following induction of labor for mid-trimester termination of pregnancy by intravaginal PGE_2 suppositories is reported.

A 23-year-old woman, gravida 3, para 1, presented at 23 weeks' gestation to the prenatal clinic of The Mount Sinai Medical Center, New York.

Termination of pregnancy was recommended on the basis of severe chronic hypertension due to diabetic renal disease and advanced diabetes mellitus (Class F). Uncontrollable hypertension during her previous pregnancy had resulted in a premature delivery at 34 weeks by low-flap transverse cesarean section.

The patient was admitted for evaluation and stabilization; B-scan ultrasonography showed a fetal biparietal diameter of 5.5 cm, consistent with 23 weeks' gestation, and clinical evaluation of uterine size was confirmatory. The blood pressure at the time of admission was 240/120 mm Hg. Funduscopic examination revealed proliferative retinopathy. The remaining physical examination was noncontributory.

The hemoglobin was 9.9 gm/dl, the white blood count was 12,600 with a normal differential, the serum creatinine was 3.9 mg/dl, and electrolytes and coagulation profile were within normal limits. A 24 hour urine collection for protein was 3 gm.

The blood sugar was satisfactorily contolled on 36 units of NPH insulin and the blood pressure was reduced to satisfactory limits on diuretics (spironolactone 250 gm. three times daily and furosemide 40 mg daily).

On day 5 of hospitalization no fetal heart beat could be detected by Doptone or real-time ultrasonography. The fetal lie was transverse within the uterine cavity; the vertex pointed toward the left uterine wall. The height of the fundus was 2 cm beneath the umbilicus. A first vaginal suppository containing 20 mg of PGE_2* was inserted and within 90 minutes regular contractions were noted sufficiently severe to require sedation with 75 mg of meperidine. Despite continuous reinsertion of vaginal suppositories at 4 hourly intervals, a decrease in uterine activity was reported over the following 12 hours.

Clinical re-evaluation at this stage revealed a slight additional decrease in uterine height, with a bulging lower uterine segment and a cervix only 1 to 2 cm dilated with partial effacement. The membranes were thought to have ruptured because clear non–blood-stained fluid drained from the vagina. The patient was asymptomatic apart from mild intermittent lower abdominal pain. The abdomen was soft, with no signs of peritoneal irritation, and oxytocin augmentation at a rate of 16 mμ/min was instigated.

Over the ensuing 24 hours six additional PGE_2 suppositories were inserted, with no change in the cervical dilatation or effacement. At this stage a dilatation and extraction was attempted under general anesthesia. However, no products of conception were noted within the uterine cavity and a defect in the left lateral uterine wall was recognized. On exploratory laparotomy an intact sac containing all products of conception was found floating free within the upper abdomen. A transverse rupture of the lower uterine wall was noted†; no free blood was observed within the peritoneal cavity. A total abdominal hysterectomy was performed and the patient's postoperative course was marked by episodes of electrolyte inbalance. She was discharged on postoperative day 8.

No case of uterine rupture in conjunction with the use of vaginal PGE_2 suppositories has been reported.‡ The recent approval of this drug for the abortion of mid-trimester pregnancies and induction of labor in association with death in utero and benign molar disease by the FDA increases the actuality of the present report.

Prostaglandins increase intrauterine pressure to levels far beyond that of normal labor.[1] The increased risk of uterine rupture after previous cesarean section is well recognized.[2] This case raises questions about the presently unlimited use of vaginal PGE_2 suppositories with previously scarred uteri.

In retrospect it must be assumed that uterine rupture in this case occurred within the first 12 hours of labor, prior to oxytocin stimulation. A decrease in uterine size and cessation of labor represent fairly typical signs of uterine rupture.[2] Other classical signs, such as vaginal bleeding and peritoneal irritation as a conse-

quence of intraperitoneal hemorrhage, severe pain, and unstable vital signs were lacking and resulted in a delay of diagnosis.

If PGE_2 suppositories are to be used in previously scarred uteri, utmost caution must be taken in order to recognize early signs of uterine rupture. The vaginal route of prostaglandin administration may carry the same risk for uterine rupture as has been reported for the intra-amniotic installation.

Preinduction use of laminaria for the unripe cervix

RICHARD LACKRITZ, M.D.
MARK GIBSON, M.D.
FREDRIC D. FRIGOLETTO, JR., M.D.

Department of Obstetrics and Gynecology, Harvard Medical School, Boston Hospital for Women, Boston, Massachusetts

LAMINARIA TENTS have been shown to be safe and effective in causing cervical dilatation and in decreasing the duration of labor when used in the second and third trimesters.[1, 2] We wish to report the results of an ongoing investigation of laminaria as an adjunct to indicated induction of labor in a select population of patients with differing maternal or fetal factors demanding delivery in the face of an uninducible (low Bishop score) cervix.

The study group were inpatients on the maternal-fetal special-care unit who had been scheduled for induction prior to enrollment in the study by the attending physician because of maternal (pre-eclampsia, diabetes mellitus [Class B, C, or D]) or fetal (isoimmune hemolytic disease) indications. Fetal maturity had been verified by ultrasound and L/S ratio in all cases. Cervical dilatation of less than 1 cm and effacement of less than 50% was a precondition for inclusion in this study. Additionally, vertex presentation, intact membranes, and absence of bleeding or evidence of placenta previa were required. The study protocol had been approved by the human investigation review board.

After informed consent had been obtained, patients were randomly allocated to either the laminaria group or the control group. Patients in the laminaria group underwent intracervical placement of 6-10 size 6B laminaria tents (Mizutani Laminaria, Inc.) after Betadine preparation of the cervix at 1800 hours on the evening prior to planned induction. Retention of laminaria was encouraged by placement of a small Betadine-impregnated vaginal gauze pack. Control patients underwent the same procedure except for placement of laminaria. Sponges and laminaria were removed at 0600 to 0700 hours the next morning.

Table I. Bishop scores prior to and after treatment

	No.	*Bishop score before treatment (mean ± S.E.)*	*Bishop score after treatment (mean ± S.E.)*	*p*
Control patients	5	2.0 ± 0.4	2.4 ± 0.2	$p > 0.05$
Laminaria	7	2.3 ± 0.4	6.3 ± 0.9	$p < 0.005$

Bishop's score was determined by the same examiner (F. F.) in all patients immediately prior to laminaria or control placement and immediately following removal the next morning. The patients, the physician evaluating cervical response (F. F.), and the physicians managing subsequent induction of labor were all unaware of whether the laminaria or control procedure had been employed.

The use of laminaria effected a significant ($p < 0.005$) increase in Bishop score from 2.3 ± 0.4 to 6.3 ± 0.9 (Table I). Baseline Bishop scores were not different between the two groups ($p > 0.05$) nor did sham treatment result in a significant change in Bishop score ($p > 0.05$) (Table I).

Meaningful comparison of the course of labor between the control and laminaria groups is difficult as there were only seven vaginal deliveries among the 12 patients. All labors were initiated with intravenous oxytocin; amniotomies were generally reserved for the active phase of labor. Among the five control patients, there were only two vaginal deliveries after labors of 20 and 31 hours; cesarean sections were performed in three patients for failure to progress, prolapsed cord, or fetal distress. Five of the seven patients receiving laminaria were delivered vaginally after a mean duration of labor of 18 hours (range 12.5 to 29 hours). One cesarean section in the laminaria group was performed for failure to progress after secondary arrest in the active phase of labor (22 hours) and the other cesarean section was performed for fetal distress after 6 hours of labor.

Laminaria were responsible for a variable degree (usually mild) of crampy pelvic discomfort, and one patient who received laminaria was in early labor the morning after placement. Bleeding, amnionitis, and endometritis did not occur among patients receiving laminaria.

Laminaria tents are effective in increasing the apparent inducibility of the unripe cervix at or near term

and appear safe and useful in selected patients. In this study, laminaria effected sufficient cervical change to permit amniotomy and direct fetal and intrauterine monitoring. Confirmation of a salutary effect on the course of subsequent induction and of acceptability morbidity awaits a larger experience with this technique. Continued carefully monitored investigation of the use of laminaria for indicated induction of labor is warranted.

Annual Clinical Meeting of Association of Planned Parenthood Physicians

The Annual Clinical Meeting of the Association of Planned Parenthood Physicians will be held in Philadelphia, Pennsylvania, at the Hilton Hotel, October 11-12, 1979.

For information contact: George R. Huggins, M.D., Secretary, Planned Parenthood–World Population, 810 Seventh Ave., New York, New York 10019.

Perinatal Seminars

Perinatal Resources, Inc., Columbus, Ohio, announces the following Perinatal Seminars:

1. Current Developments in Perinatology, June 14-17, 1979, at Sheraton Islander Inn, Goat Island, Newport, Rhode Island

2. Review of Obstetrics and Gynecology, July 27-29, 1979, at Kings Island Inn, Mason, Ohio

3. A Review Course in Perinatology, September 27-30, 1979, at Fairmont Hotel, New Orleans, Louisiana

4. The Richard Torpin Memorial Postgraduate Course II—Obstetrics, September 30–October 9, 1979, at the Athens Hilton, Athens, Greece

5. Current Concepts in High Risk Obstetrics, January 23-27, 1980, at Aladdin Hotel, Las Vegas, Nevada

For information concerning each of these Seminars, contact Julie Williams, Perinatal Resources, Inc., Gibralter House, 2400 Coventry Road, Columbus, Ohio 43221.

The Treatment of Primary Breast Cancer: Management of Local Disease

The National Cancer Institute of the National Institutes of Health is sponsoring a consensus development conference: The Treatment of Primary Breast Cancer: Management of Local Disease. The conference will be held on June 5, 1979, at the National Institutes of Health Campus in Bethesda, Maryland, in Masur Auditorium (Building 10, Clinical Center) from 8:00 AM to 5:00 PM. Seating is limited and preregistration is required. For further information contact: Ms. Betty Doolittle, NIH-NCI-DCT, Landau Bldg., Room 8C08, Bethesda, Maryland 20014.

Central and Peripheral Regulation of Prolactin Function

An International Symposium on "Central and Peripheral Regulation of Prolactin Function" will be held in Taormina, Italy, October 11-13, 1979, under the auspices of the Italian Society of Endocrinology, the Italian Society of Fertility and Sterility, the Italian Society of Obstetrics and Gynaecology, and the Italian Society of Pharmacology.

For information contact: Umberto Scapagnini, M.D., Department of Pharmacology, Città Universitaria, Via A. Doria, 6, Catania 95100, Italy.

Second Annual Comprehensive Review of Obstetrics and Gynecology

The Second Annual Comprehensive Review of Obstetrics and Gynecology, presented by Baylor College of Medicine, Department of Obstetrics and Gynecology, will be held at the Marriott Hotel at the Astrodome, 2100 S. Braeswood Blvd. at Greenbriar, Houston, Texas 77030, October 26-31, 1979.

For information contact: The Office of Continuing Education, Baylor College of Medicine, Texas Medical Center, Houston, Texas 77030. Telephone: (713) 790-4941.

Fourth Annual Frank R. Lock Symposium in Obstetrics and Gynecology

The Fourth Annual Frank R. Lock Symposium in Obstetrics and Gynecology will be presented April 11-12, 1980, at Babcock Auditorium, Winston-Salem, North Carolina.

For information contact: Division of Continuing Education, 300 S. Hawthorne Road, Bowman Gray School of Medicine, Winston-Salem, North Carolina 27103. Telephone: (919) 727-4450.

One Hundred Fiftieth Anniversary Scholarships

As part of its One Hundred Fiftieth Anniversary Celebration this year, the Rochester Institute of Technology (RIT), in New York, will award individual $1,500 scholarships to 150 lucky babies born on June 12, 1979.

It was on that date 150 years ago that the Rochester Athenaeum, RIT's predecessor, was founded.

Parents of all "anniversary" babies need only to submit a brief letter giving the name of their baby and their home address and telephone number. The first 150 respondents, as determined by postmark of the letters, will be declared winners of the scholarships. However, they also must be admitted to the Institute when ready for college.

A list of alternates will be chosen by the same process.

Funds for the scholarship program in the amount of $225,000—the largest scholarship fund ever awarded at RIT—are being provided by Mr. and Mrs. J. Warren McClure of Key Largo, Florida, and Charlotte, Vermont.

The scholarships will be available starting in 1997, when the recipients are ready for enrollment at RIT. The award winners will be known as the "McClure Scholars." The scholaships are applicable to full-time or part-time/day or evening education, and may be used until 2002.

Parents should send their letters to: RIT McClure Scholars, Rochester Institute of Technology (1829), One Lomb Memorial Dr., Rochester, New York 14623. Deadline for this registration step is October 1, 1979.

The Institute reserves the right to verify the date of birth of the baby. This scholarship offering is void where prohibited by law.

The Institute will announce the names of the lucky 150 winners, and the alternate list during RIT's One Hundred Fiftieth Anniversary Celebration weekend, October 19-21, 1979.

Seventh Annual Convention of The National Intravenous Therapy Association, Inc.

The National Intravenous Therapy Association, Inc., announces its Seventh Annual Convention, to be held June 10-14, 1979, at the Chicago Marriott, Chicago, Illinois.

BELLERGAL-S™ TABLETS

Composition: Each Bellergal-S Tablet contains: phenobarbital, USP, central sedative (Warning: May be habit forming), 40.0 mg; Gynergen (ergotamine tartrate, USP) sympathetic inhibitor, 0.6 mg; Bellafoline (levorotatory alkaloids of belladonna, as malates) parasympathetic inhibitor, 0.2 mg.

Properties and Therapeutics: Based on the concept that functional disorders frequently involve hyperactivity of both the sympathetic and parasympathetic nervous systems, the ingredients in Bellergal are combined to provide a balanced preparation designed to correct imbalance of the autonomic nervous system. The integrated action of Bellergal is effected through the combined administration of ergotamine and the levorotatory alkaloids of belladonna, specific inhibitors of the sympathetic and parasympathetic respectively, reinforced by the synergistic action of phenobarbital in dampening the cortical centers.

Indications: Bellergal is employed in the management of disorders characterized by nervous tension and exaggerated autonomic response:

Menopausal disorders with hot flashes, sweats, restlessness and insomnia.

Cardiovascular disorders with palpitation, tachycardia, chest oppression and vasomotor disturbances.

Gastrointestinal disorders with hypermotility, hypersecretion, "nervous stomach," and alternately diarrhea and constipation.

Genitourinary – uterine cramps, etc.

Premenstrual tension.

Interval treatment of *recurrent, throbbing headache.*

Contraindications: Peripheral vascular disease, coronary heart disease, hypertension, impaired hepatic or renal function, sepsis, third trimester of pregnancy and glaucoma. Hypersensitivity to any of the components.

Precautions: Even though the ergotamine tartrate content of this product is extremely low and untoward effects have been rare and insignificant, caution should be exercised if large or prolonged dosage is contemplated, and physicians should be alert to possible peripheral vascular complications in patients highly sensitive to ergot. Due to presence of a barbiturate, may be habit forming.

Side Effects: Blurred vision, dry mouth, flushing, drowsiness occur rarely.

Dosage: Bellergal-S Tablets: One in the morning and one in the evening.

How Supplied: Bellergal-S Tablets (compressed, scored tablets of tricolored pattern: dark green, orange and light lemon yellow) in bottles of 100.

NONHORMONAL therapy for menopausal vasomotor instability is receiving renewed attention.

BELLERGAL-S™

TABLETS

Each Bellergal-S Tablet contains: phenobarbital, USP, central sedative (Warning: May be habit forming), 40.0 mg; Gynergen® (ergotamine tartrate, USP) sympathetic inhibitor, 0.6 mg; Bellafoline® (levorotatory alkaloids of belladonna, as malates) parasympathetic inhibitor, 0.2 mg.

Long clinical experience has established the effectiveness of Bellergal-S Tablets in managing menopausal disorders characterized by exaggerated autonomic response—hot flashes, sweats, restlessness, and insomnia.

Because Bellergal-S reduces autonomi nervous system activity, symptoms of vasomotor instability are eliminated or significantly reduced. *Bellergal-S does not contain estrogen in any form.* That's one reason why it is receiving renewed attention from physicians who wish to avoid the potential complications of estrogen therapy in vasomotor instabili

So when estrogen therapy is undesirable... prescribe Bellergal-S Tablets.

Please see prescribing information on an adjoining page.

Why the choice is Cu-7®

intrauterine copper contraceptive

1. She wants nonhormonal contraception.
2. She wants to space her family.
3. She smokes.
4. She has passed the "Pill" years.

Freedom—intrauterine contraception is the most convenient of all contraceptive methods.

Comfort—smallest inserter diameter of all IUDs. This means minimal discomfort during insertion.

Cu-7	Lippes Loop® D	Saf-T-Coil® (Nullip)	Saf-T-Coil® (Standard)
3.07 mm.	5.33 mm.	3.76 mm.	4.50 mm.

Security—high efficacy and relatively low incidence of expulsion and medical removal.

(Rates—based on labeling claims—expressed as events per 100 women through 12 months of use for parous women)*	Cu-7[1]	Lippes Loop D[2]	Saf-T-Coil[2]
Pregnancy	1.9	2.7	2.4
Expulsion	5.7	12.7	18.3
Medical Removal	10.9	15.2	15.6

*These rates are derived from separate studies conducted by different investigators in several population groups. Different rates have been reported from other clinical trials.

References: 1. Data on file at Searle Laboratories. 2. Physicians' Desk Reference, Medical Economics Company, Oradell, N.J., 1978, pp. 1216, 1521.

Intrauterine contraception is not appropriate for all women. Please see complete product information prior to use. A brief summary of product information appears on the next page

Description: The plastic component of the Cu-7 is composed of pharmaceutical grade polypropylene homopolymer with barium sulfate added to render it radiopaque. Its shape approximates the number 7. It is substantially smaller than previously available intrauterine devices; the vertical dimension measures 36 mm. and the horizontal, 26 mm.

Coiled around the vertical limb is a pure, virgin electrolytic copper wire providing approximately 200mm^2 of exposed copper surface area. A retrieval thread is fastened to the free end of the vertical limb of the Cu-7.

The Cu-7 is supplied with a simple tubular polypropylene inserter. All components are sterile.

Mode of Action: Available data indicate that the contraceptive effectiveness of the Cu-7 is enhanced by a minute quantity of copper released continuously from the coiled copper into the uterine cavity.

The exact mechanism by which metallic copper enhances the contraceptive effect of an IUD has not been conclusively demonstrated. Various hypotheses have been advanced, the most common being that copper placed in the uterus interferes with enzymatic or other processes that regulate blastocyst implantation.

Animal studies suggest that copper may play an additional role by reduction of sperm transport within the uterine environment.

Indication and Usage: The Cu-7 is indicated for contraception.

Contraindications: The Cu-7 should not be inserted when any of the following conditions exist: pregnancy or suspicion of pregnancy; abnormalities of the uterus resulting in distortion of the uterine cavity; acute pelvic inflammatory disease or a history of repeated pelvic inflammatory disease; postpartum endometritis or infected abortion in the past three months; known or suspected uterine or cervical disease such as hyperplasia or carcinoma including unresolved, abnormal "Pap" smear; vaginal bleeding of unknown etiology; untreated acute cervicitis until infection is controlled; diagnosed Wilson's disease; known or suspected allergy to copper; previous ectopic pregnancy, and significant anemia.

Warnings

1. Pregnancy: (a) Long-term effects. The long-term effects on the offspring of the presence of copper in the uterus when pregnancy occurs with the Cu-7 are unknown.

(b) Septic abortion: Reports have indicated an increased incidence of septic abortion associated in some instances with septicemia, septic shock and death in patients becoming pregnant with an IUD in place. Most of these reports have been associated with the mid-trimester of pregnancy. In some cases, the initial symptoms have been insidious and not easily recognized. If pregnancy should occur with a Cu-7 in situ, the Cu-7 should be removed if the thread is visible or, if removal proves to be or would be difficult, interruption of the pregnancy should be considered and offered to the patient as an option, bearing in mind that the risks associated with an elective abortion increase with gestational age.

(c) Continuation of pregnancy. If the patient chooses to continue the pregnancy and the Cu-7 remains in situ, she must be warned of the increased risk of spontaneous abortion and the increased risk of sepsis, including death. The patient must be closely observed and she must be advised to report immediately all abnormal symptoms, such as flu-like syndrome, fever, abdominal cramping and pain, bleeding, or vaginal discharge, because generalized symptoms of septicemia may be insidious.

2. Ectopic pregnancy: (a) A pregnancy which occurs with an IUD in situ is more likely to be ectopic than a pregnancy occurring without an IUD. Therefore, patients who become pregnant while using a Cu-7 should be carefully evaluated for the possibility of an ectopic pregnancy.

(b) Special attention should be directed to patients with delayed menses, slight metrorrhagia and/or unilateral pelvic pain, and to those patients who wish to interrupt a pregnancy occurring in the presence of a Cu-7, to determine whether ectopic pregnancy has occurred.

3. Pelvic infection: An increased risk of pelvic inflammatory disease associated with the use of IUDs has been reported. While unconfirmed, this risk appears to be greatest for young women who are nulliparous and/or who have a multiplicity of sexual partners. Salpingitis can result in tubal damage and occlusion, thereby threatening future fertility. Therefore, it is recommended that patients be taught to look for symptoms of pelvic inflammatory disease. The decision to use an IUD in a particular case must be made by the physician and patient with the consideration of a possible deleterious effect on future fertility.

Pelvic infection may occur with a Cu-7 in situ and at times result in the development of tubo-ovarian abscesses or general peritonitis. The symptoms of pelvic infection include: new development of menstrual disorders (prolonged or heavy bleeding), abnormal vaginal discharge, abdominal or pelvic pain, dyspareunia, fever. The symptoms are especially significant if they occur following the first two or three cycles after insertion. Appropriate aerobic and anaerobic bacteriologic studies should be done and antibiotic therapy initiated promptly. If the infection does not show marked clinical improvement within 24 to 48 hours, the Cu-7 should be removed and the continuing treatment reassessed on the basis of the results of culture and sensitivity tests.

4. Embedment: Partial penetration or lodging of the Cu-7 in the endometrium or myometrium can result in a difficult removal. This may occur more frequently in smaller uteri. (See removal instructions.)

5. Perforation: Partial or total perforation of the uterine wall or cervix may occur with the use of the Cu-7, usually during insertions into patients sooner than two months after abortion or delivery or in uterine cavities too small for the Cu-7. The possibility of perforation must be kept in mind during insertion and at the time of any subsequent examination. If perforation occurs, laparotomy or laparoscopy should be performed as soon as medically feasible and the Cu-7 removed. Abdominal adhesions, intestinal penetration, intestinal obstruction, and local inflammatory reaction with abscess formation and erosion of adjacent viscera may result if the Cu-7 is left in the peritoneal cavity.

6. Medical diathermy: The use of medical diathermy (short-wave and microwave) in a patient with a metal-containing IUD may cause heat injury to the surrounding tissue. Therefore, medical diathermy to the abdominal and sacral areas should not be used on patients using a Cu-7.

7. Effects of copper: Additional amounts of copper available to the body from the Cu-7 may precipitate symptoms in women with undiagnosed Wilson's disease. The incidence of Wilson's disease is 1 in 200,000.

Precautions

1. Patient counseling: Prior to the insertion the physician, nurse, or other trained health professional must provide the patient with the Patient Brochure. The patient should be given the opportunity to read the brochure and discuss fully any questions she may have concerning the Cu-7 as well as other methods of contraception.

2. Patient evaluation and clinical considerations: a) A complete medical history should be obtained to determine conditions that might influence the selection of an IUD. A physical examination should include a pelvic examination, "Pap" smear, gonorrhea culture and, if indicated, appropriate tests for other forms of venereal disease. The physician should determine that the patient is not pregnant.

(b) The uterus should be carefully sounded prior to the insertion to determine the degree of patency of the endocervical canal and the internal os, and the direction and depth of the uterine cavity. Exercise care to avoid perforation with the sound. DO NOT USE THE Cu-7 INSERTION INSTRUMENT AS A SOUND. In occasional cases, severe cervical stenosis may be encountered. Do not use excessive force to overcome this resistance.

(c) The uterus usually sounds to a depth of 6 to 8 cm. Insertion of a Cu-7 into a uterine cavity measuring less than 6.5 cm. by sounding may increase the incidence of pain, bleeding, partial or complete expulsion, perforation, and possibly pregnancy.

(d) To reduce the possibility of insertion in the presence of an existing undetermined pregnancy, the optimal time for insertion is the latter part of the menstrual flow or one or two days thereafter. The Cu-7 should not be inserted post partum or post abortion until involution of the uterus is complete. The incidence of perforation and expulsion is greater if involution is not complete.

It is, however, necessary to place the Cu-7 as high as possible within the uterine cavity to help avoid partial or complete expulsion that could result in pregnancy.

Since the Cu-7 represents a different design in intrauterine contraception, physicians are cautioned that it is imperative for them to become thoroughly familiar with the instructions for use before attempting placement of the Cu-7.

(e) IUDs should be used with caution in those patients who have an anemia or a history of menorrhagia or hypermenorrhea. Patients experiencing menorrhagia and/or metrorrhagia following IUD insertion may be at risk for the development of hypochromic microcytic anemia. Also, IUDs should be used with caution in patients receiving anticoagulants or having a coagulopathy.

(f) Syncope, bradycardia or other neurovascular episodes may occur during insertion or removal of IUDs, especially in patients with a previous disposition to these conditions.

(g) Patients with valvular or congenital heart disease are more prone to develop subacute bacterial endocarditis than patients who do not have valvular or congenital heart disease. Use of an IUD in these patients may represent a potential source of septic emboli.

(h) Use of an IUD in those patients with acute cervicitis should be postponed until proper treatment has cleared up the infection.

(i) Since the Cu-7 may be partially or completely expelled, patients should be reexamined and evaluated shortly after the first postinsertion menses, but definitely within three months after insertion. Thereafter annual examination with appropriate medical and laboratory evaluation should be carried out. The Cu-7 should be replaced every three years.

(j) The patient should be told that some bleeding or cramps may occur during the first few weeks after insertion, but if these symptoms continue or are severe she should report them to her physician. She should be instructed on how to check after each menstrual period to make certain that the thread still protrudes from the cervix and cautioned that there is no contraceptive protection if the Cu-7 has been expelled. She should also be cautioned not to dislodge the Cu-7 by pulling on the thread. If a partial expulsion occurs, removal is indicated and a new Cu-7 may be inserted. The patient should be told to return within three years for removal of the Cu-7 and for replacement if desired.

(k) A copper-induced urticarial allergic skin reaction may develop in women using a copper-containing IUD. If symptoms of such an allergic response occur, the patient should be instructed to tell the consulting physician that a copper-containing device is being used.

(l) The Cu-7 should be removed for the following medical reasons: menorrhagia and/or metrorrhagia producing significant anemia; uncontrolled pelvic infection; intractable pain often aggravated by intercourse, dyspareunia; pregnancy, if the thread is visible; endometrial or cervical malignancy; uterine or cervical perforation; or any indication of partial expulsion.

(m) If the retrieval thread cannot be visualized it may have retracted into the uterus or have been broken off, or the Cu-7 may have been expelled. Localization usually may be made by feeling with a probe; if not, x-ray or sonography can be used. When the physician elects to recover a Cu-7 with the thread not visible, the removal instructions should be considered.

(n) If any patient with a Cu-7 suddenly develops overt clinical hepatitis or abnormal liver function tests, appropriate diagnostic procedures should be initiated.

Adverse Reactions: Perforations of uterus and cervix have occurred. Perforation into the abdomen has been followed by abdominal adhesions, intestinal penetration, intestinal obstruction, local inflammatory reaction with abscess formation and erosion of adjacent viscera. Pregnancy has occurred with the Cu-7 in situ and when the Cu-7 has been partially or completely expelled.

The incidence of spontaneous abortion, when conception occurs with intrauterine devices in situ, appears to be increased over that in unprotected women. Insertion cramping, usually of no more than a few seconds duration, may occur; however, some women may experience residual cramping for several hours or even days. Intermenstrual spotting or bleeding or prolonged or increased menstrual flow may occur.

Pelvic infection including salpingitis with tubal damage or occlusion has been reported. This may result in future infertility. Complete or partial expulsion of the Cu-7 may sometimes occur, particularly in those patients with uteri measuring less than 6.5 cm. by sounding. Urticarial allergic skin reaction may occur. The following complaints have also been reported with IUDs although their relation to the Cu-7 has not been established: amenorrhea or delayed menses, backaches, cervical erosion, cystic masses in the pelvis, vaginitis, leg pain or soreness, weight loss or gain, nervousness, dyspareunia, cystitis, endometritis, septic abortion, septicemia, leukorrhea, ectopic pregnancy, difficult removal, uterine embedment, anemia, pain, neurovascular episodes including bradycardia and syncope secondary to insertion, dysmenorrhea, and fragmentation of the IUD.

Directions for Use: The Cu-7 is to be placed within the uterine cavity. See the Procedure for Insertion for two insertion techniques.

The small diameter of the Cu-7 facilitates easy insertion in nulligravidous and nulliparous, as well as parous women. The optimal time of insertion is during the latter part of the menstrual flow or one or two days thereafter. The cervical canal is relatively more patent at this time, and there is little chance that the patient may be pregnant.

Present information indicates that efficacy is retained for 36 months. There is no evidence that contraceptive efficacy decreases with time up to three years of use, but until adequate data indicating a longer effective life become available, the Cu-7 must be removed within 36 months from the date of insertion and a new one inserted if desired. If partial expulsion occurs, removal is indicated, and a new Cu-7 may be inserted. Removal of the Cu-7 may also be indicated in the event of heavy or persistent bleeding.

The physician should become thoroughly familiar with the instructions for use before attempting insertion or removal of the Cu-7.

Clinical Efficacy: In clinical trials of the Cu-7 conducted by Searle Laboratories, use effectiveness was determined as follows for parous and nulliparous women, as tabulated by the life table method. (Rates are expressed as cumulative events per 100 women through 12, 24, and 36 months of use.)

This experience encompasses 387,131 woman-months of use, including 12 months for 11,517 women, 24 months for 7,895, and 36 months for 3,661.

	12 Months		24 Months		36 Months	
	Parous	Nulliparous	Parous	Nulliparous	Parous	Nulliparous
Pregnancy	1.9	1.7	2.9	2.6	3.4	3.4

How Supplied

Available in cartons of 6, 30 and 100 sterile units (Cu-7 with an inserter) and sufficient patient leaflets and identification cards.

Please see complete product labeling for additional information, including insertion and removal instructions.

Cu-7® intrauterine copper contraceptive

—the leading IUD

8B4

How much estrogen does it really take to control nature?

A lot less than everyone once thought. Just a few years ago, a 50-mcg dosage was considered low. Today, there's an effective combination oral contraceptive containing 30 mcg of estrogen: Loestrin 1.5/30.

In spite of a 40% reduction in the dose of estrogen, efficacy of Loestrin 1.5/30 is considered comparable to that of combination oral contraceptives containing higher levels of estrogen.

Irregular bleeding is somewhat more frequent with Loestrin 1.5/30 than with combinations containing larger doses of estrogen. With continued use, however, the frequency decreases.

And if you're concerned about your patients' intake of estrogen over an extended period of time, Loestrin 1.5/30 contains 30 mcg of ethinyl estradiol, so patient exposure to estrogen is reduced.

LOESTRIN® 1.5/30

(1.5 mg norethindrone acetate and 30 mcg ethinyl estradiol tablets, USP)

a 30-mcg alternative to higher estrogen

Brief Summary of Prescribing Information
LOESTRIN® 1.5/30
(1.5 mg norethindrone acetate and 30 mcg ethinyl estradiol tablets, USP) See section under Special Notes on Administration and How Supplied.

DESCRIPTION
Loestrin 1.5/30 Products are progestogen-estrogen combinations.

INDICATION AND USAGE
Loestrin 1.5/30 Products are indicated for the prevention of pregnancy in women who elect to use oral contraceptives.

In clinical trials with Loestrin 1.5/30 involving 17,139 therapy cycles, there was a pregnancy rate of 0.49 per 100 woman years.

Dose-related risk of thromboembolism from oral contraceptives: Studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. It is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance.

CONTRAINDICATIONS
1. Thrombophlebitis or thromboembolic disorders
2. A past history of deep-vein thrombophlebitis or thromboembolic disorders
3. Cerebral vascular or coronary artery disease
4. Known or suspected carcinoma of the breast
5. Known or suspected estrogen-dependent neoplasia
6. Undiagnosed abnormal genital bleeding
7. Known or suspected pregnancy (See No. 5 under WARNINGS.)

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, and hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well-established. Studies have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic.

Cerebrovascular disorders: In a collaborative study in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers, and the risk of thrombotic stroke was 4.0 to 9.5 times greater.

Myocardial infarction: An increased risk of myocardial infarction associated with oral contraceptives has been reported confirming a previously suspected association. These studies found that the greater the number of underlying risk factors (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) for coronary artery disease, the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor.

It has been estimated that users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are smokers have about a fivefold increased risk of fatal infarction compared to users who do not smoke, but about a tenfold to twelvefold increased risk compared to nonusers who do not smoke. The amount of smoking is also an important factor.

Risk of dose: In an analysis of data, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives; however, the quantity of estrogen may not be the sole factor involved.

Estimate of excess mortality from circulatory diseases: The risk of diseases of the circulatory system is concentrated in older women, in those with a long duration of use, and in cigarette smokers.

A study of available data from a variety of sources concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke.

The risk of thromboembolic and thrombotic diseases associated with oral contraceptives increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia, and especially by cigarette smoking.

The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders. Should any occur or be suspected, the drug should be discontinued immediately.

A fourfold to sixfold increased risk of postsurgery thromboembolic complications has been reported in users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

2. *Ocular lesions:* Neuro-ocular lesions, such as optic neuritis or retinal thrombosis, have been associated with the use of oral contraceptives. Discontinue the oral contraceptive if there is unexplained sudden or gradual, partial, or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions.

3. *Carcinoma:* Long-term continuous administration of estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver.

In humans, an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women has been reported. However, there is no evidence suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only oral contraceptives.

Studies found no evidence of increase in breast cancer in women taking oral contraceptives; however, an excess risk in users with documented benign breast disease was reported.

There is no confirmed evidence of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of users is, nevertheless, essential. In cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer, or who have breast nodules, fibrocystic disease, or abnormal mammograms, should be monitored with particular care.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with oral contraceptives. Because hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage, they should be considered in women presenting abdominal pain and tenderness, abdominal mass, or shock.

A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Usage in or Immediately Preceding Pregnancy: Birth Defects in Offspring, and Malignancy in Female Offspring:* During early pregnancy, female sex hormones may seriously damage the offspring.

An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of oral contraceptives in pregnancy.

There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives.

Pregnancy should be ruled out before continuing an oral contraceptive in any patient who has missed two consecutive menstrual periods. If the patient has not adhered to the schedule, the possibility of pregnancy should be considered at the time of the first missed period, and oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed.

Women who discontinue oral contraceptives with the intent of becoming pregnant should use an alternate form of contraception for a period of time before attempting to conceive.

Administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives.

7. *Carbohydrate and Lipid Metabolic Effects:* Because decreased glucose tolerance has been observed in a significant percentage of patients, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives.

An increase in triglycerides and total phospholipids has been observed.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving oral contraceptives. The prevalence in users increases with longer exposure. Age is also strongly correlated with development of hypertension. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure.

9. *Headache:* Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of oral contraceptive

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, nonfunctional causes should be borne in mind. In undiagnosed abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy.

Women with a past history of oligomenorrhea or secondary amenorrhea, or young women without regular cycles should be advised that they may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast Feeding:* Oral contraceptives may interfere with lactation. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs.

PRECAUTIONS
1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another examination.

2. Preexisting uterine leiomyomata may increase in size.

3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree.

4. Oral contraceptives may cause fluid retention and should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated.

5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice. If jaundice develops, the medication should be discontinued.

6. Steroid hormones may be poorly metabolized and should be administered with caution in patients with impaired liver function.

7. Users may have disturbances in normal tryptophan metabolism, which may result in a relative pyridoxine deficiency.

8. Serum folate levels may be depressed.

9. The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted.

10. Certain endocrine and liver function tests and blood components may be affected.
(a) Increased sulfobromophthalein retention. (b) Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability (c) Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone. (d) Decreased pregnanediol excretion. (e) Reduced response to metyrapone test.

Drug interactions: Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin and an association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and ampicillin.

ADVERSE REACTIONS
An increased risk of the following serious adverse reactions has been associated with oral contraceptives.

Thrombophlebitis; Pulmonary embolism; Coronary thrombosis; Cerebral thrombosis; Cerebral hemorrhage; Hypertension; Gallbladder disease; Benign hepatomas; Congenital anomalies.

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed. Mesenteric thrombosis, Neuro-ocular lesions, eg, retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms; breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma; breast changes; change in weight; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately post partum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature; intolerance to contact lenses.

The following adverse reactions have been reported and the association has been neither confirmed nor refuted.

Premenstrual-like syndrome; cataracts; changes in libido; chorea; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; vaginitis; porphyria.

Special Notes on Administration
Loestrin 21 1.5/30 (1.5 mg norethindrone acetate and 30 mcg ethinyl estradiol tablets, USP)—Menstruation usually begins two or three days, but may begin as late as the fourth or fifth day, after discontinuing medication.

Loestrin Fe 1.5/30—Menstruation usually begins two or three days, but may begin as late as the fourth or fifth day, after the brown ferrous fumarate tablets have been started.

Because of the relatively low estrogenic content, Loestrin 1.5/30 is not a good cyclic regulator. There are patients whose inherent hormone balance will require larger amounts of estrogen than that contained in Loestrin 1.5/30 to achieve cyclic regularity. These patients experience altered bleeding patterns, which do not conform to treatment schedules.

The physician should be alert to the fact that the irregular bleeding patterns could mask bleeding from organic cause, and appropriate diagnostic measures should be taken if the bleeding persists or continues after changing to a higher estrogen-content product.

After several months, bleeding may be reduced to a virtual absence; reduced flow may be a result of medication and not indicative of pregnancy.

HOW SUPPLIED
Loestrin Fe 1.5/30 is available in compacts each containing 21 green tablets and 7 brown tablets. Each green tablet contains 1.5 mg of norethindrone acetate and 30 mcg of ethinyl estradiol. Each brown tablet contains 75 mg of ferrous fumarate. Available in packages of five compacts and packages of five refills.

Loestrin 21 1.5/30 is available in compacts each containing 21 tablets. Each green tablet contains 1.5 mg of norethindrone acetate and 30 mcg of ethinyl estradiol. Available in packages of five compacts and packages of five refills.

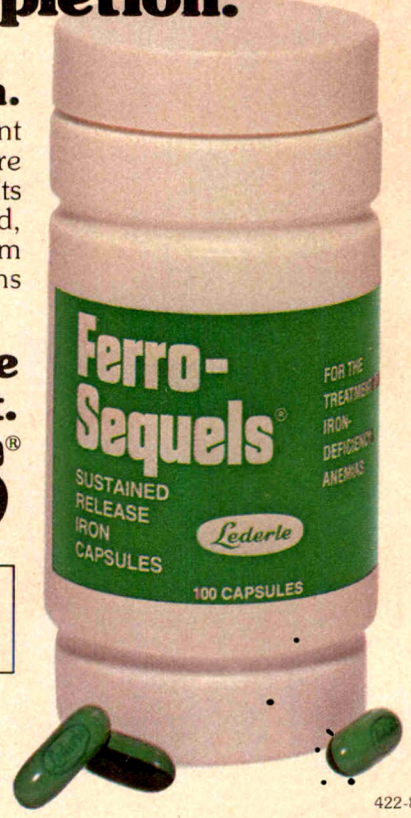
95% of American women of child-bearing age have inadequate iron intake[1]. About 50% have laboratory evidence of iron depletion.[2]

Just any iron may not solve the problem.



Any iron may cause GI irritation and constipation. To avoid patient resistance—especially during pregnancy when iron requirements are greater than ever—be specific. Recommend FERRO-SEQUELS.® Its delayed release avoids absorption of iron in the stomach. Instead, most of the iron is released gradually in the duodenum for optimum absorption and minimum irritation. And FERRO-SEQUELS contains a stool softener to help prevent constipation.

An iron that encourages compliance is an iron worth being specific about.

FERRO·SEQUELS®

Sustained Release Iron Capsules

Each capsule contains:	
Ferrous Fumarate (equivalent to approx. 50 mg. of elemental iron)	150 mg.
Dioctyl Sodium Sulfosuccinate	100 mg.

We've got all of the good guys and none of the bad guys.

Carnation Instant Nonfat Dry Milk has taken all the good parts of whole milk like protein, calcium, and B-vitamins—and has eliminated the bad...like fat.

In addition, Carnation Instant Nonfat Dry Milk is fortified with vitamins A and D. And since it starts out dry, you can control the balance of protein and solids to suit any low-fat diet.

We even have these free diet plans to make things better:

1. Pregnancy Weight Control.
2. Reducing.
3. Cholesterol Control.
4. Hypoglycemia.
5. Low Sodium.
6. Bland Ulcer.
7. Diabetic.

We can't think of a reason not to prescribe Carnation Instant Nonfat Dry Milk to all of your patients.

For a free supply of any of the diet plans listed, circle the corresponding number(s): 1, 2, 3, 4, 5, 6, 7.

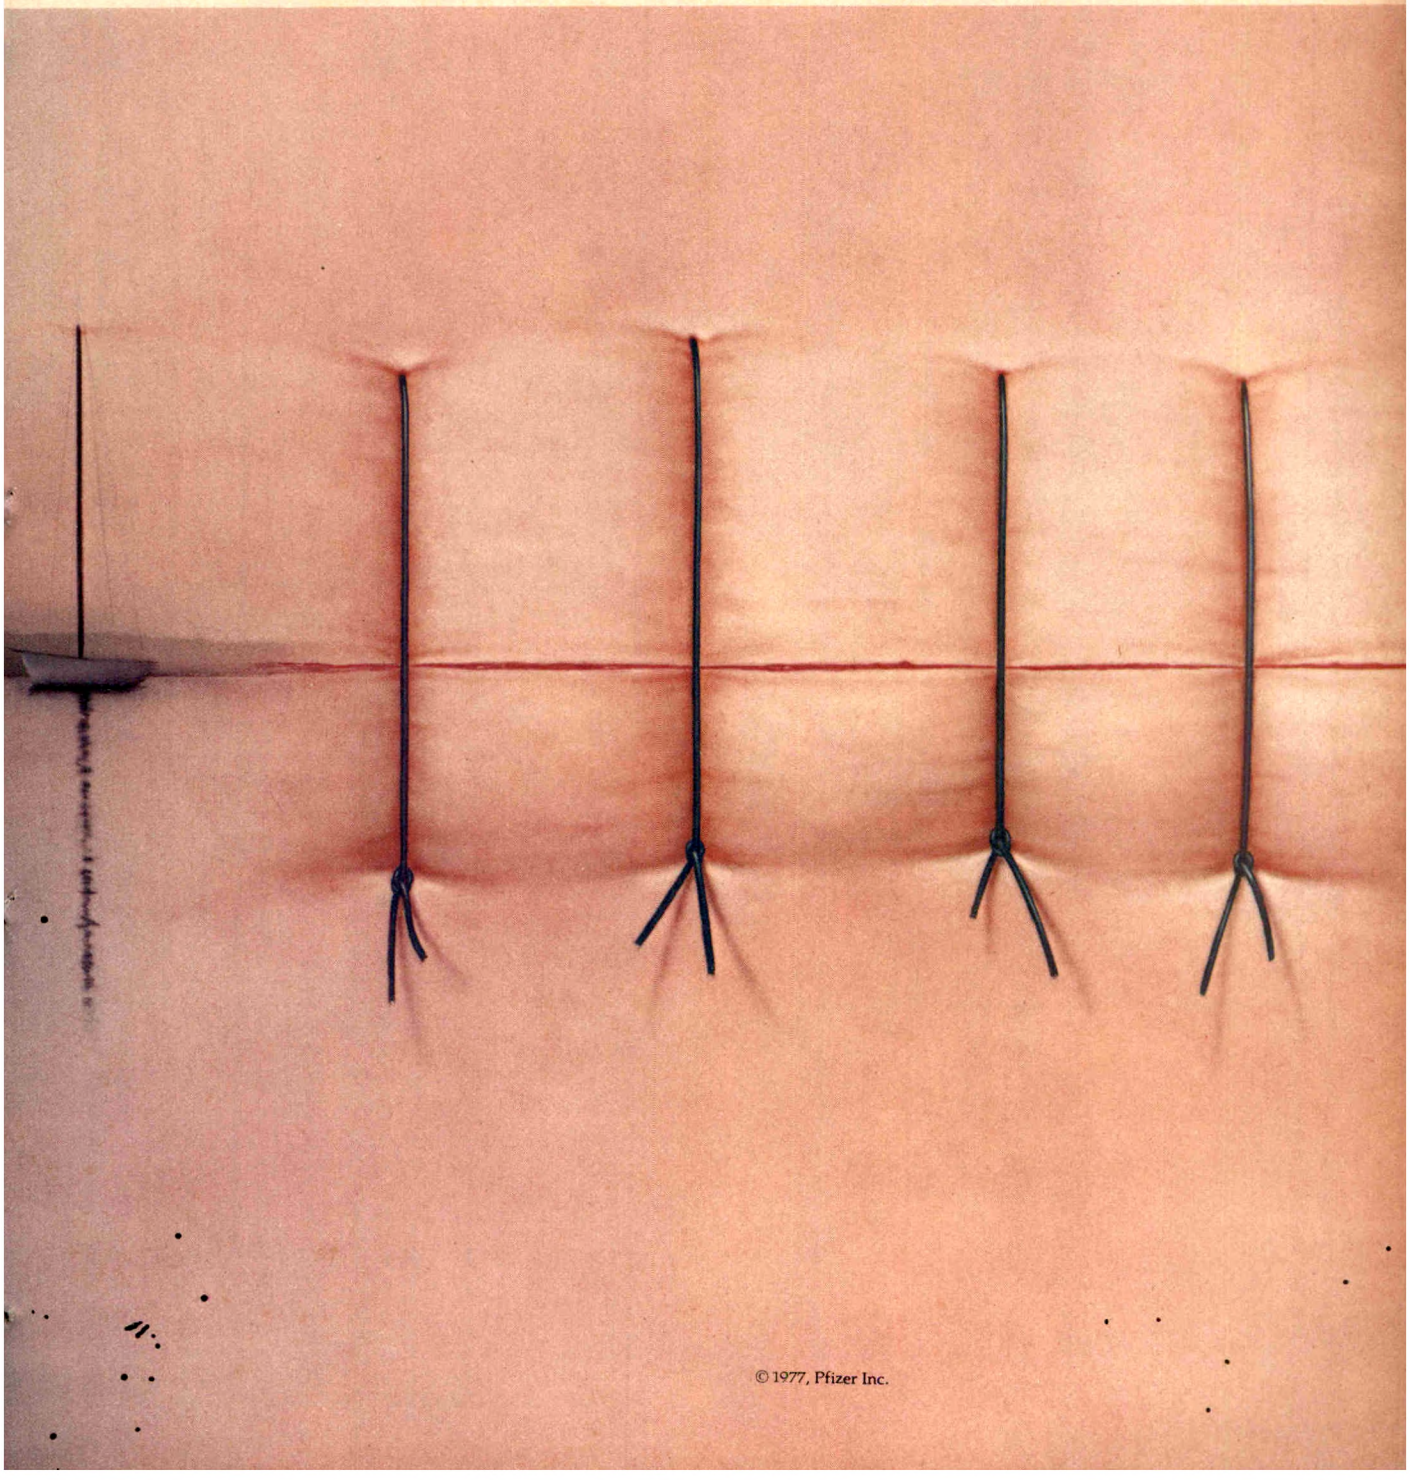
The Calm introduction to surgery



Vistaril® I.M.

(hydroxyzine HCl)

—allays anxiety
—reduces narcotic requirements
—and controls emesis

Please see Brief Summary on following page for contraindications, precautions and adverse reactions.

© 1977, Pfizer Inc.

Vistaril® I.M.
(hydroxyzine HCl)

100 mg/2 ml—50 mg/ml and
25 mg/ml Vials and Isojects®

preoperatively and postoperatively

- **allays presurgical anxiety...allays the anxiety that may heighten the perception of postoperative pain**
- **may enhance the effects of analgesics and reduce narcotic requirements**
- **controls postoperative emesis**
- **vital signs are seldom impaired (Involuntary motor activity, including rare instances of tremor and convulsions, has been reported, usually with higher than recommended dosage.)**

BRIEF SUMMARY
VISTARIL® (hydroxyzine hydrochloride)
Intramuscular Solution/For Intramuscular Use Only
Contraindications: Hypersensitivity to hydroxyzine. The solution is for intramuscular use only and should not, under any circumstances, be injected subcutaneously, intra-arterially, or intravenously.

Hydroxyzine, when administered to the pregnant mouse, rat, and rabbit, induced fetal abnormalities in the rat at doses substantially above the human therapeutic range. Since adequate data are not available to establish safety in early pregnancy, hydroxyzine is contraindicated during this period.
Precautions: HYDROXYZINE MAY POTENTIATE THE ACTION OF CENTRAL NERVOUS SYSTEM DEPRESSANTS SUCH AS NARCOTICS AND BARBITURATES. In conjunctive use, dosage for these drugs should be decreased as much as 50%. Because drowsiness may occur, patients should be cautioned against driving a car or operating dangerous machinery. The usual precautions for intramuscular injection should be followed; soft-tissue reactions have rarely been reported when proper technique has been used. Hydroxyzine intramuscular solution should be injected well within the body of a relatively large muscle. Inadvertent subcutaneous injection may result in significant tissue damage. In adults, the preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus), or the mid-lateral thigh. In children, preferably the mid-lateral muscles of the thigh. In infants and small children, the upper outer quadrant of the gluteal region should only be used when necessary, as in burn patients, in order to minimize the possibility of damage to the sciatic nerve. The deltoid area should be used only if well developed, such as in certain adults and older children, and then only with caution to avoid radial nerve injury. Intramuscular injections should not be made in the lower and middle thirds of the upper arm. Aspiration is necessary to help avoid inadvertent intravascular injection.
Adverse Reactions: Drowsiness may occur; if so, it is usually transitory and may disappear in a few days of continued therapy or upon dosage reduction. Dryness of the mouth may occur with higher doses. Involuntary motor activity, including rare instances of tremor and convulsions, has been reported, usually with doses considerably higher than those recommended.
Supply: Vistaril (hydroxyzine HCl) Intramuscular Solution: 25 mg/ml—10 ml vials; 50 mg/ml—2 ml and 10 ml vials; Isoject®, 25 mg/ml and 50 mg/ml—1 ml fill; 100 mg/2 ml—2 ml fill.

Military Depot: NSN 6505-00-052-1367 (50 mg/ml, 10 ml vials)

VA Depot: NSN 6505-00-052-1367B (50 mg/ml, 10 ml vials)

EDITORS! REVIEWERS! AUTHORS!

For you . . . a new book that contains virtually everything you want to know about

THE SCIENTIFIC JOURNAL: EDITORIAL POLICIES AND PRACTICES

Guidelines for Editors, Reviewers, and Authors

In 1665 the first scholarly journal was published in France. Since that time, there has been no one source of editorial guidelines for journal editors. This new book now provides you with such a source.

YOU DECIDE YOUR OWN APPROACH!

Presenting the advantages and disadvantages of each specific decision, eminent editors offer you various recommendations, discussions, and opinions concerning the problems you may encounter:

"Because we are aware that there is no 'right' policy on most editorial matters, we have tried not to prescribe rules, but have, instead, explored various facets of the problems that confront the editor in his daily work."

The book is divided into two general sections: editorial policies, which usually require major decisions; and editorial practices, which involve minor decisions, often about format or mechanical style. You'll find essays exploring: the manuscript reviewing system; special types of manuscripts (abstracts, transactions, solicited manuscripts, book reviews). You'll value chapters which cover: information for authors; copyright; errata; references cited; copy-editing; journal cover; etc.

From "the purpose of scientific journals" to "binding practices," this new book contains virtually everything you want to know as editor, reviewer, or author. See for yourself!

By Lois DeBakey, Ph.D. In collaboration with: Paul F. Cranefield, M.D., Ph.D.; Ayodhya P. Gupta, M.D.; Franz J. Ingelfinger, M.D.; Robert J. Levine, M.D.; Robert H. Moser, M.D.; J. Roger Porter, Ph.D.; and F. Peter Woodford, Ph.D. August, 1976. 128 pages, 6″ × 9″. Price, $12.50.

NEW Phase-Control Focused Transducers

FOR GREATLY IMPROVED IMAGE

Why is ultrasound being called a "vital diagnostic tool in obstetrics"?

Because it enables you to see inside the uterus.

With the ADR Real-Time Scanner, you can not only see the fetus, you can see it moving, see the fetal heart beating as early as eight weeks' gestation.

ADR's high-resolution image helps you assess fetal presentation, localize the placenta, confirm suspected multiple pregnancies or incomplete abortion, measure BPD's or crown-rump lengths to estimate gestational age. And when amniocentesis or intrauterine transfusion is required, the ADR Scanner helps you determine the site, and guide insertion of the needle to increase the efficiency and safety of the procedure.

Physicians in more than 500 hospitals and private practices are using the ADR Scanner daily in these and other important decisions. And their patients are reassured by seeing their babies, too.

ADR Ultrasound has far more clinical and technological experience than anyone else in our field, so you can be assured of proven reliability and the latest advances in image quality and convenience, such as electronic calipers, digital freeze-frame and automatic photo control. Our portable scanners are easy to operate and economical, too. Hands-on training courses are available through ADR's education department and regional medical centers.

See for yourself

But you don't have to believe us—let us show you. Return the coupon today—or call toll-free (800) 528-1447—for more information, a video tape presentation, or to arrange for a demonstration in your office.

While you're at it, ask us for the names of ADR customers in your area—they'll tell you why they consider the ADR Scanner a "vital diagnostic tool." *

1. *81-mm. BPD confirms 33-week gestation.* Case history: On bimanual examination, patient feels large for dates. Ultrasound measurement of BPD confirms that gestational age is compatible with menstrual history.
2. *Scan verifies posterior placenta previa, 31-week gestation.* Case history: Patient admitted to hospital with heavy vaginal bleeding. Ultrasound scan confirms diagnosis of posterior placenta previa.
3. *Real-time scan demonstrates viable fetus and two masses.* Case history: Patient with history of uterine fibroids was first scanned after a positive pregnancy test. Real time demonstrates viable 10-week gestation and two masses: uterine fibroid and corpus luteum cyst.
4. *Serial sonography monitors cyst.* Case history: Bimanual examination detects mass in patient following positive pregnancy test. Ultrasound revealed 14-week fetus and very large corpus luteum cyst. Subsequent scans demonstrated gradual decrease in size of cyst.

*Queenan, J.T., Contemp. Ob. Gyn. 9:10, March 1977.

EDITORS! REVIEWERS! AUTHORS!

For you . . . a new book that contains virtually everything you want to know about

THE SCIENTIFIC JOURNAL: EDITORIAL POLICIES AND PRACTICES

Guidelines for Editors, Reviewers, and Authors

In 1665 the first scholarly journal was published in France. Since that time, there has been no one source of editorial guidelines for journal editors. This new book now provides you with such a source.

YOU DECIDE YOUR OWN APPROACH!

Presenting the advantages and disadvantages of each specific decision, eminent editors offer you various recommendations, discussions, and opinions concerning the problems you may encounter:

"Because we are aware that there is no 'right' policy on most editorial matters, we have tried not to prescribe rules, but have, instead, explored various facets of the problems that confront the editor in his daily work."

The book is divided into two general sections: editorial policies, which usually require major decisions; and editorial practices, which involve minor decisions, often about format or mechanical style. You'll find essays exploring: the manuscript reviewing system; special types of manuscripts (abstracts, transactions, solicited manuscripts, book reviews). You'll value chapters which cover: information for authors; copyright; errata; references cited; copy-editing; journal cover; etc.

From "the purpose of scientific journals" to "binding practices," this new book contains virtually everything you want to know as editor, reviewer, or author. See for yourself!

By Lois DeBakey, Ph.D. In collaboration with: Paul F. Cranefield, M.D., Ph.D.; Ayodhya P. Gupta, M.D.; Franz J. Ingelfinger, M.D.; Robert J. Levine, M.D.; Robert H. Moser, M.D.; J. Roger Porter, Ph.D.; and F. Peter Woodford, Ph.D. August, 1976. 128 pages, 6″ × 9″. Price, $12.50.

Information for authors

Submission of contributions. Manuscripts should in general be sent to a particular Editor according to the following plan: If it is from the southeastern quadrant of the United States or from Canada, or if it has been presented before one of the official sponsoring societies, to Dr. Brewer; if from the northeastern quadrant (including Ohio), or if it is a Clinical Opinion or a Letter to the Editors, to Dr. Zuspan; if from the north central states, any of the United States west of the Mississippi, Hawaii, Alaska, or abroad, to Dr. Quilligan.

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. Therefore, all manuscripts must be accompanied by the following written statement, signed by one author: "The undersigned author transfers all copyright ownership of the manuscript (title of article) to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

All articles published in this JOURNAL must be contributed to it exclusively. Articles previously published in another language are not acceptable.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority.

Articles dealing with human experimentation cannot be accepted unless the experiment was approved by the author's local Human Experimentation Committee.

Statements and opinions expressed in the articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantee, warrant, or endorse any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

Manuscripts. Manuscripts should be typewritten on one side of the paper only, with double spacing and liberal margins. The original and one copy of the manuscript are required. References should be placed at the end of the article. They should include name of author(s), article title, name of periodical, volume, page, and year. Name of periodical should conform to that shown in latest *List of Journals Indexed in Index Medicus*. For reference style see current issue of JOURNAL. Authors are encouraged to limit references to *16, except* for Communications in Brief, limited to *2*, Current Investigation and Clinical Opinion, limited to *6*, and Current Developments, for which there is *no* limit. Illustrations accompanying manuscripts should be numbered, provided with suitable legends, and marked lightly on the back with the author's name. Authors should indicate on the manuscript the approximate position of tables and text figures.

Tables should be typed on separate sheets of paper, not in the text, with one table to a page. They should be numbered in sequence and each must be referred to at an appropriate point in the text. Captions of the tables should be brief, yet indicate clearly the purpose or content of each table. Rows and columns in the table should precisely define the nature of the data in each. Abbreviations in tables should be used as little as possible and if abbreviations are used they should be explained in a footnote to the table.

An abstract of 50 to 150 words, to be published as an introduction, should accompany each manuscript and should be typed on a separate sheet of paper.

A footnote should be included which gives the name and complete mailing address of the person to whom reprint requests and correspondence should be sent.

A Guide to Writing for the American Journal of Obstetrics and Gynecology may be obtained from the Publisher on request.

Illustrations. A reasonable number of halftone illustrations will be reproduced free of cost to the author, but special arrangements must be made with the Editors for color plates, elaborate tables, or extra illustrations. Original drawings or graphs should be drawn with black India ink. Typewritten or freehand lettering is not acceptable. All lettering must be done professionally. **Do not send original art work, x-ray films, or ECG tracings.** Glossy print photographs are preferred, for good black and white contrast is essential.

Announcements. Announcements of meetings must be received by Dr. Brewer at least 2½ months prior to the time of the meeting. Such announcements should concern major meetings and other significant activities. Announcements of symposia or seminars for which fees are charged are not published in the scientific pages of the JOURNAL but may be submitted for paid advertisements, if desired.

Letters to the Editors. A brief Letter to the Editors commenting upon some article which has appeared in the JOURNAL will be considered for publication. The writer of the original article will have an opportunity to reply to unfavorable comments. A brief case presentation of special interest in the form of a Letter to the Editors will also be considered for publication. All such letters should be sent to Dr. Zuspan.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie.

Reprints. Reprints of articles must be ordered from the Publishers, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63141, who will send their schedule of prices. Individual reprints of an article must be obtained through the author.

A step down...

PERSONALIZED LIBRARY CASES

Keep your personal copies of AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY in these specially designed library file cases. Designed to keep your journal copies near at hand in your office, library, or home.

Your case is heavy bookbinder's board in a rich red Kivar cover. Files are scuff-resistant and washable.

Lettering is stamped in gold leaf and the cases make a fit companion for the most costly binding.

Files are reasonably priced—only $4.95 each, postpaid (3 for $14., 6 for $24.). Add $1.00 postage per case for orders outside U. S. Satisfaction unconditionally guaranteed or your money back! Use the coupon for prompt shipment.

ormation for this product.

"Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism. . ." than those that contain 50 mcg of estrogen. . . and in terms of contraception, 50 mcg products have the same range of effectiveness as those with higher doses of estrogen.

Ortho-Novum 1/50 TRADEMARK 21- and 28-day regimens.

ch yellow tablet contains 1 mg norethindrone and 0.05 mg mestranol.
ch green tablet in the 28-day regimen contains inert ingredients.

e Prescribing Information, a summary of which is on the next page.

Ortho Pharmaceutical Corporation 1979

OJ 1714-A

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables, and references. The physician should be thoroughly familiar with the complete prescribing information and patient information before prescribing the product.

INDICATION: CONTRACEPTION. The pregnancy rate in women using conventional combination oral contraceptives (containing 35 mcg or more of ethinyl estradiol or 50 mcg or more of mestranol) is generally reported as less than one pregnancy per 100 woman-years of use. Slightly higher rates (somewhat more than one pregnancy per 100 woman-years of use) are reported for some combination products containing 35 mcg or less of ethinyl estradiol, and rates on the order of three pregnancies per 100 woman-years are reported for the progestogen-only oral contraceptives. Table 1 gives ranges of pregnancy rates reported in the literature for other means of contraception. The efficacy of these means of contraception (except the IUD) depends upon the degree of adherence to the method.

Table 1: Pregnancies Per 100 Women-Years. IUD, less than 1-6; Diaphragm with spermicidal product (creams or jellies), 2-20; Condom, 3-36; Aerosol foams, 2-29; Jellies and creams, 4-36; Periodic abstinence (rhythm) all types, less than 1-47; 1. Calendar method, 14-47; 2. Temperature method, 1-20; 3. Temperature method—intercourse only in postovulatory phase, less than 1-7; 4. Mucus method, 1-25; No contraception, 60-80. **DOSE-RELATED RISK OF THROMBOEMBOLISM FROM ORAL CONTRACEPTIVES:** Two studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral contraceptives be started on preparations containing .05 mg or less of estrogen.

CONTRAINDICATIONS: Oral contraceptives should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed, abnormal genital bleeding. 7. Known or suspected pregnancy (see WARNINGS, No. 5).

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Four principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. Overall excess mortality due to pulmonary embolism or stroke is on the order of 1.0 to 3.5 deaths annually per 100,000 users and increases with age. **CEREBROVASCULAR DISORDERS:** In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than in nonusers and the risk of thrombotic stroke was 4.0 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION: An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia), the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. The annual excess case rate (increased risk) of myocardial infarction (fatal and nonfatal) in oral contraceptive users was estimated to be approximately 7 cases per 100,000 women users in the 30-39 age group and 67 cases per 100,000 women users in the 40-44 age group. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10-to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent. **Risk of Dose:** In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only oral contraceptives have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk. The risk of thromboembolic and thrombotic disorders, in both users and nonusers of oral contraceptives, increases with age. Oral contraceptives are, however, an independent risk factor for these events. **ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES:** A large prospective study carried out in the United Kingdom estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of oral contraceptives according to age, smoking habits, and duration of use. The overall excess death rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking, and duration of use, nor to compare the effects of continuous versus intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for five or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for five or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. This study reports that the increased risk of circulatory diseases may persist after the pill is discontinued. Another study published at the same time confirms a previously reported increase of mortality in pill users from cardiovascular disease. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of oral contraceptives) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The findings of this analysis are shown in Figure 1 below. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke. (The rates given for pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 cigarettes a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50 percent.) The mortality associated with oral contraceptive use in nonsmokers over 40 is higher than with any other method of contraception in that age group. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia and especially by cigarette smoking. The risk of myocardial infarction in oral contraceptive users is substantially increased in women age 40 and over, especially those with other risk factors. Based on the data currently available, the following chart gives a gross estimate of the risk of death from circulatory disorders associated with the use of oral contraceptives:

SMOKING HABITS AND OTHER PREDISPOSING CONDITIONS—RISK ASSOCIATED WITH USE OF ORAL CONTRACEPTIVES

Age	Below 30	30-39	40+	
Heavy smokers	C	B	A	A—Use associated with very high risk.
Light smokers	D	C	B	B—Use associated with high risk.
Nonsmokers (no predisposing conditions)	D	C,D	C	C—Use associated with moderate risk.
Nonsmokers (other predisposing conditions)	C	C,B	B,A	D—Use associated with low risk.

The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four- to six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2. OCULAR LESIONS. There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue oral contraceptive medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions and institute appropriate diagnostic and therapeutic measures. 3. CARCINOMA. Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in oral contraceptives, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on oral contraceptives. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time oral contraceptives were first given, polycystic ovaries), nearly all occurred in women who had used a sequential oral contraceptive. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only oral contraceptives. Several studies have found no increases in breast cancer in women taking oral contraceptives or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with oral contraceptives, found an excess risk in the subgroups of oral contraceptive users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of oral contraceptives has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. *Trademark

Women, by regimen of control and age of woman.

Traditional contraception and abortion	0.3	0.4	0.4	0.8	1.4	0.8

4. HEPATIC TUMORS. Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study showed that oral contraceptive formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of oral contraceptives. Two studies relate risk with duration of use of the contraceptive, the risk being much greater after four or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time. 5. USE IN OR IMMEDIATELY PRECEDING PREGNANCY, BIRTH DEFECTS IN OFFSPRING, AND MALIGNANCY IN FEMALE OFFSPRING. The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be on the order of 1 to 4 in 1000 exposures. Although there is no evidence at the present time that oral contraceptives further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including oral contraceptives, in pregnancy. One case control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if the progestogen-only oral contraceptives are used), and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy. 6. GALLBLADDER DISEASE. Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives and estrogens. In one study, an increased risk appeared after two years of use and doubled after four or five years of use. In one of the other studies, an increased risk was apparent between six and twelve months of use. 7. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. An increase in triglycerides and total phospholipids has been observed in patients receiving oral contraceptives. The clinical significance of this finding remains to be defined. 8. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in patients receiving oral contraceptives. In some women hypertension may occur within a few months of beginning oral contraceptive use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two and a half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in oral contraceptive users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. Hypertension that develops as a result of taking oral contraceptives usually returns to normal after discontinuing the drug. 9. HEADACHE. The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of oral contraceptives and evaluation of the cause. 10. BLEEDING IRREGULARITIES. Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Postuse anovulation, possibly prolonged, may also occur in women without previous irregularities. 11. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. 12. BREAST FEEDING. Oral contraceptives given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of oral contraceptives should be deferred until the infant has been weaned. **PRECAUTIONS: General:** 1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another physical examination being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by oral contraceptive therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping oral contraceptives, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. **INFORMATION FOR THE PATIENT: (See Patient Package Insert). DRUG INTERACTIONS:** Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and ampicillin. **CARCINOGENESIS, PREGNANCY, NURSING MOTHERS: See CONTRAINDICATIONS and WARNINGS. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS): Thrombophlebitis. Pulmonary embolism. Coronary thrombosis. Cerebral thrombosis. Cerebral hemorrhage. Hypertension. Gallbladder disease. Liver tumors. Congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis. Neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea, usually the most common adverse reaction. Vomiting, occurs in approximately 10% or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Dysmenorrhea. Amenorrhea during and after treatment. Temporary infertility after discontinuance of treatment. Edema. Chloasma or melasma which may persist. Breast changes: tenderness, enlargement, and secretion. Change in weight (increase or decrease). Change in cervical erosion and cervical secretion. Possible diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Increase in size of uterine leiomyomata. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome. Cataracts. Changes in libido. Chorea. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. (ORTHO-NOVUM 1/50□21 and ORTHO-NOVUM 1/50□28 contain tartrazine. Allergic reactions have been reported with the ingestion of this dye in some patients.) **ACUTE OVERDOSE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Business communications

Business communications. All communications in regard to advertising, subscriptions, changes of address, etc., should be addressed to the Publisher, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63141.

Annual subscription rates.

	U. S.	*All Foreign Countries*
Institutional*	$47.00	$64.00
Personal†	$32.00	$49.00
Student, resident†	$25.60	$42.60

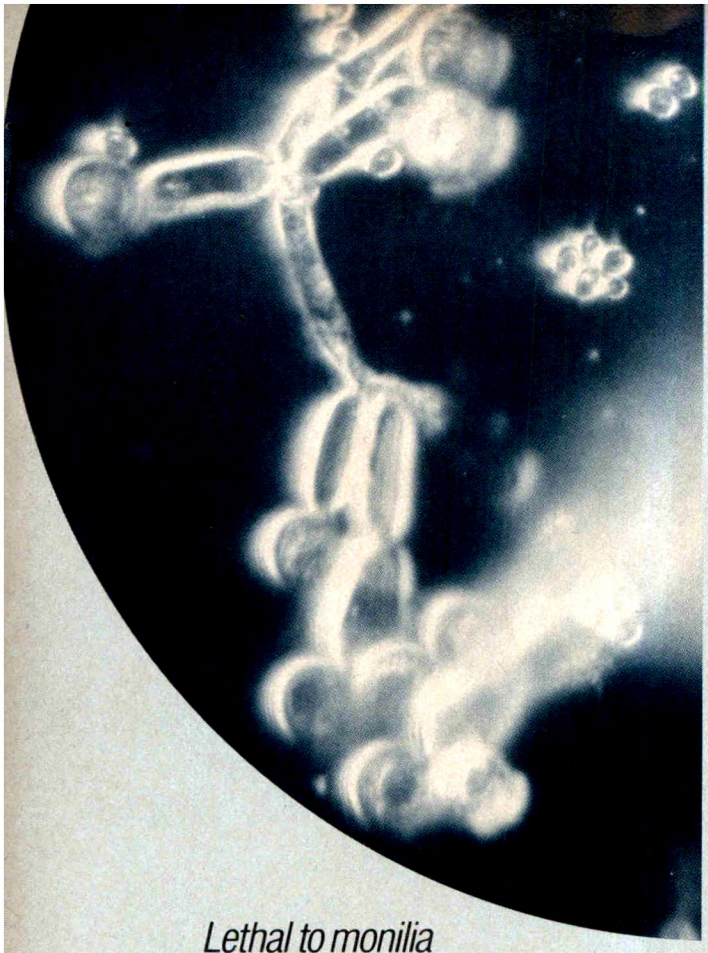
Single copies are $4.50 postpaid. Remittances should be made by check, draft, or post office or express money order, payable to this JOURNAL.

*Institutional (multiple-reader) subscriptions are available to public and private libraries, schools, hospitals, and clinics; city, county, state, provincial, and national government bureaus and departments; and all commercial and private institutions and organizations.

†Personal subscriptions and all student-rate subscriptions must be in the names of, billed to, and paid by individuals. All student-rate requests must indicate training status and name of institution.

Publication order. The semimonthly issues of this JOURNAL form three volumes per year; the index is in the last issue of the volume—in the April 15, August 15, and December 15 issues.

Change of address notice. Six weeks' notice is required to effect a change of address. Kindly give the exact name under which a subscription is entered, the name of this JOURNAL, and the full form of both old and new addresses, including the ZIP code number.



Advertisements. Forms close 25th of second previous month for the 1st of month issue; 15th of preceding month for the 15th of month issue. Advertising rates and page sizes will be given on application. Neither the Editor(s) nor the publisher guarantee, warrant, or endorse any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

Bound volumes. Publishers' Authorized Bindery Service, 4440 West Roosevelt Road, Chicago, Illinois 60624, will quote prices for binding complete volumes in permanent buckram.

The appearance of a code at the bottom of the first page of an original article in this JOURNAL indicates the copyright owner's consent that copies of the article may be made for personal or internal use, or for the personal or internal use of specific clients. This consent is given on the condition, however, that the copier pay the stated per copy fee through the Copyright Clearance Center, Inc., P.O. Box 765, Schenectady, N. Y. 12301, (518) 374-4430, for copying beyond that permitted by Section 107 or 108 of the U.S. Copyright Law. This consent does not extend to other kinds of copying, such as copying for general distribution, for advertising or promotional purposes, for creating new collective works, or for resale.

Lethal to monilia

Gentle to patients

IN MONILIASIS

BETADINE® Microbicides Vaginitis Regimen

High cure rate... rapid symptomatic relief

High cure rate is achieved in monilial vaginitis with the topical regimen employing BETADINE Microbicides:

BETADINE® SOLUTION
BETADINE® VAGINAL GEL*
(povidone-iodine)
BETADINE® DOUCHE

Easy-to-follow regimen

In the office, swab the cervix and vulvovaginal area with BETADINE Solution which is promptly and decisively microbicidal. Prescribe BETADINE Vaginal Gel (povidone-iodine), one applicatorful of which is to be inserted each night, followed the next morning by BETADINE Douche in therapeutic concentration.

After 2 weeks

The patient returns for an office visit after two weeks of therapy. In more resistant cases, the regimen may have to be continued through 1 or 2 cycles. BETADINE Microbicides are virtually nonirritating to vaginal mucosa and do not stain skin and natural fabrics.

Lethal to other vaginal pathogens too

The broad-spectrum microbicidal action of BETADINE Microbicides kills not only monilia, but also *Trichomonas* and *Hemophilus vaginalis*. Unlike exclusively antimonilial agents, the BETADINE MICROBICIDES VAGINITIS REGIMEN is not contraindicated when *Trichomonas* or *H. vaginalis* is present.

BETADINE Microbicides kill both gram-positive and gram-negative bacteria (including antibiotic-resistant strains), fungi, viruses, protozoa and yeasts. Their microbicidal action is maintained in the presence of blood, serum, and vaginal secretions.

*BETADINE Vaginal Gel (povidone-iodine) has been evaluated as possibly effective for use in the management of *Trichomonas vaginalis* vaginitis, monilial vaginitis and nonspecific vaginitis.

Purdue Frederick

See adjoining page for brief summary.

Now available...
BETADINE® Douche Kit

For douching in the BETADINE Microbicides Vaginitis Regimen, you can now prescribe BETADINE Douche Kit for a complete douching system, or BETADINE Douche 8 oz. for use with a gravity-flow douche bag or bulb syringe.

BETADINE Douche Kit contains:

(1) BETADINE Douche concentrate for making the douche solution
(2) Comfortable-to-use, squeezable, plastic syringe bottle
(3) Anatomically-correct cannula
(4) Instruction booklet
— Complete, ultra-modern, convenient douching system
— Provides the benefits of microbicidal BETADINE Douche

For a therapeutic concentration using BETADINE Douche Kit, instruct the patient to: Pour one (1) tablespoonful of BETADINE Douche concentrate into the syringe bottle provided in the kit. Add lukewarm water up *to the top of the syringe bottle.* Attach nozzle and shake gently to mix. Douche, *then repeat the procedure.*

For a therapeutic concentration using BETADINE Douche 8 oz., instruct the patient to: Add two (2) tablespoonfuls to a quart of lukewarm water, for use with a gravity-flow douche bag or bulb syringe.

BETADINE® Vaginal Gel (povidone-iodine)
Brief Summary

For use in the treatment of Trichomonas vaginalis vaginitis, monilial vaginitis and nonspecific vaginitis.

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows: possibly effective for use in the management of trichomonas vaginalis vaginitis, monilial vaginitis and nonspecific vaginitis. Final classification of the less-than-effective indications requires further investigation.

Precaution

If irritation, redness or swelling develops, discontinue use. The rare individual with history of iodine sensitization should not use this product, pending further investigation.

IMPORTANT NEW BOOKS FROM G.K.HALL & CO.

INTRAUTERINE DEVICES AND THEIR COMPLICATIONS
by David A. Edelman, Ph.D.
Gary S. Berger, M.D.
Louis Keith, M.D.
0-8161-2134-6 $20.00 est. 156 pp. August

Intrauterine contraception continues to be of major importance in both developing and developed nations. Approximately fifteen million devices are in use; three to four million of them in the United States. This new book provides the first comprehensive view of the use of IUDs. The authors analyze the large body of relevant literature emerging from recent research and assess the nature, frequency and treatment of IUD complications.

Contents: *Preface; In Memoriam; Chapter 1 - Development, Mechanisms of Action and Evaluation of IUD Research; Chapter 2 - IUD Insertion; Chapter 3 - Uterine Perforation, Appendix A; Chapter 4 - Pelvic Inflammatory Disease, Appendix B, Appendix C; Chapter 5 - Bleeding; Chapter 6- Cervical and Uterine Pathology; Chapter 7 - Intrauterine Pregnancy; Chapter 8 - Ectopic Pregnancy; Chapter 9 - Return to Fertility After IUD Discontinuation; Chapter 10 - IUD Complications in Perspective*

ADOLESCENT PREGNANCY:
Perspectives for the Health Professional
edited by Peggy B. Smith, Ph.D. and
David M. Mumford, M.D.
with a foreword by Joseph Califano, Secretary
Department of Health, Education, and Welfare
0-8161-2121-4 $16.50 est. 156 pp. October

The editors present thirteen perspectives on the medical, psychological, social, cultural, economic, and legal issues related to adolescent pregnancy. The essays suggest new approaches that will help physicians, nurses, psychologists, social workers, educators, and other health professionals to deal more effectively with this pressing problem.

Contents: *Foreword - Joseph Califano, Secretary, U.S. Dept. of Health, Education, and Welfare; Chapter 1 - Adolescent Psychosexual Development by Joan Sheff Lipsitz, Ph.D.; Chapter 2 - Economics of Adolescent Pregnancy by Ralph Ingersoll, M.D.; Chapter 3 - Psychiatric Aspects by David D. Youngs, Jr., M.D.; Chapter 4-Adolescent Obstetrics and Gynecology by Ivor L. Safro, M.D.; Chapter 5 - Sociological Implications of Adolescent Parenthood by Frank Furstenburg, Jr., Ph.D.; Chapter 6 - Programs for Sexually Active Teens by Peggy B. Smith, Ph.D.; Chapter 7 - Venereal Disease and the Adolescent by David M. Mumford, M.D.; Chapter 8 - Adolescent Pregnancy Termination by Alfred N. Poindexter, M.D., and Raymond H. Kaufman, M.D.; Chapter 9 - Parenthood Education by Peggy B. Smith, Ph.D.; Chapter 10 - Legal Aspects of Adolescent Pregnancy by Carla Dowben, J.S. and Peggy Bunch, J.D.; Chapter 11 - Ethics of Adolescent Sexuality by Konstantin Kolenda, Ph.D.; Chapter 12 - Sex Education by Peggy B. Smith, Ph.D.; Chapter 13 - Sexual Counseling for Adolescents by Patricia Schiller, J.D.*

Saf-T-Coil®— in use for over 10 years

Saf-T-Coil is an IUD found comparable to the "pill" in use effectiveness.[1-2]

Five-year study[2]—27,712 insertions—541,248 women/months of use:

- a low 0.8% *in situ* pregnancy rate
- high 80% continuation rate
- 11.9% expulsion rate
- 8.0% removal rate

Subsequently, the investigators made Saf-T-Coil their "device of first choice."

1. Caraway, A.F.: Florida's Experience with an Intrauterine Device for the Nulliparous Patient. Presented at the International Family Planning Research Association Meeting, Palm Springs, California, October 21, 1974.
2. Caraway, A.F. and Vaughn, B.J.: J. Reprod. Med. *10*:170, April 1973.

Life table data—46,721 women/months

Clinical trials were conducted with Saf-T-Coil in which use effectiveness was determined as follows for parous women, as tabulated by the life table method.[3-7] This experience is based on 46,721 women/months of use including 4,231 women who completed 12 months of use and 1,842 women who completed 24 months of use. Rates are expressed as events per 100 women through 12 and 24 months of use.

	12 Months	24 Months
Pregnancy	2.4 (0.42-2.8)	3.1 (0.42-3.8)
Expulsion	18.3 (7.8-29.0)	18.8 (9.0-21.5)
Medical Removal	15.6 (4.8-18.7)	23.2 (9.0-27.0)
Continuation Rate	70.4 (55.2-88.0)	59.8 (57.0-81.5)

7. Tietze, C.: Report of a New IUD: The Double Coil. Advances in Planned Parenthood, III:85, 1967.

Three Saf-T-Coil sizes ensure contraceptive effectiveness throughout her reproductive years: Saf-T-Coil Nullip 25-S for the nulliparous and young woman, Saf-T-Coil 32-S for the primiparous woman and Saf-T-Coil 33-S for the multiparous woman.

Every Saf-T-Coil is made of inert plastic with no copper additives. And with every Saf-T-Coil—Saf-T-Sound®—the sterile, disposable intrauterine probe that helps make fitting easier and more accurate.

Caution: Federal law restricts this product to sale by or on the order of a physician.
Contraindications: Should not be used in: pregnancy or suspicion of pregnancy; abnormalities of the uterus resulting in distortion of the uterine cavity; acute pelvic inflammatory disease or a history of repeated pelvic inflammatory disease; postpartum endometritis or infected abortion in the past three months; known or suspected uterine or cervical malignancy including unresolved, abnormal "Pap" smear; genital bleeding of unknown etiology; untreated acute cervicitis until infection is controlled.

Saf-T-Coil®

Transactions of the Forty-sixth Annual Meeting of the Central Association of Obstetricians and Gynecologists

Time

Presidential address

WILLIAM B. GODDARD, M.D.
Lakewood, Colorado

THERE IS NO HIDDEN meaning in today's title, nor is it the acronym of some mysterious government agency or new form of health care. It is a discussion of the use and misuse of our professional time. It is an attempt to communicate to you the distillation of many discussions with friends, random thoughts during boring meetings, starts and false starts, broken New Year's resolutions, a few successes, and many failures. I suspect many of you will meet yourselves in the coming discussion.

A young man who graduated from medical school in my day had achieved much. He had been at or near the top of his class in high school and college and had gone through four years of training with men and women of similar achievements. He had mastered a great deal of cognitive knowledge and put in long, but productive hours. He knew how to study and more often than not was personable and had a wide range of interests. He then entered the internship for a one- to two-year period. He absorbed much knowledge in a short period of time, lived and breathed medicine, and spent long hours in the hospital. His course had many of the characteristics of a fugue.

He then moved on to residency and got more of the same. This was not necessarily at the demand of the senior staff, but frequently at the demand of his own desire for accomplishment. He frequently never left the hospital on the same calendar day as the one on which he entered. He was expected to tend the laboring mother all night, operate all morning, and solve problems in the clinic all afternoon. This pattern of life went on for three or four years. The resident emerged from these years superbly trained in obstetrics and gynecology, but he also had learned something else, and that was how it is to function when one is always tired. We train our residents to be tired. I submit that this is learned behavior, that many physicians never overcome this training, and this is an important reason that the physician's working habits are so markedly different from those of other people in our society. I do not think any of us need to look very far without thinking of people who have carried this habit the rest of their lives. This attitude, though less prominent in younger physicians, does not seem to have changed very much over the years. It is today enough of a problem that the Resident Physicians Section of the A. M. A. has found it necessary to set up a "Work Group on The Well-Being

Presented at the Forty-sixth Annual Meeting of the Central Association of Obstetricians and Gynecologists, Kansas City, Missouri, October 13-15, 1978.
Reprint requests: Dr. William B. Goddard, 2020 Wadsworth Blvd., Suite 16, Lakewood, Colorado 80215.

0002-9378/79/120355+05$00.50/0 © 1979 The C. V. Mosby Co.

of Physicians in Training" and write, in their own words, "A Survivor's Manual."[1] Of course, we did voluntarily choose this training and none of us can plead that we were innocent when we entered it. I do not intend to discuss the so-called Type A personality and whether it is a fact or fiction, but I submit that we come out of our training program into practice feeling that most of our waking hours will be spent with medicine.

This habit is also seen in other professions, such as law and accounting, but is epitomized in medicine. The academician, too, is forever in trouble with time, though many university academic departments are wiser than we are; their departmental chairmanships are rotated, are frequently fobbed off on one of the newer members, and are not considered an honor. I have for years felt that the Chairmanship of a Department of Obstetrics and Gynecology is in many ways equivalent to being ridden out of town on a rail. It is the honor of the thing that makes up for the discomfort.

Time also is a problem in business and if you have ever found yourself on a businessman's mailing list, you will know that brochures for sessions on "The Management of Time", "Delegation of Authority", "Management by Objective," and similar titles are subjects of many symposia. As an aside, if you physicians think the cost of postgraduate medical education is high, you should see the tuition for these symposia.

So lack of time is a universal problem. We are all somewhat like the white rabbit of Lewis Carroll: "I'm late, I'm late, I'm late, for a very important date."

Let us look around us—and that includes in the mirror—how do doctors use their professional or working time? I am impressed that we do not use our time at all. Others use our time for us. We go in the morning to the operating room. We go at 7:30 for no sensible reason other than that nurses' morning shifts begin at 7:00 and it takes a half hour to get ready. We begin not when we wish to begin, but when the nurses wish us to begin. We may wait inordinate amounts of time between operations, and when we go on rounds we find that our patients are missing due to the requirements of x-rays, laboratory, and other hospital schedules. But then we do not schedule rounds at a predictable time, so we cannot complain. We go to the office where, to quote a well-known private practice analyst, "fifty percent of our practice is run by the patients, thirty-five percent by the office help, and fifteen percent by the physician."

One of our patients' major complaints is we do not schedule their appointments with any consideration for their time. We complain that we see too many patients, but how many of us, when a patient complains that she is unable to get an appointment, squeeze her in rather than compliment our receptionist on keeping to our agreed schedule. Soon our receptionist learns that we really like to be overscheduled. I submit that this attitude is a direct carryover from our residency days and one that we should be able to cure.

Many practicing physicians consider the telephone a monster rather than a quick and reliable means of communication. A query of these doctors reveals that they have never learned to set up guidelines for their receptionists to facilitate communication. It takes only a moment between patients to approve a plan of action with your nurse and a long time if you try to do it yourself. This, and I speak from experience, can be done very smoothly. In one hospital where I work, pagers are carried into the operating room. I for one have no interest in knowing in the middle of a hysterectomy that Mrs. Smith wishes her birth control prescription refilled before lunch.

The last major category of professional time is Committees and Meetings. You may not know it, but the true contents of Pandora's box was very probably a printing press and a committee meeting agenda.

John Galbraith, in *The New Industrial State*,[2] discussed committees pointed out that power once transferred to the committee could not be retrieved, and discussed the effect of this fact on decision making. However, he discussed another type of committee. He called these ceremonial or representational committees and felt that they were useful to give apparent representation to various groups within power structures, but had no real input into the decision-making process. Do you see yourself there? I serve on far fewer committees since recognizing this fact and I would like to suggest to you that you look at the committee meetings you attend, divide them into the two functional groups—decision-making and ceremonial—attend the first and ignore the second. Do this for a year and then look back; you will note that the world is unchanged

Another time waster, supposedly needed for good medical care, is the hospital meeting. Does anyone, including the Joint Commission on Accreditation, really believe that these hours of jumping from subject to subject, and self-serving audit to self-serving audit, really improve the care of the patient? If they do not, why do we continue to go? An integrated postgraduate course on a single subject, or a meeting such as this one, is more likely to improve your care of the patient. Useless meetings are a major problem in our profession.

A largely unrecognized time problem in our profession is the medical record. In one of the buildings of the Mayo Clinic there used to be a glass case and in that case was a large, solid, bound book, the first case-book

of the Mayo Clinic. In that book appeared page after page of patient visits. Each visit was headed by the patient's name, and in the front of the book was a list of patients arranged alphabetically, and after each patient's name was recorded the number of each page on which a visit by that patient appeared. In reading those I was impressed: first, the penmanship was much better; second, the grammar was much better; third, the observations were more carefully made; fourth, the only change in recording of medical data since that time has been to put those patient visits on individual sheets of paper and file them in a manila folder. The narrative record is unchanged.

The recently popular problem-oriented chart may be an improvement in the proper hands, but on many charts, the beloved "SOAP" consists of substituting subjective for history, objective for physical, assessment for diagnosis, and plans for treatment, without real change in content or organization.

I would like to suggest that the best medical charts in the world are the obstetric charts. They are time-oriented, they are tabular, and many parameters are graphed rather than written. The flow and direction of the patient's condition are obvious at a glance, and deviations from normal are quickly spotted. This chart organization gives a clarity comparable to the temperature chart. Can we not in some manner apply this notion to the gynecologic chart and, indeed, to all medical charts? There are some physicians who, at least in their offices, have applied this to their own charting and it gives much more clarity and much more accuracy to their management. We should begin to push the expansion of this idea into the hospitals.

You may say, "So what!" If the social anthropologists are correct, we do not think abstractly, we think in a language, and our charts are the language of medicine.

Mathematics has developed only as the mathemetician has been able to manipulate agreed-upon symbols and the same development is true of physics and chemistry. The symbolic logic of George Boole has become the basis of the entire world of the computer.

I would suggest that medicine can progress rapidly only in the areas in which we abandon the narrative form, develop agreed-upon symbols to represent our basic information about the patient, and then learn to manipulate those symbols in a mathematical manner. The mathematics is already available, and has been available since the nineteenth century, in the form of Bayes' Theorem and other formulas, but the data on which to operate have not been available. This lack of data is primarily because of our primitive method of record keeping and the habits of thought engendered by that record keeping.

For simple examples of what I am talking about, I refer you to *Surgical Decision Making*, by Eiseman and Wotkyns,[3] and to Chapter 17 of *Costs, Risks and Benefits of Surgery*.[4] Most of us do not have twenty years of experience in medicine. We have one year's experience repeated twenty times. The purpose today is not to inflict upon you a radical medical record, but to get you thinking that our present record is primitive and needs improvement. We think the way we write, not the other way around, and the medical record has been an impediment to clear medical thinking.

If time is a problem, how are we to obtain time? Different things work for different people. Almost every person I have known who accomplishes a great deal, whether it be in medicine or in cultivating roses, does it in the morning. There are no interruptions; the phone does not ring. There are no hospital committee meetings, the children are not up—nor, for that matter, is the sun.

You may say, "I used to be able to do it, but I cannot any more." I am indebted to Prof. John Beazley for the following practical hint: set your alarm clock five minutes early. It is too short a time to go back to sleep and you can make a cup of coffee. After several days, add five more minutes, and so on until you have an hour or more. This is a recent experiment which appears to be bearing fruit.

Another suggestion, which is not yet bearing much fruit, is to structure your time. This seems to be the most difficult discipline of all for physicians. The telephone intrudes, we add that extra patient, the previous surgeon goes over his scheduled time in the operating room, meetings run overtime, and on and on. Have your secretary call you 55 minutes into every committee meeting with a carefully scheduled emergency call. It is interesting how this speeds up agendas and assists in the structuring of your time.

Another suggestion is the retreat. Its increasing popularity in business and hospital planning sessions is evidence of its usefulness. Its advantages are total absence of the daily routine of office and family, concentration on the subject at hand, and interaction with others of similar interests. But does a retreat need to be a group session? Do you remember studying for your Boards? Do you remember writing a paper? Do you remember that one's efficiency seemed to be greatest then, with the pressure of time at your back and a clearly defined goal? Have you considered a similar approach to reading the medical literature, rereading Shakespeare's plays, or, for that matter, learning to program a computer? The concept of the retreat is worthwhile even though you are the only one retreating.

Another suggestion is to delegate authority. We physicians are egoists and compulsives and we have difficulty with consistent delegation of authority. It is this ability to delegate that separates the truly good administrator from others. It is an ability that appears to be almost wholly lacking in physicians, particularly those in private practice. It is said that behind every great man stands a good executive secretary, and a look at the salaries of executive secretaries in corporations should convince you of the truth of this statement. Conscious and consistent delegation of authority can be learned. It is in this area that the practice management consultant gives his message, a message frequently ignored.

A major opportunity for the physician to improve his use of time is through the use of computers. Please note that I am suggesting the use of the computer as a means of changing our way of thought, i.e., as a process rather than an end in itself. This notion is quite different from the usual use of computers today.

We are all aware of the cute phrases, such as "garbage in, garbage out," "IBM stands for "I've been moved;" and "a computer can make more mistakes in 20 seconds than 20 men working 20 years." These phrases do have a ring of truth to them, but something new and spectacular, and as yet dimly recognized, is happening in the computer field. Until the last three years, the computer has been a big device, growing ever bigger, requiring air-conditioned rooms, mahouts who tend it from birth to retirement, and a large supply of kilobucks. Many physicians who have tried to use computers have been turned off due to their complexity and the professional programmer's attitude of Procrustes; he cuts you to fit his programs.

But something has happened. In about 1975, due to the plummeting cost of integrated circuitry, the microcomputer developed; progress has been rapid since. Look back to 1961 when IBM introduced the 360 Series Computer. You can buy, today, a computer with the power equal to the largest pre-1961 machine for about $3,500. If you wish to add all of the bells and whistles, and a good printer, you will have a tough time spending more than $6,000. You can have a computer, which fits on your desk, more powerful than any computer made before 1961, for less than the price of a new car.

Is this too good to be true? What are the problems? It is slow, and when it comes to getting it to do what you want it to do, there is as yet no programming help out there whatsoever. The cliché that the computer does what you told it to do and not what you thought you told it to do, has never been closer to the truth. However, new languages are rapidly developing which will allow you to talk to the stupid things in comfortable, English phrases, and programming the computer yourself is becoming easier.

The most common computer language at present is BASIC, but BASIC is twenty years old and new languages, such as Pascal, and a medically oriented one with the delightful acronym of MUMPS, are becoming popular for the nonprofessional user.

There are many people standing behind airline and hotel reservation counters who do not think computers are hard to use. Why not doctors? The breakthroughs in computer price and languages are giving us an opportunity to change our modes of thought and structure our knowledge.

A final problem in our use of time is the divided nature of our specialty.

For many years, we have been trained as obstetricians and gynecologists and it has been felt, and properly so, that a specialist must know the female in both her pregnant and her nonpregnant state. When it comes to practice, we have a double specialty, with obstetric practice patterns quite different from gynecologic practice patterns. In the days when I practiced both sides of the specialty, I recognized a constant need for changing of my mental gears from day to day and minute to minute and over the years it became increasingly frustrating.

The historical thrust of medicine has been toward greater and greater specialization, not less and less, and I must question the virtues of the continued practice by one individual of the double specialty. The old eye, ear, nose, and throat physician has disappeared; "ear, nose, and throat" is separating into ear on the one hand and nose and throat on the other, and no one is mourning the passing. The general internist is disappearing into the specialty of family practice and is being replaced by the cardiologist, the gastroenterologist, the pulmonary specialist, the endocrinologist, the allergist, the specialist in diabetes, and the specialist in arthritis. This is reckoned as progress and probably is.

In our specialty, we have the identifiable subspecialties of reproductive endocrinology, oncology, and maternal-fetal medicine, and we, too, reckon this as progress. Can we logically cling to the notion that we are obstetricians and gynecologists and are we surgeons or primary-care physicians? With that sentence I plead guilty to having fallen into a semantic trap, only recently recognized. Primary-care physicians and surgical specialists are not opposite sides of the same coin. Recently, our secretary has been appointed a Governor of the American College of Surgeons. In our spring *Newsletter,* he encouraged our members, as surgical specialists, to apply also for membership in that organization.

For these efforts he received a critical letter from the Director of The American College of Surgeons saying, and I quote, "The official position of obstetrics-gynecology at the present time is that they represent a primary-care specialty, and as such, it appears anomalous to categorize them as a surgical specialty." Further on "Obstetrics/gynecology is widely thought of as a non-surgical discipline."[5] The semantic trap is the notion that surgical care is episodic and that long-term periodic evaluation of an individual's problems (primary care) is somehow "unsurgical" and, therefore, to be condemned.

Stay out of the trap of believing first, that primary care and surgical specialization are mutually exclusive, and second, that periodic evaluation is somehow demeaning to the surgeon and that episodic care is not.

Is it not time to consider separating *at the practice level* obstetrics from gynecology? Obstetrics is a 24 hour, quasiemergency form of medicine, with the proper prenatal evaluation of the mother and fetus becoming an increasingly important and increasingly complicated activity. Much of it requires the presence in the hospital of both patient and physician. Delivery is becoming simpler. It is a pity, but manipulative obstetrics is rapidly becoming a lost art, and it appears that an increasingly common indication for cesarean section is "threatened spontaneous delivery." Whether the exploding levels of cesarean-section deliveries are the wave of the future, or a temporary aberration, only the future will tell, but certainly, obstetrics is more complicated, more time consuming, and more demanding of the physician than it used to be in the days of general anesthesia and "perineal obstetrics."

On the other hand, gynecology also is becoming more complicated, despite the belief of some that all we can do is hysterectomies. Most evaluations of gynecologic-endocrine problems are still done by the ordinary practicing gynecologist. Most malignancy is still treated by him and the clinical acumen required for the use of estrogen and the birth control pills is certainly not decreasing. Our surgery is changing; the colposcope, the laparoscope, and the operating microscope are developing in our specialty a whole class of what I choose to call "instrument-dependent" surgical procedures. Most gynecologic practice is of a scheduled, structured type and most of our surgery is planned and elective as opposed to urgent and emergent.

Thus it appears that the modern obstetrician-gynecologist is on the horns of a dilemma. Each half of his double specialty requires different work patterns and, most importantly, different habits of thought. It is any wonder that many are frustrated? This is not advocacy of return to the old Johns Hopkins type of complete separation, but the formal recognition within the field of obstetrics/gynecology of the already existing differences in interests of men within our own specialty. Why advocate this? I would be terribly unhappy if you interpret this as an attempt to destroy our cohesiveness, for rather it is an attempt to strengthen our double specialty. Obstetrics/gynecology has recognized the need for recognition of special-interest groups within the specialty by the formation of the three presently approved subspecialty groups. We need to add at least one more: gynecologic surgery. We may need to add others in the future. It may be good that we have been rebuffed by the American College of Surgeons, for this may stimulate expanded recognition of special interest groups within the traditional organization of our specialty, for only in this way will obstetrics/gynecology continue to grow.

This has been a somewhat personal talk, but all experience is personal and if some of you agree with these ideas and are encouraged to try them, or if you disagree and are encouraged to prove me wrong, then the talk will have been worthwhile.

Prolactin-secreting pituitary adenomas in women

II. Menstrual function, pituitary reserves, and prolactin production following microsurgical removal

WILLIAM R. KEYE, JR.*

San Francisco, California

A prospective study of 46 women with prolactin-secreting pituitary adenomas and amenorrhea and/or galactorrhea was performed to determine the influence of the selective transsphenoidal removal of these tumors on pituitary and reproductive function. This procedure was effective in restoring menstrual function in 34 of 41 women and in eliminating lactation in 30 of 40 women. Tumor size and preoperative serum prolactin concentrations were the most important factors in predicting the postoperative disappearance of symptoms. Normal menstrual function returned in 33 of 34 women with tumors <2 cm in diameter but in only one of seven women with tumors >2 cm. Similarly, galactorrhea disappeared in 29 of 34 women with tumors <2 cm but in only one of six women with larger tumors. Menses returned in 31 of 32 women and galactorrhea disappeared in 25 of 31 women with preoperative serum prolactin levels below 200 ng/ml; conversely, menses returned in only three of nine women and lactation ceased in one of six women with preoperative serum prolactin concentrations above 200 ng/ml. Prolactin concentrations decreased in 42 of 43 patients following the removal of pituitary adenomas and returned to normal in 30. Postoperative pituitary reserves of adrenocorticotropic hormone, growth hormone, luteinizing hormone, and follicle-stimulating hormone were normal in most patients. These data indicate that the removal of prolactin-secreting pituitary adenomas by a neurosurgeon accomplished in this surgical technique is effective in restoring menstrual function and eliminating lactation in most women, especially if the tumor is <2 cm in diameter and the preoperative serum prolactin concentration is <200 ng/ml.

PRIOR TO 1974, reports of the neurosurgical removal of pituitary adenomas in women with amenorrhea or galactorrhea described a discouraging incidence of operative complications and postoperative pituitary dysfunction. These results were due in part to the surgical techniques and in part to the destruction of normal pituitary tissue by relatively large tumors. Since 1974, there have been several reports of the selective microsurgical removal of small prolactin-secreting adenomas (microadenomas) with infrequent complications and preservation of normal pituitary function.[1-7] However, factors that influence the postoperative pituitary and reproductive function of women with prolactin-secreting adenomas have not been elucidated in these reports.

Therefore, we studied the influence of the duration of amenorrhea and galactorrhea, age at the time of

0002-9378/79/120360+06$00.60/0 © 1979 The C. V. Mosby Co.

surgery, preoperative and postoperative prolactin serum concentrations, and tumor size on the resumption of menses and disappearance of galactorrhea following the transsphenoidal removal of prolactin-secreting adenomas. In addition, we determined the postoperative reserves of pituitary trophic hormones and quantitated serum prolactin concentrations during the first 12 months postoperatively.

Material and methods

Clinical material. Forty-six women, aged 15 to 50, with histologically proved prolactin-secreting pituitary adenomas were studied. These women presented with primary amenorrhea, secondary amenorrhea of at least 6 months' duration, and/or galactorrhea. The presumptive diagnosis of a pituitary adenoma was made on the basis of an elevated serum prolactin level and an abnormal hypocycloidal polytomogram. A detailed review of the historical data and physical features of 25 of these patients has been reported previously.[7]

Each patient was evaluated by at least one of the authors prior to surgery and at 3 to 6 month intervals following surgery.

Treatment. Transsphenoidal microsurgical exploration of the sella was performed on all 46 patients. Adenomas were identified and selectively removed in toto when possible. In addition, the tumor site was curetted and treated with absolute alcohol. Three patients in whom removal of the adenoma was judged incomplete at the time of operation received postoperative irradiation.

Endocrine evaluation. Baseline serum concentrations of luteinizing hormone (LH), follicle-stimulating hormone (FSH), prolactin, thyroid-stimulating hormone (TSH), cortisol, and growth hormone (GH) were obtained preoperatively and on at least one occasion at 3, 6, or 12 months postoperatively. In addition, anterior pituitary trophic hormone reserves were determined for LH, FSH, adrenocorticotropic hormone (ACTH), and GH prior to surgery and at 3, 6, or 12 months postoperatively. To assess LH and FSH reserves, gonadotropin-releasing hormone* (GnRH) was administered as an intravenous bolus of 100 μg at t = 0. GnRH was administered in the early follicular phase in women who were menstruating. Blood samples were obtained through an indwelling catheter at t = −30, −15, 0, +5, +10, +15, +20, +25, +30, +45, +60, +90, and +120 minutes and assayed for LH and FSH. To assess GH and ACTH reserves, insulin tolerance tests were performed with crystalline insulin (0.1 U/kilogram of body weight), administered as an intravenous bolus at t = 0. Blood samples were obtained through an indwelling catheter at t = −10, 0, +15, +30, +45, and +60 minutes and assayed for GH, cortisol, and glucose. An increase of 5 ng/milliliter or more of growth hormone and an increase of 8 μg/milliliter or more of cortisol were considered normal.

Assay procedures. Serum LH and FSH were measured by radioimmunoassay as previously described.[8] Results are expressed as equivalents of the Second International Reference Preparation of Human Menopausal Gonadotropin in milli–International Units (mIU) per milliliter of serum. Serum prolactin concentrations were measured by a homologous radioimmunoassay and are expressed as nanograms of human prolactin (VLS No. 3 standard) per milliliter of serum.[9] Immunoreactive human GH was assayed according to the modified method of Grodsky and Forsham.[10] Plasma cortisol was determined by a fluorometric method.[11]

Results

Postoperative reproductive function. Menses returned in 34 of the 41 patients (83%) with preoperative amenorrhea who were observed from 3 months to 3 years postoperatively. Seven women have not resumed menses after surgery. No menstrual information is available in three patients who were lost to follow-up following their initial postoperative examination. Two women had preoperative amenorrhea because of a previous hysterectomy, one of whom also had ovarian failure.

Lactation has disappeared in 30 of the 40 patients (75%) with preoperative galactorrhea who have been observed from 3 months to 3 years postoperatively. Two patients did not have galactorrhea prior to surgery and no current information is available on four patients.

Relation to age. When patients were placed in order according to age, a difference in postoperative return of menses was observed between women less than 30 years of age and those more than 30 years of age at the time of surgery (Table I). This difference was, however, not statistically significant. The return of menses was more frequent in women less than 30 years of age at the time of surgery (24 of 26 or 92%) than in women over the age of 30 (10 of 15 or 67%). However, four of the five women over 30 years of age with persistent amenorrhea had tumors larger than 2 cm in diameter, three of whom were judged to have subtotal removal of tumor. In addition, the two patients with persistent amenorrhea who were under 30 years of age at the time of surgery also had tumors greater than 2 cm in diameter.

There was no apparent relation between the postop-

Table I. Return of menses following surgical removal of a prolactin-secreting adenoma

	Total No. of patients	Return of menses	
		No.	%
Age (yr.):			
<30	26	24	92
>30	15	10	67
Duration of amenorrhea (yr.):			
<2	11	11	100
2-5	15	13	87
5-10	9	7	78
>10	6	3	50
Preoperative prolactin level (ng/ml):			
21-50	11	10	91
51-100	9	9	100
100-200	12	12	100
>200	9	3	33
Postoperative prolactin (ng/ml):			
<20	23	22	97
21-50	8	8	100
>50	8	3	37
Tumor size (cm):			
<1	18	18	100
1.1-2	16	15	94
>2	7	1	14

erative cessation of galactorrhea and age at the time of surgery. There was no evidence of spontaneous galactorrhea following surgery in 12 of 16 patients (75%) who were 30 years of age or older at the time of surgery. Spontaneous galactorrhea was absent postoperatively in 18 of 24 women (75%) who were under the age of 30 at the time of surgery.

Relation to duration of amenorrhea. When patients were ranked according to the duration of amenorrhea, there appeared to be a slight difference between those with greater than and those with less than 5 years of amenorrhea (Table I). Menses returned following surgery in 10 of 15 (67%) women who had amenorrhea for 5 years or more prior to surgery and in 24 of 26 (92%) women who had less than 5 years of amenorrhea. However, four of the five patients with persistent postoperative amenorrhea who had greater than 5 years of amenorrhea also had tumors greater than 2 cm in diameter. Similarly, both patients with persistent amenorrhea who had less than 5 years of preoperative amenorrhea had tumors greater than 2 cm in diameter. There did not appear to be a relation between the duration of preoperative galactorrhea and the cessation of lactation following surgery. Galactorrhea disappeared in 11 of 14 (79%) women with galactorrhea for 5 years or more and 19 of 26 (73%) of those with galactorrhea for less than 5 years.

Relation to prolactin concentration. Menses resumed in 31 of 32 (97%) women (Table I) with preoperative serum prolactin concentrations less than 200 ng/ml compared to three of nine with prolactin concentrations greater than 200 ng/ml ($p < 0.05$). However, menses returned significantly more often (31 of 32 or 97%) in women with preoperative serum prolactin concentrations less than 200 ng/ml ($p < 0.05$). Postoperatively, lactation disappeared in five of nine (56%) with preoperative prolactin concentrations greater than 200 ng/ml and in 25 of 31 (80%) with prolactin concentrations less than 200 ng/ml. The return of menses and cessation of galactorrhea were also related to the postoperative prolactin concentrations, as menses returned in only three of eight (38%) with postoperative prolactin concentrations greater than 50 ng/ml, while menses returned in 30 of 31 (97%) with prolactin concentrations 50 ng or less ($p < 0.05$) (Table I). Similarly, galactorrhea occurred in four of eight 50%) with postoperative prolactin concentrations greater than 50 ng/ml and 26 of 30 (87%) with prolactin concentrations less than 50 ng/ml. Postoperative prolactin concentrations or complete postoperative clinical data were not available for eight patients.

Relation to size of adenoma. As noted above, tumor size at the time of surgery was the factor most closely related to postoperative return of menses or disappearance of lactation (Table I). Only one of seven patients (14%) with a tumor 2 cm or greater in diameter as compared to 33 of 34 (97%) with tumors less than 2 cm in diameter had a postoperative return of menses ($p < 0.005$). Similarly, one of six women (17%) with tumors 2 cm or greater and 29 of 34 (85%) with tumors less than 2 cm had postoperative disappearance of lac-

tation. Information was incomplete regarding lactation following surgery in six patients.

Postoperative prolactin concentrations. The serum prolactin concentration was determined within the first 3 months following surgery in 43 patients. In 42 patients, the postoperative prolactin concentration was lower than prior to surgery (66 ± 7 versus 234 ± 97 ng/ml). The prolactin concentration did not change in the remaining patient. Postoperative serum prolactin concentrations were normal (<20 ng/ml) in 28 women and elevated in 15 in the first 3 months following surgery.

In addition, serum prolactin concentrations were determined at 6 or 12 months following surgery in 25 patients, 14 of whom had normal prolactin concentrations at 3 months (Fig. 1). The serum prolactin concentration remained normal at 6 or 12 months in the 14 patients who had normal prolactin concentrations at 3 months following surgery. Serum prolactin levels continued to fall in four of the eight who had elevated levels at 3 months and who did not have postoperative pituitary irradiation with a return to normal in two patients. All three patients who had postoperative irradiation had a continued fall in prolactin concentration.

The fall of prolactin soon after surgery was paralleled by the rapid disappearance of amenorrhea in those who resumed menses following surgery. Detailed menstrual information, available in 30 of the 34 patients in whom menses resumed, indicated menstrual bleeding within the first 3 months in 22 patients, with five of these 22 noting menses within the first postoperative month. Menses returned 6 months or more following surgery in eight patients. The mean time to return of menses was 3.4 ± 0.8 months in these 30 women. All 10 women in whom menses resumed within the first 2 months following surgery had normal postoperative prolactin concentrations, whereas only 10 of 20 (50%) in whom menses resumed 3 months or more after surgery had normal prolactin concentrations within the first 3 months after surgery. Detailed information was available in 29 of the 30 patients who noted a cessation of lactation following surgery. Lactation had ceased in 17 patients by 3 months, in 27 patients by 6 months, and in 29 patients by 12 months. Postoperative prolactin concentrations were normal in 15 of the 17 who noted the disappearance of galactorrhea within the first 3 months but were normal in only seven of 12 who noted the disappearance of lactation 3 or more months following surgery.

Postoperative pituitary function. LH and FSH reserves were determined in 22 women in whom menses resumed and in five women who remained amenorrheic following surgery. LH responses to GnRH were similar to those seen in the early follicular phase of the menstrual cycle (maximal increase from baseline of 15 to 75 mIU/ml) in 17 of the 22 women in whom menses resumed postoperatively, and in three of five who remained amenorrheic. Responses were blunted in one woman in whom menses resumed and in two in whom menses did not resume. Responses similar to those seen in the late follicular phase (maximal increase from baseline greater than 100 mIU/ml) occurred in four women in whom menses resumed.

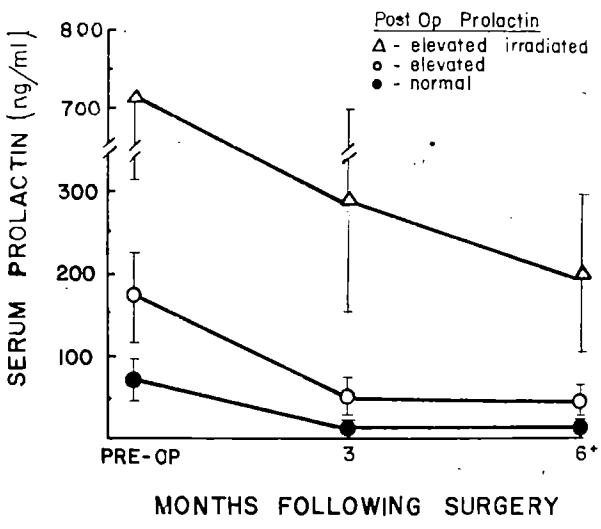

Fig. 1. Serum prolactin concentrations (mean ± SE) prior to and at 3 and 6 to 12 months following the removal of a prolactin-secreting pituitary adenoma in 25 women.

FSH levels rose in response to GnRH in all 27 women who were studied postoperatively, including the five women who remained amenorrheic. These responses were similar to those seen in the early follicular phase of the normal menstrual cycle. Postoperative GH and ACTH reserves were determined in 28 women. GH reserves, as reflected by an increase of ≥5 ng/ml, were normal in 20 of 24 women in whom menses resumed and in two of four who remained amenorrheic. Blunted or absent responses were present in the remaining six women. Pituitary ACTH reserves, as reflected by an increase of ≥8 μg/ml in the serum cortisol concentration, were normal in 22 of 24 women in whom menses resumed and four women who remained amenorrheic. Blunted responses were seen in two women, in both of whom menses returned.

Comment

This study confirms our preliminary report that suggested that the transsphenoidal removal of prolactin-secreting adenomas is effective in restoring menstrual function and eliminating lactation in most women with

these tumors.[7] In the present study, menses returned in 83% and lactation ceased in 75% of women following transsphenoidal surgery.

From the data presented here, tumor size and preoperative serum prolactin concentration appear to be the most important determinants in predicting postoperative disappearance of symptoms. Normal menstrual function returned in 33 of 34 women (97%) with tumors <2 cm in diameter but in only one of seven women (14%) with tumors >2 cm. Similarly, galactorrhea disappeared in 29 of 34 women (85%) with tumors <2 cm but in only one in six women (17%) with larger tumors. Menses returned in 31 of 32 women (97%) and galactorrhea disappeared in 25 of 31 women (80%) with preoperative serum prolactin levels below 200 ng/ml; conversely, menses returned in only three of nine women (33%) and lactation ceased in one of six women (17%) with preoperative serum prolactin concentrations above 200 ng/ml.

Consideration of certain clinical, radiologic, and endocrine observations assist in predicting which women have the greatest likelihood of normal reproductive function following surgery. A woman under the age of 30 with amenorrhea of less than 5 years' duration, who has a preoperative prolactin concentration of less than 200 ng/ml, a postoperative prolactin concentration of 50 ng/ml or less, and a tumor of less than 2 cm in diameter has greater than a 90% chance of resuming menses. Conversely, women over 30 years of age with long-standing amenorrhea, greatly elevated preoperative and postoperative prolactin levels, and large tumors have less likelihood that menses will resume. It is, therefore, important to screen young women with amenorrhea and/or galactorrhea of short duration for prolactin-secreting adenomas. At present such screening consists of measurement of the serum prolactin concentration followed by hypocycloidal polytomography of the pituitary sella in hyperprolactinemic women. The combination of hyperprolactinemia and an abnormal polytomogram has been found to be associated with a tumor over 90% of the time.[12]

If these adenomas are not the result of altered hypothalamic and/or neurotransmitter function, one would expect a return of normal pituitary endocrine dynamics and reproductive function following the selective removal of these tumors. Such a return of reproductive and pituitary function did occur in most patients when total removal of the adenoma was accomplished. While prolactin levels returned to normal in most women who had apparently complete removal of adenomas, prolactin levels remained persistently elevated in several following surgery. The persistent elevation in these patients may be due to the incomplete removal of the adenoma, the presence of an unsuspected second adenoma, a persistent abnormality in hypothalamic or neurotransmitter function, or hyperplasia of the lactotrophs which remained. The return of menses in almost all women who had complete removal of tumors and normal postoperative prolactin concentrations suggests that the hyperprolactinemia, per se, was causally related to the amenorrhea. It is unlikely that the amenorrhea was the result of a direct effect by the expanding mass of the tumor on the normal pituitary tissue, as many of the tumors were only a few millimeters in diameter, and there was very little distortion of the remaining gland with no decrease in gonadotropin reserves as determined by GnRH testing.

The selective removal of these tumors can be performed without gross disturbance of the function of the remaining pituitary gland as shown by the normal GH, ACTH, LH, and FSH reserves in most women in the postoperative period. Similar results have been reported recently by Jaquet and co-workers.[13] This demonstration of the integrity of the pituitary gland following surgery is important if one is to advocate the surgical approach to these tumors in patients whose only symptoms may be amenorrhea or galactorrhea.

In conclusion, the transsphenoidal selective removal of prolactin-secreting adenomas in women with amenorrhea or galactorrhea frequently can be accomplished with restoration of menstrual function provided that: (1) the tumor is relatively small (<2 cm in diameter), (2) the tumor is confined to the sella, and (3) the neurosurgeon is accomplished in this surgical technique. Surgery in these women almost always is followed by a return of prolactin levels to normal, the restoration of normal menses, and the disappearance of galactorrhea. Despite these encouraging findings, however, which patients should undergo such surgery remains to be established. The answer to this question awaits prospective studies comparing the long-term results of surgery, treatment with dopamine agonists such as bromergocriptine, or observation without treatment. Such a comparative study is currently in progress.

We would like to express our thanks for the assistance of Mr. Michael N. West, Ms. Donna J. Piper, Ms. Carmalita Aguirre, Mr. Boodoo Kim, Mrs. Susan Caso, and Mrs. Irma Beavans. Gonadotropin and prolactin determinations were performed utilizing radioimmunoassay materials furnished by the National Pituitary Agency, National Institute of Arthritis, Metabolism, and Digestive Diseases.

Information for authors

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. Therefore, all manuscripts must be accompanied by the following written statement, signed by one author: "The undersigned author transfers all copyright ownership of the manuscript (title of article) to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

Deformation and creep in the human chorioamniotic sac

J. PATRICK LAVERY, M.D.
C. EUGENE MILLER, PH.D.
Louisville, Kentucky

This paper presents a review of physical principles involved in deformation and creep in the human chorioamniotic membrane. These are definable rheological properties found in many materials. Experimental data are presented on 66 human fetal membranes. A difference in the stress tolerance between preterm and term membranes is demonstrated. A computer model has been devised which allows for the calculation of changes in thickness of the membrane at the point of fracture. This computer model allows for the study of the physical property of the tissue in ways which have not previously been suggested. The model suggests that the pathophysiology related to rupture of the membrane is based on changes in the thickness of this tissue occurring secondary to acute and chronic stress applications. The data derived in these experiments suggest a possible physical model for rupture of the membranes; they also introduce questions regarding the anatomic and biochemical makeup of the chorion and the amnion and the respective role that each plays in maintaining the integrity of the human chorioamniotic sac. (AM. J. OBSTET. GYNECOL. 134:366, 1979.)

RUPTURE OF THE chorioamniotic sac is a subject of critical concern in obstetrics.[1] The pathophysiology of membrane rupture remains a subject of speculation while the appropriate clinical approach is heatedly discussed.[2]

Different attempts have been made to assess the strength of the chorioamniotic sac and appreciate its particular properties. Reviews of such methodologies have been given by Danforth[3] and Artal[4] and their associates. The studies of Polishuk,[5] MacLaughlin,[6] and Parry-Jones[7] and their associates have contributed to our understanding of the physical nature of this tissue. The present research developed while the authors investigated the viscoelastic nature of human fetal membranes.[8]

Sixty-five percent of fetal membranes normally rupture during the late first stage of labor.[9] However, a significant percentage rupture at inappropriate times. Premature rupture of membranes antecedes approximately one-third of all preterm deliveries. Various clinical conditions have been associated with premature rupture, but no unique physiologic or pathologic phenomenon has been consistently present with this clinical problem.

This paper investigates two specific aspects of the nature of human chorioamniotic membranes. First, an assessment is made of the stress tolerance in term and preterm membranes prior to experimental rupture. Second, the influence of recurrent stress application in reducing the thickness of membranes as devised by a computer model is studied. The results of this research implicate the importance of Braxton-Hicks contractions as a recurrent stress application in the fatigue of the membranes. Further, the normal physiologic growth process represents a chronic stress application in the over-all test of tolerance which the human chorioamniotic sac undergoes during pregnancy.

Theoretical concepts in the rheologic literature form the basis for the calculations subsequently described. These principles can be applied to biologic material. In the early 1940's Treloar[10] reported experimental results on the deformation of thin circular sheets of rub-

0002-9378/79/120366+10$01.00/0 © 1979 The C. V. Mosby Co.

ber (an elastic material) resulting from applied pressure. A theoretical description of the Treloar deflection profiles is given in a classical text by Green and Adkins.[11] The theoretical solutions rendered by Green and Adkins compared well with the experimental results of Treloar when elastic moduli for rubber proposed by Mooney[12] were used in the theoretical analysis.

Materials and method

The technique of applying pressure to fetal membrane samples in this research is conceptually similar to that used by Graham[13] in studying the elasticity of human skin. A description of the apparatus used in the research and the details concerning its construction have been published.[8] A sketch of the features of the apparatus is shown in Fig. 1. This apparatus was employed in a research thesis[14] which developed the procedure for determining elastic moduli of fetal membranes.

Membrane samples are obtained and processed within 1 hour of delivery. Specimens approximately 12 by 12 cm are mounted across a 7.62 cm opening in a Plexiglass mold. The membrane is positioned over a cylindrical chamber (shown in Fig. 1) so that the chorion interfaces with the liquid in the cylinder. The liquid medium filling this chamber is a pseudoamniotic fluid (PAF), developed by Schwartz and associates,[15] which is chemically and osmotically similar to human amniotic fluid. The amnion which is consistently facing upward is moistened with the same fluid. With the membrane samples mounted in place, pressure is recorded by a commercial physiograph.* The applied pressure range is 0 to 100 mm Hg. The fluid is removed from the lower chamber during a 30 second time interval, creating a deflection of the membrane downward. When a pressure of 10 mm Hg is obtained the exhaust valve is closed. An aluminum rod lying on the surface of the membrane descends with the evacuation of this fluid. The deflection of this rod is measured by means of a microscope mounted on a micrometer† slide with an accuracy of 0.005 mm. After the initial deflection, a waiting period of 3 minutes elapses. During this period, the pressure continuously decreases in an exponential manner. At the end of 3 minutes, the deflection of the rod is again measured. The exhaust valve is opened and the fluid is returned to the chamber, reducing the pressure again to zero. The membrane will rise back toward its original position. The time span for this pressure reduction is likewise 30 seconds. The rod deflection is again measured. The pattern is continued with fluid removal and deflection measurements obtained with the application of 20 mm Hg. Such cycles are continued with increments of 10 mm Hg until fracture occurs. During the experiments, the membrane is continuously observed and, at the time of rupture, the location of the fracture and its form is noted.

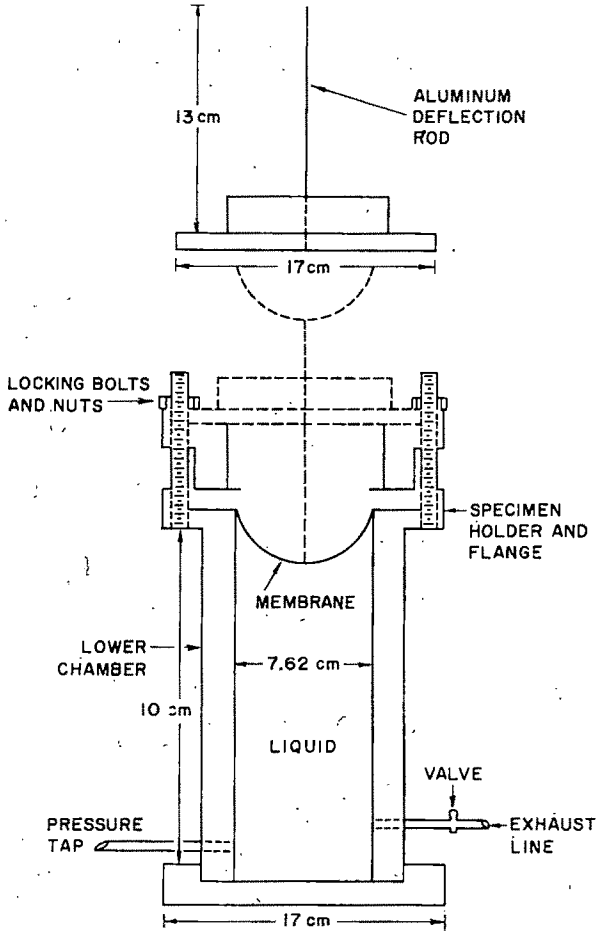

Fig. 1. Schematic diagram for membrane stress apparatus. Pressure tap extends to a transducer for recording on a physiograph.

In each cycle of experiments, the difference between the deflection reading at the end of the 3 minute cycle and the final reading when the pressure returns to zero is determined. This difference (W_0) is the pole deflection of the membrane due only to its elastic deformation. Creep (W_c) also develops in the material. This is represented by the difference between the W_0 reading and the initial reading at the beginning of the experiment.

Specimens of rubber 0.038 cm thick were placed in the apparatus. It has been shown[14] that rubber is an

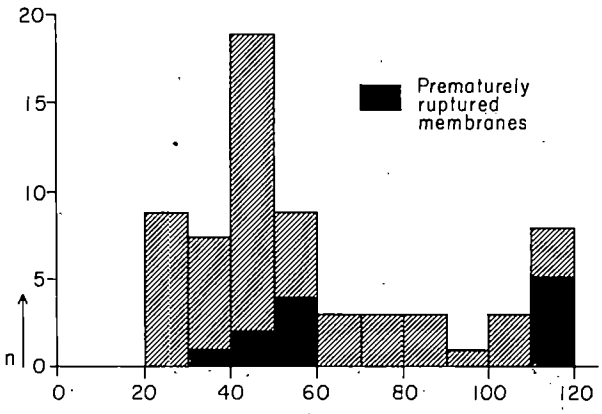

Fig. 2. P—Applied pressure at rupture (mm Hg).

elastic material, deformed in the same manner as fetal membranes. Since the elastic moduli for the rubber sample are well known, we were able to determine all of the kinematical quantities necessary to calculate extension ratios which are applicable to the fetal membranes when the deflection of the pole for fetal membranes is the same as rubber. Details for this methodology are discussed by Miller and Lavery.[16] In the present research the results of the rubber experiments present a calibration curve for determining the extension ratios once the pole deflections are measured for fetal membranes. These extension ratios are discussed subsequently.

The initial thickness of a membrane specimen in the undeformed state is measured prior to placing a part of it in the apparatus. A section of the membrane is placed between two Plexiglass plates. The membrane plate "sandwich" is placed on a flat surface. The micrometer slide comparator is placed proximate to the Plexiglass and the space between the glass loci is measured. Readings are taken between the inferior and the superior plate at five points. The average of these thicknesses constitutes the mean thickness of the membrane. This initial thickness is referred to as h_0. The thicknesses of membranes determined by means of this technique are similar to those found by other authors[4, 5] using different techniques.

In these experiments the data used in the calculations of physical properties include: pressure (P) affecting deformation of the membrane, the elastic deflection (W_0), the creep deflection (W_c), and the initial membrane thickness (h_0).

The computer program was written so that when the applied pressure (P), the maximum deflection at the pole (W_0), and the thickness of the membrane in the undeformed state (h_0) are known, then the stress distribution, the extension ratios, and the deflection profiles can be described. From this information, the

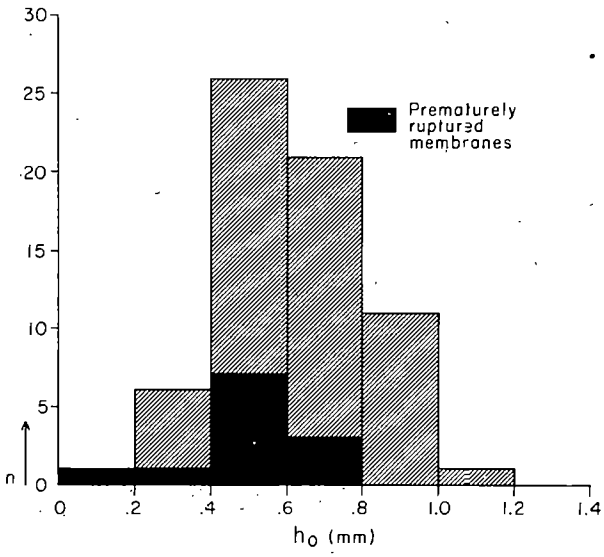

Fig. 3. Initial thickness (h_0) of membranes studied.

stress tolerance and changes in thickness during quasistatic testing have been calculated.

Results

Specimens of 66 deliveries were studied. Twelve (18%) were from gestations of less than 37 weeks.

The distribution of the maximum pressure needed to rupture the membrane is shown in Fig. 2. The results show that the rupture pressure for the largest population occurs at 40 mm Hg.

The distribution shown in Fig. 2 suggests a separate population of premature membranes which can tolerate pressures of a greater degree than normal term membranes. The shaded area in black represents the preterm part of that population. There was no apparent clinical background distinguishing these populations.

The distribution of the initial membrane thickness as measured by means of the method previously described is shown in Fig. 3.

The mean initial thickness for those membranes which rupture preterm spontaneously was 0.499 mm, for term membranes rupturing spontaneously was 0.545, and for those ruptured artificially at some point in labor was 0.643 mm.

The mean value for stress tolerance based on the rupture thickness was 124.2 kg/cm² (S.D. ± 126.3 kg/cm²) in the preterm group; for stress tolerance in term membranes rupturing spontaneously it was 49.59 kg/cm² (±69.96); for those term membranes which were ruptured artificially it was 49.61 kg/cm² (±55.32), as shown in Table I.

The difference between the stress tolerances of the preterm and term membranes was statistically sig-

Table I. Stress tolerance

*$p < 0.03$.

nificant at the $p < 0.02$ level after an univarient analysis had been performed.

This suggested that preterm membranes can tolerate more stress application than term membranes.

The thickness at rupture for each membrane was calculated by Equation (4) (see immediately preceding Discussion). The mean value for the preterm membranes was 0.097 mm; for term membranes rupturing spontaneously it was 0.177 mm (shown in Table II). These populations were shown to be different at the $p < 0.03$ level after a univarient analysis had been performed. This suggests that the preterm membranes at the time of rupture become significantly thinner than their term counterparts.

In our research, the theoretical methods of Green and Adkins[11] were modified to determine deflection profiles, stress distributions, and extension ratio distributions over the entire surface of membranes tested. In making this modification one has to satisfy all the theoretical equations rendered by Green and Adkins[11] and at the same time develop deflection profiles which agree with actual experiments. The theoretical deflection profiles were compared to experimental results. They compare the expected deflection of rubber, the experimental finding of rubber, and the experimental finding of fetal membranes (shown in Fig. 4). The agreement is sufficient so that one is able to conclude that the extension ratios and the stress distributions are acceptable, especially in the range of $x = (r/a)$ from 0.2 to 0.5. This demonstration substantiates the subsequent principles employed in the mathematical model used to calculate stress tolerance and dynamic changes in thickness. The term r is the radial measure from the pole and a is the inner radius of the lower cylinder shown in Fig. 1. The elastic extension ratio distributions as a function of the radial distance from

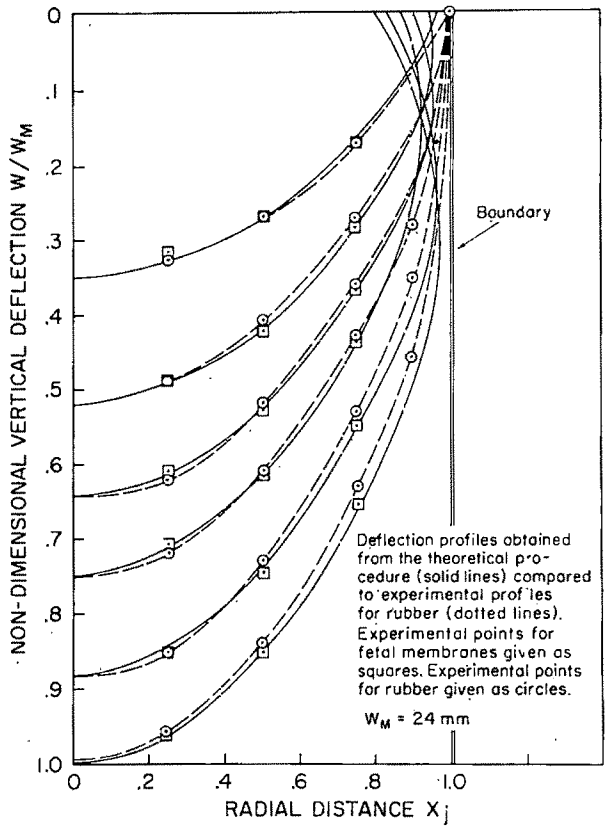

Fig. 4. Initial thickness of membranes prior to experimentation.

the pole are given in Fig. 5. There are three such relationships. One relationship (λ_1) describes extension ratios along longitudinal lines on the deformed membrane; a second relationship (λ_2) describes extension ratios along latitudinal lines on the deformed membrane; the extension ratio (λ_3) describes the change in thickness in a plane which transects the membrane in the deformed state. The curves shown in Fig. 5 are drawn for deflection $W_0 = 0.84$ cm produced by a pressure of 10 mm Hg in a representative specimen. The material whose deformation is described in Fig. 5 is a fetal membrane sample having an initial thickness of 0.380 mm. The stress distribution for the same membrane is given in Fig. 6. Only two curves are given in Fig. 6, since in the direction of λ_3 through the thickness of the membrane the stress is equal to zero. The curves such as shown in Fig. 5 and 6 can be produced for any fetal membrane whose elastic extension at the pole (W_0), the pressure producing the deflection (P), and the initial thickness (h_0) are known. These are the quantities which are measured in the present research. The elastic moduli and the stored elastic energy per unit volume can be calculated once the stress distribution and extension ratio distributions are known if one

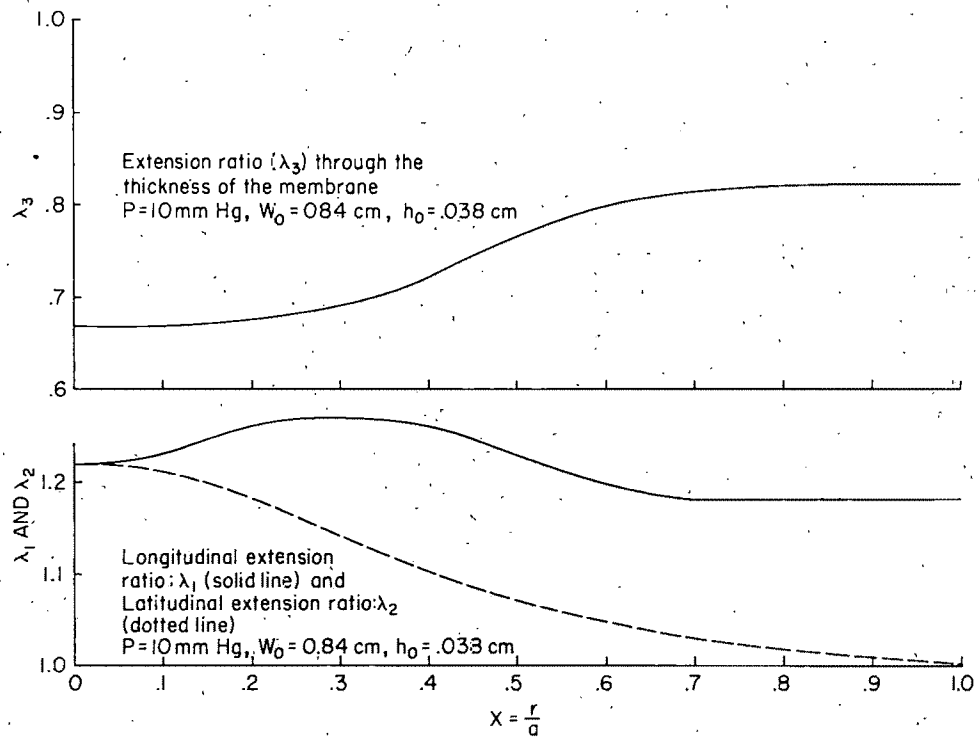

Fig. 5. Extension ratios.

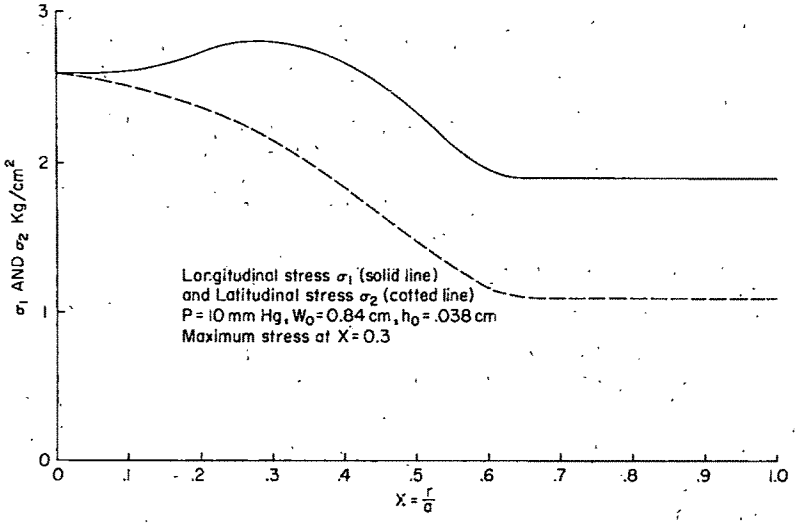

Fig. 6. Longitudinal and latitudinal stress.

assumes as for rubber that the elastic portion of fetal membranes is a Mooney material,[12] an idealization which is supported by Blatz[18] in describing the nature of biologic tissue.

One observes in Fig. 6 that the maximum stress occurs at x = 0.3. This means that as the membrane deformed, the maximum stress occurred at a point three-tenths from the center pole. This is the location where the fetal membranes tested most generally rupture (Fig. 7). For each of the fetal membrane samples used in the research, the stress distribution was determined for a deformation resulting from 10 mm Hg pressure application and subsequent increments.

With the use of the experimental data for the 66 membranes described earlier, the maximum longitudinal extension ratio (λ_1) and the maximum longitudinal stress (σ_1) for each membrane just prior to rupture was calculated. Also, the value of the extension ratio through the thickness of the membrane (λ_3) was calculated for each membrane specimen. The maximum calculated longitudinal stress is called stress tolerance of the membrane and is measured in kilograms per

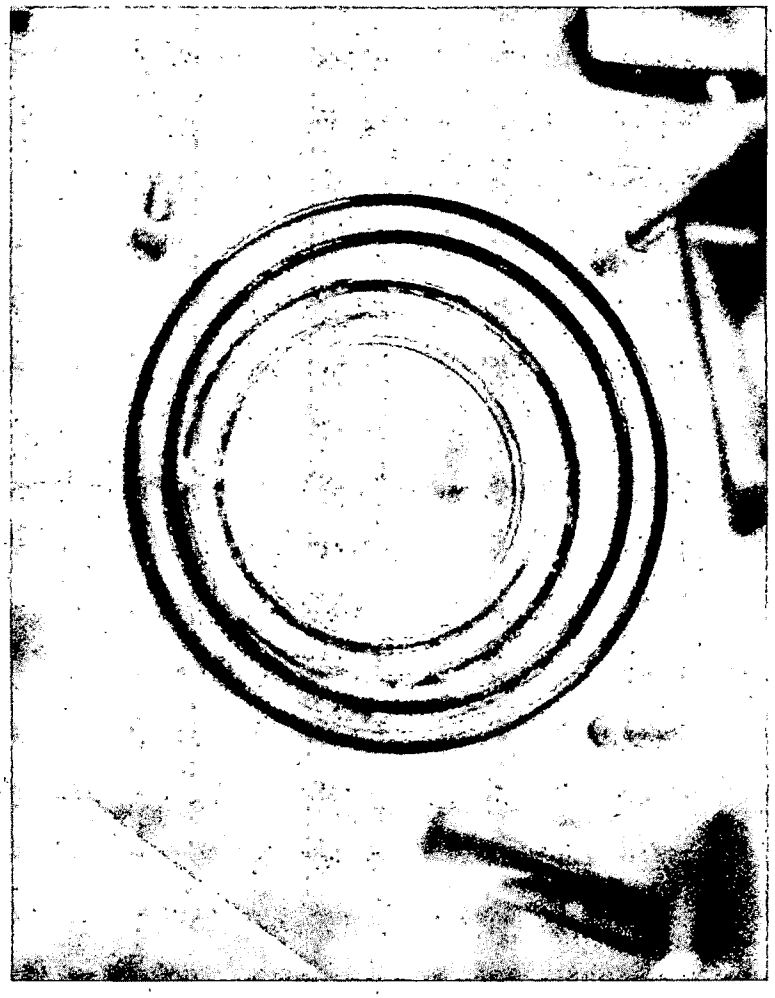

Fig. 7. Membrane after fracture with locus of rupture about 0.3 from center, the calculated point of maximum stress.

square centimeter. When the thickness of the membrane at the time of rupture is used to calculate the stress, stress tolerance is denoted by σ_{rr}.

The value of h_r (thickness at rupture) is calculated by considering the reduction in thickness resulting each time a pressure is applied to the membrane extending it elastically and causing it to creep. The creep extension is nonrecoverable. Hence, the reduction in thickness is regulated by the elastic extension ratio (λ_3) and the creep extension ratio (W_c/W_0). As one applies pressure from 0 to 10 mm Hg the nonrecoverable reduction in thickness is:

$$\Delta h = h_o \cdot (1 - \lambda_3) \cdot \frac{W_c}{W_o} \qquad (1)$$

and the resting thickness after the applied pressure on the membrane is reduced to zero becomes:

$$h_1 = h_o \cdot \left\{1 - (1 - \lambda_3) \cdot \frac{W_c}{W_o}\right\} \qquad (2)$$

That is, the initial thickness less the loss of thickness after the first cycle of pressure application. If one considers each 10 mm Hg increment of pressure application and reduction to be one cycle and the membrane ruptures in the nth cycle, the thickness of the membrane at the start of the nth cycle is:

$$h_r = h_o \cdot \left\{1 - (1 - \lambda_3) \cdot \frac{W_c}{W_o}\right\} n - 1. \qquad (3)$$

Also, in the nth cycle the thickness is further reduced by λ_3. Hence, the rupture thickness is:

$$h_r = \lambda_3 h_o \cdot \left\{1 - (1 - \lambda_3) \cdot \frac{W_c}{W_o}\right\} n - 1. \qquad (4)$$

When the maximum longitudinal stress (σ_1) is known for a pressure of 10 mm Hg the maximum stress at rupture can be calculated from the formula:

$$\sigma_{rr} = \frac{(\sigma_1)\,(n)\,(h_o)}{(h_r)} \qquad (5)$$

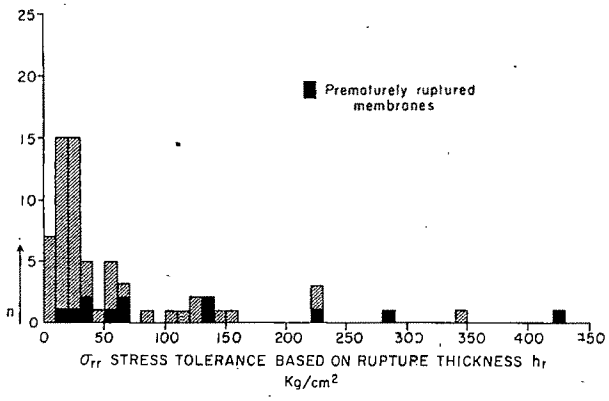

Fig. 8. Stress tolerance based on calculated thickness at time of rupture.

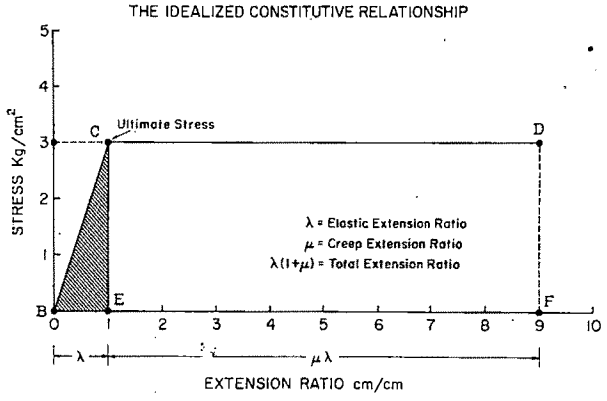

Fig. 9. Idealized relationship with the application of stress and response of creep and extension.

where n is the cycle during which rupture occurs. On the basis of Eq. (5) the stress tolerance based on the rupture thickness is calculated for the 66 membranes. The results are shown in Fig. 8. The solid parts express that number in the population which are preterm membranes.

Comment

The pressure at rupture data in our experiments agrees with the work done by Meudt and Meudt.[17] In their work, they found that the mean bursting pressure in their series of membranes studied was 399 mm Hg. The stress required to rupture the membrane increases not only with increasing pressure but also with the square of the diameter of the test sample. These authors[17] used diameters of 27 mm, whereas diameters of 76.2 mm were used in this research. The bursting pressure in our experiment should be approximately one-eighth of their values and this is indeed so.

Stress distribution and extension ratios are calculated quantities with the use of the experimental data. The method of calculation depends upon concepts and formulas which would be foreign to most obstetric readers. However, these concepts can be found in a recent publication.[16] The following discussion concerns an evaluation of stress and extension ratio distribution along deformed membrane surfaces.

When pressure is applied to the chorioamniotic membrane, the stretch which occurs develops internal stresses. These stresses resist the applied pressure and maintain the integrity of the membrane. Stress is an internal force divided by the cross-sectional area over which it acts and is expressed in kilograms per square centimeter. The total stretched extension of the membrane after pressure application is composed of two components, one of which is recoverable when the pressure is removed and the other of which is not recoverable. The recoverable component is called the elastic extension and the nonrecoverable component is called the creep extension. The percentage of deformation along any linear plan through the membrane relative to its original state is called the extension ratio. This extension ratio is measurable in three planes, namely, latitudinal, longitudinal, and transecting planes.

The elastic extension ratio is the elastic extension divided by the initial length. The ratio is expressed in centimeters per centimeter. The total extension ratio is defined as the total extension, i.e., the sum of the elastic extension and the creep extension divided by the initial length. The idealized relationship is demonstrated in Fig. 9. Here an application of pressure from point B toward point C will create the ultimate stress which a given tissue may be able to tolerate. This does not necessarily mean the point of fracture, for the material may continue to extend itself, i.e., from point B to points E and F, and maintain its integrity. It is only when point D is reached, that is, where the ultimate stress has been exerted and there is no more creep to be exhausted, that fracture occurs. Furthermore, in the range BE the extended material is totally recoverable. This is the nature of an elastic material. These two extension properties occur concomitantly in the experimental setting.

CD represents the creep extension of the material and the area enclosed in the rectangle CDFE represents the energy dissipated per unit volume during deformation. This energy is nonrecoverable and is lost with extension. The slope of the line BC represents the elastic modulus. This is the ultimate stress divided by the elastic extension ratio in the deformed material. This is the quality of the material to spring back to its original shape.

As the slope of the line BC increases, the elastic modulus will increase and the material will become

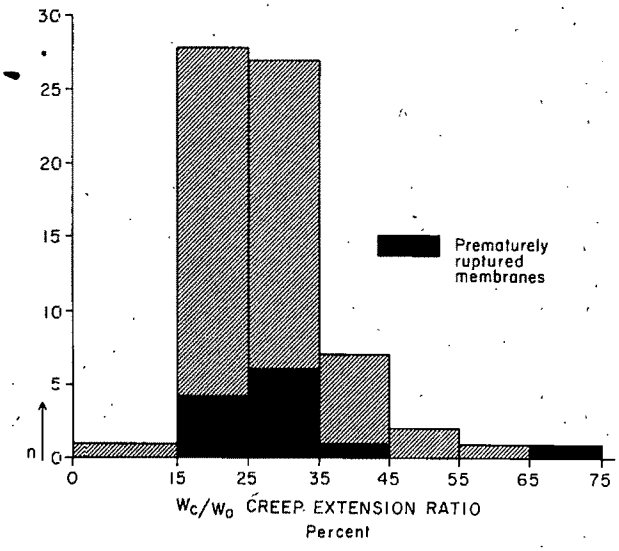

Fig. 10. Creep extension ratio represents the percentage of extension lost to nonrecoverable length (creep). Most membranes lose 15 to 45% of their elastic deformation.

stiffer. That is, there will be less recoverable extension for stress application. If equal forces are applied to two materials there is less extension in the material with a higher modulus. Also, as one stretches a material such as the chorioamniotic membrane, it will become thinner. If one removes the pressure prior to rupture, recovery will be determined by the size of the elastic extension ratio. The extension ratios demonstrated in the formula listed above are related to the thickness of the membrane at any given point. Thus, after any deformation of the membrane, it will become thinner than it was originally before the pressure application. That amount of nonrecoverable thickness is related to the nonrecoverable extension or creep.

If the membranes develop a high elastic modulus after several cycles of stretching and exhibit decreasing amounts of creep extension, it is possible that the stiffening phenomenon indicates that the material is being strain hardened. Following periods of strain hardening, the material ruptures quickly, losing its ability to creep.

The phenomena of extension, recovery, and creep (loss of recoverable material) are not sequential but concomitant. The above discussion represents an idealized picture of a dynamic biologic process. However, it does allow us a reasonable construct for the actual physical changes that occur.

Polishuk and associates[19] contended that membranes did not have a uniform tensile strength. This is consistent with biologic variability and is not an unexpected finding. Also, within any one sample of complex biologic material one should expect to find areas of local

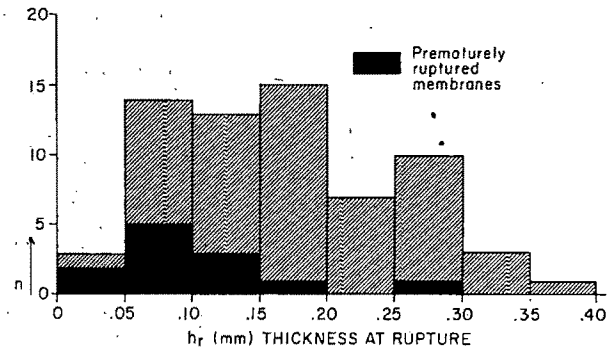

Fig. 11. Calculated thickness at rupture.

weakness which can decrease the tensile strength. Artal and associates,[4] employing an uniaxial extension apparatus, noted that there were no statistically significant differences in rupture tension between prematurely and spontaneously rupturing membranes. However, they did observe that prematurely rupturing membranes were thinner at the rupture site. These data were obtained by a microelectrode and are consistent with our calculated thickness.

The average values of W_c and W_0 are used to develop a W_c/W_0 ratio for each membrane. This value is the creep/extension ratio for the specimen. It represents the amount of nonrecoverable extension to recoverable extension. The bar graph in Fig. 10 shows the distribution of these ratios for the 66 membranes studied. The graph indicates that the majority of membranes have creep/extension ratios that fall between 15 and 35%. The grouping also shows that the percent of the nonrecoverable energy is not significantly influenced by gestational age. These data reflect the basic response of the membranes to stress applications and relaxation. They do not indicate how much stress was tolerated, however, by any particular membrane.

The data presented in Fig. 8 on stress tolerance are not in agreement with those of Polishuk. To the contrary, using our biaxial system, the preterm population was able to tolerate a greater stress application than the term membranes. Further data will be required to assess if this change is progressive throughout gestation. The difference in findings may be related to the calculation of stress tolerance based on the change in membrane thickness during stress application. Further, increasing gestational age may make membranes less tolerant of fracture, and preterm rupture could be primarily associated with local defects.

Such results lead us to believe that the membranes which clinically rupture prior to 37 weeks' gestational age are capable of sustaining higher stress application than those membranes which come to term. This was confirmed by analysis at the $p < 0.02$ level. However,

each of the preterm membranes used in the experiments did rupture prematurely between 28 and 36 weeks! Some flaw in those membranes at a local site or change in the character of a local area must account for the lowering of the stress tolerance at the time of rupture.

Stress tolerance involves many factors, significant of which is the reduction of thickness due to a sequence of pressure applications which takes place in the physiologic state of uterine contracture. With each pressure application, a deformation in the membrane results. Upon relaxation of the pressure only partial recovery is expected. Some permanent set remains in the membrane. Its dimensions may be larger in one plane but will thin out in others. The thinned section will now experience a greater stress when the pressure is reapplied. If the stress is too great, the membrane will rupture.

The preterm membranes thin out during the course of stress application to a greater degree than the term population. Their thickness was comparable prior to stress application with those membranes which spontaneously rupture at term.

This finding is not surprising when we recall that changing elastic moduli are related to membrane thickness. It could be postulated that during the course of pregnancy with recurrent stress applications (i.e., Braxton-Hicks contractions) and growth, a change occurs in the elastic moduli of the chorioamniotic membranes, making some of them "stiffer." When these term membranes are exposed to stress application, their tendency may be to fracture at a point of lesser thickness than the preterm membranes. Further work will be necessary to confirm this observation. However, to support this concept, there are two clinically observable processes which operate on "changing" the membrane thickness and enhancing the likelihood of rupture. These are commonly appreciated biologic stresses of pregnancy: (1) the inherent and chronic physiologic stress of growth and (2) the acute stress application of Braxton-Hicks contractions. Parry-Jones and Pyria[7] have described that after 28 weeks the intact fetal membranes are under tension. With the growth of the uterine cavity by term, this stretching extends the chorioamniotic sac to at least twice its resting size. Bourne[20] observed little mitotic activity after the first trimester in the membranes. On a molecular level accomodation to expanding growth requires adaptation to significant if gently applied growth stresses by cellular stretching rather than cell replication.

Alvarez and Caldeyro[21] have demonstrated that episodes of uterine contractions are physiologically present throughout pregnancy. Although these are often not of great intensity, we do find that membranes rupture after a series of recurrent low pressure applications. Toppozada and associates[22] studied patients in labor and observed that the contraction causing membrane rupture was not the strongest to which they were subject in 86% of cases. The results in Fig. 11 show that the preterm membranes have rupture thickness significantly ($p < 0.03$) less than term membranes. In our experiments and previous work[4, 6, 17] the rupture thickness of the amnion was the critical and final layer. This thinning to a greater degree suggests that in the preterm group there is greater ability to creep. There is less strain hardening than at term.

Fig. 11 demonstrates that the thickness at rupture of the membrane in preterm membranes is less than the thickness of term membranes. Hence, if local flaws in the chorion of these preterm membranes did exist, the stress placed on the amnion may have been far beyond the membranes' ability to tolerate the stress.

Separate functions are served by the chorion and the amnion. When they function in concert, the sac's integrity is maintained. Where there is dissonance in one member (presumably the chorion) the integrity is likely to fail. Early histologic investigation by Fetry[23] suggested weakness in the intermediate area of the membranes and that this shearing is the initiation of failure. Meudt and Meudt[17] took this up in their investigations. Neither chorion nor amnion alone could tolerate the mean bursting pressure which both together could tolerate. It would seem that different properties of the separate membranes serve distinct functions. Artal and associates[4] noted that there was reduced thickness near the site of prematurely rupturing membranes and Polishuk and associates[5] found weaker tensile strength at the rupture site. We contend that it is the change in thickness of the amnion when exposed to stress application, either chronic or acute, that predisposes to rupture. Further, once the point of ultimate stress is reached, recovery of elasticity is no longer available and fracture is imminent. Without support afforded by the chorion the amnion's stress tolerance is impaired by extension and will rupture.

The results of our research suggest the following model of the membrane rupture.

In certain cases, flaws develop in the chorion based on a phenomenon yet to be elucidated which prevent its appropriate elastic recovery. The physical properties demonstrated in this paper may well have biochemical correlates in tissue. The amnion is more resilient and returns to its original state more readily because of its biochemical and molecular constitution. As the chorion becomes progressively thinner, deforming by the physiologic stress of both growth and contractions, the

membrane ultimately exceeds its point of critical stress tolerance. The progressive thinning, with ultimate exposure of the amnion, leads to failure. This may occur at any time in gestation. The factors which account for this deficiency form the basis for further investigation.

Premature rupture of the membranes then may represent the concomitant effect of exagerated physiologic forces, i.e., increased contractions and growth and physical local defect which interfere with the naturally supporting roles of the chorion and the amnion.

Prolonged pregnancy was rigorously defined in 180 gravid women without other complications. Patients were randomly assigned to be serially followed, either by amniocenteses or by oxytocin challenge tests (OCT's). Induction of labor, based upon only (1) a finding of meconium in the amniocentesis group or (2) a positive test in the OCT group, was nearly three times more frequent in the amniocentesis group. The incidence of meconium, which overall was 22% initially and 44% at delivery, as well as the frequencies of obstetric and perinatal complications, were similar in both management groups. Although meconium was significantly associated with abnormal labor progression, intrapartum fetal distress, and low 1 and 5 minute Apgar scores, induction of labor after discovery of meconium, when compared to nonintervention, did not improve perinatal outcome. It is concluded that a search for meconium is of little value in the management of prolonged pregnancy. (AM. J. OBSTET. GYNECOL. 134:376, 1979.)

AN OTHERWISE uncomplicated pregnancy lasting 42 or more weeks is associated with a greater risk of perinatal death and morbidity than is a similar gestation completed at or near term.[1, 2] Recognition of this increased perinatal risk has led to a variety of schemes designed to improve fetal and neonatal outcome, but considerable disagreement regarding optimal management of prolonged pregnancy continues to exist for several reasons.[3] First, a prospective analysis of the precise causes of perinatal death and morbidity associated with this condition is not available. Also, the clinical definition of neonatal morbidity (i.e., "postmaturity syndrome") is subjective at best.[4, 5] In addition, proposed methods of antenatal fetal assessment and obstetric management have not been rigorously compared in published clinical trials. The obstetrician is therefore left in the unenviable position of trying to prevent possible perinatal death and disability with much advice—but little proved counsel—concerning problems that may or may not actually be encountered.

One characteristic feature of many prolonged pregnancies is meconium staining of the amniotic fluid which, when present, is said to be associated with even higher perinatal risk.[5–8] Because of the overall increased risk, and before biochemical or biophysical means were available to assess fetal well-being, antenatal discovery of meconium via amnioscopy or amniocentesis was interpreted as a sign of intrauterine compromise and therefore as an indication for delivery.[9–10]

Conceptual and practical problems exist if the management of prolonged pregnancy is based upon a search for meconium. Although meconium has been found to be associated with suboptimal perinatal outcome, its validity as an indicator of fetal distress is less well established. In the large series of patients reported by Saling,[11] 98.3% of the fetuses had normal scalp-

blood pH values at the time meconium was detected during antenatal assessment. However, pH assessment was not done for those fetuses without meconium. More recently, Miller and associates[12] reported that intrapartum meconium in the absence of concurrent fetal heart rate (FHR) or acid-base abnormalities does not indicate fetal compromise. These results suggest that the suboptimal outcome associated with meconium may be unrelated to intrauterine distress, but instead to other events that may occur during labor and delivery (i.e., induction of labor with resultant hypoxia,[13] cesarean section,[14] or meconium aspiration[15]). Even if meconium were to be established as a valid and specific indicator of intrauterine compromise, its antenatal detection presents practical problems. Amniocentesis is an invasive procedure with a slight but finite fetal risk.[16, 17] In addition, both the normally decreasing volume of amniotic fluid after 36 gestational weeks and the oligohydramnios frequently encountered in prolonged pregnancy may make the detection of meconium technically difficult.

Taken together, these reasons suggest that an alternative approach to the management of prolonged pregnancy may be warranted. The oxytocin challenge test (OCT) has been suggested as a noninvasive means of assessing fetal well-being in a variety of high-risk obstetric conditions.[18] An uncontrolled clinical experience with 183 prolonged-pregnancy patients suggested that accurate fetal assessment was easily and safely accomplished with the OCT.[19] Moreover, the analysis of this experience revealed that the presence of antenatal meconium did not correlate with either a positive OCT or abnormal FHR patterns during labor. Therefore, for patients with prolonged pregnancy, a prospective and randomized clinical trial comparing the OCT and antenatal detection of meconium by amniocentesis was undertaken. This report summarizes the results of that trial.

Materials and methods

The trial was conducted between August 1, 1975, and July 31, 1976. At a suspected gestational age of 42 weeks, each patient was evaluated by one of the investigators; patients with other obstetric complications were excluded. A diagnosis of prolonged pregnancy was made if the menstrual history was reliable (i.e., the exact date of the last menstrual period was known, its duration and flow had been normal for that patient, and oral contraceptives had not been used within 3 months of that period), consistent with at least 42 gestational weeks, and confirmed by at least one of the following clinical assessments: (1) pelvic examination prior to 12 weeks; (2) ultrasonic cephalometry between 20 and 30 weeks; or (3) auscultation of unamplified fetal heart tones for at least 22 weeks. If the menstrual history was unreliable, a diagnosis of prolonged pregnancy was assigned if any two of these three clinical assessments were consistent with at least 42 gestational weeks.

The study protocol was explained and an informed consent was obtained. Based upon the last digit of the previously designated hospital number, women were then randomly assigned to be followed antenatally either by OCT's or by amniocenteses. These procedures were performed as previously described.[18, 20] Regardless of group assignment, each woman initially had an amniocentesis performed. Women followed by amniocenteses had the procedure repeated weekly unless meconium was discovered or no fluid could be obtained; in either case, they were admitted for induction of labor. Patients followed by OCT's had the procedure repeated weekly unless the test was positive, in which case they also were admitted for induction of labor. All inductions were conducted with intravenous oxytocin under surveillance of continuous, direct FHR and intrauterine pressure monitoring. Patients with clear fluid on amniocenteses or negative OCT's also had continuous, electronic monitoring whenever they presented with ruptured membranes or in active labor. Other management decisions during labor and delivery were made without consultation with or knowledge of the investigators conducting the antenatal assessments. Cesarean section was performed for the following indications: (1) inability to induce active-phase labor within 24 hours of beginning oxytocin, (2) arrest of cervical dilatation or arrest of descent in the presence of adequate uterine contractions,[21, 22] and (3) intrapartum fetal distress defined by recurrent late decelerations or severe variable decelerations[23] unresponsive to usual methods of intrauterine resuscitation.[24] Every meconium-stained baby was intubated and direct tracheal aspiration was performed.[15] Serum glucose was determined within 2 hours of birth and feeding was begun as soon after 2 hours as the condition of the infant permitted. Subsequent to admission into the clinical trial, seven patients (four in the amniocentesis group and three in the OCT group) either developed hypertension (3) or were found to have a breech presentation when admitted for labor (4). These late-developing problems were considered to possibly complicate data interpretation, and therefore these seven patients were not considered in the data analysis. Ninety patients thus remained in each group and the data from these were analyzed by chi-square test with Yates' correction; $P < 0.05$ was considered significant.

Table I. Comparison of obstetric and perinatal complications in patients with prolonged pregnancy managed by amniocentesis or OCT

Complication	Management group

†Repetitive late or severe variable decelerations (see Methods).
‡Weight under tenth percentile for gestational age.[25]
§Hypoglycemia (serum glucose <30 mg/dl) occurred in 12 babies. One infant had Group B streptococcal sepsis.

Results

The group of women managed by weekly amniocenteses (N = 90) did not differ statistically from the group managed by weekly OCT's (N = 90) with regard to maternal age, parity, race, or neonatal sex ratio (data not shown). Likewise, the incidence of meconium at initial amniocentesis (22% overall) and at delivery (44% overall) was not statistically different, whether management was by amniocentesis (27% and 47% initially and at delivery, respectively) or by the OCT (18% and 41% initially and at delivery, respectively).

Obstetric and perinatal complications for the two management groups are compared in Table I. There were 2.6 times as many inductions of labor in the amniocentesis group (29/90 or 32% with meconium discovered antenatally) as in the OCT group (11/90 or 12% with an antenatal positive OCT, $P < 0.005$). By contrast, abnormal labor, fetal distress, cesarean section, low 1 and 5 minute Apgar scores, fetal growth retardation (below the tenth percentile for gestational age[25]), neonatal morbidity, and perinatal death occurred with similar frequencies in both management groups. Documented meconium pneumonitis did not occur in any infant. Neonatal hypoglycemia (serum glucose < 30 mg/dl) was significantly associated ($P < 0.05$) with fetal growth retardation and low 5 minute Apgar scores (data not shown). Three of the four perinatal deaths were due to lethal congenital anomalies; the fourth occurred in a meconium-stained, growth-retarded infant 2 hours following amniocentesis and while awaiting the availability of a fetal monitor so that induction of labor could begin. Postmortem examination failed to reveal a cause of death. Specifically, the amniotic fluid was not bloody, the cord-blood hematocrit was normal, and no hematoma of the cord or needle puncture of the baby could be identified. For the entire 180 pregnancies, combined perinatal death and serious morbidity (fetal growth retardation, low 5 minute Apgar scores, neonatal hypoglycemia, and sepsis) was 13% (24/180).

Compared to pregnancies where the amniotic fluid remained clear, those obstetric and perinatal complications occurring more frequently in the presence of meconium were (in order of increasing statistical significance): abnormal labor, intrapartum fetal distress, and low 5 and 1 minute Apgar scores ($P < 0.05$ to $P < 0.001$, Table II). The increased incidence of low 1 and 5 minute Apgar scores associated with meconium was not due to cesarean operations. Thus, compared to vaginal deliveries (with or without meconium) or to abdominal deliveries when the amniotic fluid was clear, cesarean sections performed in the presence of meconium were not associated with an increased incidence of low scores. For primigravid (but not parous) women with meconium, an increased incidence of low 1 minute Apgar scores was found if there was fetal distress in labor (7/11 or 64%) compared to those without distress (7/29 or 24%, $P < 0.05$). Although the occurrence of meconium did not significantly affect the overall cesarean section rate, primigravidas (10/40 or 25%) were more likely than parous women (1/39 or 3%) to be delivered abdominally if meconium was present ($P < 0.025$).

Table III demonstrates similar rates of obstetric and perinatal complications in patients with meconium, irrespective of antenatal management. Of the 42 amnio-

centesis-group patients ultimately proving to have meconium, labor was induced in 29 because meconium was detected by amniocentesis. Meconium developed in the 13 remaining pregnancies within the week following a clear amniocentesis, but before delivery occurred. Obstetric and perinatal complications were not statistically different in these two subgroups of patients with meconium who were followed by amniocenteses. Further consideration of the entire group followed by amniocenteses indicated nearly four times the rate of intrapartum fetal distress in women whose labor was induced because of meconium (7/29 or 24%) compared to women for whom labor was not induced (4/61 or 7%, $P < 0.05$).

Of the 24 OCT-group patients with meconium noted at initial amniocentesis, labor was induced only if and when the OCT became positive. As noted for the amniocentesis group, complication rates were not statistically different, irrespective of whether the meconium was first noted at initial amniocentesis or at delivery. A positive OCT was not associated with meconium, either at initial amniocentesis or at delivery (2/37 or 5% of patients ultimately proving to have meconium had positive OCT's and 9/53 or 17% of patients never having meconium had positive OCT's; $P > 0.2$).

Table IV shows the infrequent rates of obstetric and perinatal complications in the 44 OCT-group women who had clear amniotic fluid and negative OCT's throughout the study period.

Comment

The fetus participating in a prolonged pregnancy faces considerable risk as evidenced by the 13% incidence of perinatal death and serious morbidity demonstrated in this prospective study of carefully defined prolonged gestations. That this risk was not found to be even higher[5] may in part be attributable to continuous FHR monitoring of all patients during labor[26] and definitive management of airway meconium at the time of delivery.[15] Conversely, the lower perinatal risk suggested by other investigators[5] may have resulted from inclusion, among those studied, of pregnancies incorrectly identified as prolonged. A direct comparison of reported risk is difficult in the absence of uniform clinical criteria to define prolonged pregnancy.

The identification of meconium-stained amniotic fluid is somewhat more objective. Meconium was present in 22% of prolonged pregnancies at the time of initial entry into this study. The incidence of meconium increased to 44% by the time delivery occurred. Corroborating the increased perinatal risk previously reported,[1, 2, 5, 6] statistically significant increases in the

frequencies of abnormal labor, fetal distress in labor, and low 1 and 5 minute Apgar scores were found when meconium was present. This study does not, however, answer the question of whether meconium directly causes or is simply associated with obstetric and perinatal complications. There is no doubt that neonatal death and morbidity can be directly caused by aspiration of meconium at the time of birth.[15] However, in this study the increased frequency of other obstetric and perinatal complications associated with meconium, despite the absence of a single instance of meconium pneumonitis, suggests that further study will be required to resolve this important question.

The demonstration of low oxygen saturations (15 to 25%) in umbilical vein blood following meconium passage[27] shows that meconium can be associated with intrauterine compromise. Observations such as these, together with the increased perinatal risk reported in the presence of meconium, undoubtedly led to the empirical practice of using meconium as an antenatal monitor of fetal well-being. In the absence of appropriate controls, the reports of favorable perinatal outcome when meconium was used as an indication for induction of labor[8-11, 27-30] are difficult to evaluate. In fact, the good results may have been due in part to the probability that the acid-base status was normal in nearly all of the fetuses at the time meconium was discovered.[11]

In the present study, the finding of meconium did not correlate with a positive OCT, and there was no increase in perinatal death and morbidity rates when induction of labor was avoided following antenatal detection of meconium. These results support and extend to the antenatal period the previous observations of Miller and associates[12] that in the absence of biochemical or biophysical evidence of hypoxia or asphyxia, meconium is of little consequence or significance to the fetus. Green and Paul[31] recently reported a large, retrospective experience with amniocentesis in prolonged pregnancy. They found no perinatal deaths associated with meconium, noted 10 perinatal deaths when there was no meconium at amniocentesis, and concluded that the test was of questionable value when used solely for the detection of meconium. Taken together, all of these findings suggest that meconium is not a sensitive or specific indicator of intrauterine compromise. In fact, it has been suggested that a fetus may pass meconium as a consequence of vagal stimulation or maturation of the gastrointestinal system and that this might account for the prevalence of this clinical sign in prolonged pregnancy.[12]

Amniocentesis or amnioscopy must be employed in order to establish a diagnosis of meconium during the antenatal period. The former procedure carries a small but finite fetal risk,[16, 17] whereas the latter is technically difficult and may cause rupture of fetal membranes.[9, 10, 32] The present study suggests that fetal well-being in prolonged pregnancies can be monitored effectively by a noninvasive and technically simple method—the OCT—without increasing obstetric and perinatal complications compared to monitoring by amniocentesis. Conversely, the results suggest that in order for amniocentesis to be as effective as the OCT, nearly three times as many inductions of labor—with an attendant increased rate of fetal distress—must be performed.

Two general considerations in the management of prolonged pregnancy emerge from this study. (1) Since improvement in perinatal outcome does not occur following induction of labor for meconium (compared to women with meconium followed by OCT's), the use of an invasive procedure for its detection (amniocentesis) is probably not warranted. The importance of avoiding the attendant risks of amniocentesis is further emphasized by the finding of a large subgroup of prolonged pregnancies (48% of those followed by OCT's, Table IV) which are essentially uncomplicated and at low risk. An important exception to this generalization may be the geographical necessity for delivery in an institution not equipped for continuous FHR monitoring or not having personnel available to insure adequate airway and subsequent neonatal management 24 hours a day. In this situation, discovery of meconium could facilitate maternal/fetal transfer to a better equipped and better staffed institution. (2) Although cervical status and the place of elective induction of labor was not directly addressed in this study, the data presented suggest management alternatives in this regard. Attempted induction with an unfavorable cervix may safely be avoided if fetal status can be monitored by the OCT. Furthermore, should uncertainty exist regarding length of gestation, awaiting the onset of spontaneous labor may prevent iatrogenic prematurity and its sequalae.[33] As noted previously, this recommendation remains unchanged regardless of the presence of meconium. However, the 22% of women who initially have clear fluid but then go on to develop meconium before delivery raises the question of whether elective induction of women without meconium could prevent the obstetric and perinatal complications associated with it. A randomized trial comparing induction of labor with expectant management under OCT control in women without meconium would be necessary to resolve this issue. However, since the presence of meconium and the status of the cervix need not be considered in prolonged pregnancies followed by

OCT's, maximal flexibility in planning patient management is assured.

Finally, since obstetric and perinatal complications do occur in prolonged pregnancy not accompanied by meconium or a positive OCT, continued research into alternative methods of fetal surveillance and obstetric management is necessary. The extremely low false-negative rate associated with the OCT[18] makes it an ideal research tool to be matched against other proposed methods of management in future controlled, clinical trials.

Discussion

DR. ROBERT H. MESSER, Albuquerque, New Mexico. While it is generally recognized that the perinatal death rate is increased in prolonged pregnancy, there is not general agreement on the management of this obstetric complication. In fact, this controversy has been going on for many years. The rigorous definition of prolonged pregnancy employed by the authors lends credence to their conclusions. They have chosen a middle road between total noninterference and delivery by

one means or another of all prolonged pregnancies. This is a conservative course which recommends noninterference unless there is objective evidence of significant (perhaps life-threatening) distress, their evidence being the OCT. I agree with this approach.

Since the factors controlling the length of human gestation are still poorly understood, we have freedom to hypothesize. Let me propose an iconoclastic thought. Is it not possible that human pregnancy is sophisticated enough that the maternal-fetal unit adjusts to adversity, and that Mother Nature compensates by deviation from normal gestational length, and this actually serves to ameliorate outcome as long as survival occurs? Thus, in fact, might not some of the infants actually be better off left in the uterus? The natural tendency is to believe that because a pregnancy is beyond 42 weeks this state threatens the fetus and causes an increased perinatal death rate. Perhaps the shoe is on the other foot. Perhaps a threatened fetus prefers to stay in the uterus and the prolonged pregnancy is the result, not the cause, of an abnormal pregnancy. This would explain the higher incidence of anomalies as shown by Evans and also the increase in dysmature and undergrown infants shown by McClure Brown.

There are some examples which suggest that this may indeed be the case. It is estimated that late in pregnancy the fetal diet consists of the equivalent of 6 to 10 gm/kg/day of protein (amino acids, etc.) and is rich in 2- and 3-carbon sugars. Yet, my friends in neonatology tell me that they cannot exceed 3 to 4 gm/kg/day of protein, and 2- and 3-carbon sugars present high osmolality problems in neonatal nutrition. Even normal newborn infants *lose* weight in the first few days after birth, do they not? Why is it so hard to prove the logical-seeming idea that protein deprivation in economically depressed societies is the cause of high rates of premature birth, or the cause of mental retardation? As shown by Cheek and Hill, the primate has a remarkable capacity to protect fetal brain development from adverse effects of maternal protein deprivation as well as placental insufficiency induced by vascular occlusion. The children of the starved Dutch women of the Second World War are normal or superior intellectually.

In a fascinating and carefully controlled experiment, Riopelle and Hale[1] have recently shown that when primates are in an environment exposed partly to the elements, protein deprivation *prolongs* rather than shortens gestation. In fact, reduction of protein from 4 to 2 or 1 gm/kg/day lengthened gestation by 8.5 days, which is a 5% increase for the rhesus monkey. Perhaps even though things may not be going well, or perhaps because so, the primate fetus prefers to stay where he is.

As an incidental, I would like to ask the authors if they practice aspiration prior to delivery of the shoulders of meconium babies, since our experience has been similar to the Denver experience in dramatic reduction of meconium pneumonitis.

DR. THOMAS H. KIRSCHBAUM, East Lansing, Michigan. Among gravidas with a pregnancy greater than 42 weeks in duration by presumably accurate history and physical examination, there is a small subset whose fetuses are destined to respond unfavorably to labor as manifest, retrospectively, by an increased incidence of fetal distress, of diminished Apgar score at birth, and of perinatal morbidity and death in comparison to pregnancies not so specified. The problem in management is to identify these postmature fetuses, minimizing false-positive errors which have the force of including normal infants simply the products of post-date pregnancies, and false-negative errors which enable postmature fetuses to fail to receive the special management they deserve. Further, the suspect pregnancies should be subjected to a course of management which will be effective in benefitting the postmature fetuses and not impairing the prospects for the post-date fetuses.

The authors, employing treatment protocols which employ the OCT and meconium staining on amniocentesis, have failed to define an effective treatment protocol. Their experience supports the contention of others that meconium staining of amniotic fluid is an insufficiently strong predictor of fetal distress in utero to be useful in this regard. Regrettably, their experience enables them justifiably to say little, if anything, about the usefulness of the OCT.

To be of clinical value, a test of antenatal well being must meet three requirements. (1) It must show a correlation with adverse perinatal outcome, a status which both meconium-stained amniotic fluid and a positive OCT enjoy. (2) The test must have a causal relationship strong enough to be a useful predictor of fetal distress in utero. That this is not the case for meconium-stained amniotic fluid has been known for several years.[1] The work reported here allows no comment in regard to the predictiveness of the positive OCT. (3) Therapeutic protocols must be shown to exist, employing the test, which suffice to lower perinatal morbidity and death rates.

In part, the negative result in this study is a function of experimental design. The authors have compared the use of the OCT as a predictor to meconium staining, not in comparison to simple expectant management. Therefore, only statements of relative, not absolute, value can be made about the OCT since management employing a useless indicator cannot be used as a standard against which to measure achievement. Experimental design is not structured to provide data which allow exploration of the validity of the OCT as a predictor of fetal distress in utero. Indeed, the author's contention that the OCT is an ideal research tool to be

used as a standard in evaluating new techniques for the diagnosis of fetal distress seems clearly incorrect. Though the incidence of false negative findings appears to be small, false positives have been reported in the range of 25% to 50% and speak against the usefulness of this determination except as a negative indicator. Since use of meconium staining as a predictor of fetal distress is known to be ineffective in reducing perinatal morbidity death rates, and results of the OCT do not differ significantly in this respect, all that can be said from the employment of the research protocol is that the OCT is equally useless. The choice of perinatal morbidity and death as an outcome measurement necessitates the employment of a complex function, not just of the utility of the OCT, but of the hazard of repeated amniocenteses, the induction of labor with various conditions of the cervix, and of the efficiency of intrapartum FHR monitoring.

In brief, the authors have failed to provide useful counsel based on rigorous data evaluation in a field marked, as they correctly point out, by too much unsubstantiated advice. Rather, they have added more advice of the same kind, and in so doing, they have joined several investigators who have contributed to an important problem in our discipline. Several techniques in fetal appraisal have been incorporated in clinical practice without rigorous objective proof of value as measured by their predictive strength and the prevention of perinatal morbidity and death. Some of these determinations have inappropriately in turn been used as standards by which to judge other newer techniques. Until such controlled objective appraisal of the value of the techniques for determining fetal distress in utero is made, advice based on opinion will continue to supplant counsel based on fact in the subspecialty of maternal and fetal medicine.

1. Fenton, A. N., and Steer, C. M.: Fetal distress, AM. J. OBSTET. GYNECOL. 83:354, 1962.

DR. DAVID M. BARTON, Boise, Idaho. I would like to inquire about the comments concerning the value of estriol determinations following postmaturity or postdatism, and if some of the assumptions about well being, regardless of some of the parameters studied, would apply. I wonder about those cases of placental sulfatase deficiency and their increased incidence of postmaturity and how this might be correlated with the OCT.

DR. JOHN C. MORRISON, Memphis, Tennessee. While I concur with the comments of Dr. Kirschbaum as far as the analysis of data is concerned, I still think the literature would probably support the use of the OCT and perhaps the nonstress test in assessing gestations where meconium is present.

Also, I was impressed by the cases of the intrauterine growth retardation which Dr. Huddleston mentioned, and its relationship to possible fetal death. I would like to add a word of caution that in the pregnancy, postdates or otherwise, which may be complicated by intrauterine growth retardation, amniocentesis indeed may cause fetal distress by decreasing uterine blood flow. This situation may be similar to those at cesarean section where manipulation of the uterus appears to decrease placental blood flow through sympathetic stimulation. Perhaps fetal monitoring of patients after amniocentesis or other invasive techniques in the gestation complicated by suspected intrauterine growth retardation might be appropriate.

PROF. C. EUGENE MILLER, Louisville, Kentucky. From theoretical considerations we know that smooth muscle in the uterus produces a stress between 2.7 and 3.2 kg/cm.^{2} It appears that the magnitude of this stress is important in regard to the length of pregnancy.

I would like to know if in using the OCT challenge test the authors were concerned about such stresses and, if so, would they find acceptable the stress values quoted above?

DR. CHARLES A. WHITE, JR., Morgantown, West Virginia. I would like to ask about the group of patients that was followed by amniocentesis in which there was no evidence of meconium staining.

Am I correct in my assumption that this group did not exhibit any deaths during the next few days until the onset of labor? Was there any difference in the ability of that group of infants to tolerate labor as compared to those in which meconium staining was demonstrated?

DR. CROSBY J. EATON, Albuquerque, New Mexico. I wonder about the significance of the negative OCT test as much as I wonder about things like HPL and so on which I think have fallen by the way.

At our institution in Albuquerque, within a 3-week period, we had two patients in whom the fetuses died within 36 hours of a perfectly normal OCT because of prolonged pregnancy.

I do feel that this may be a useful tool, but I do not think that we can call it a totally reassuring thing to find a negative OCT test.

I would like to hear the comments of the essayists with respect to that.

DR. JAMES SEBASTIAN, Duluth, Minnesota. How long did you wait, 43 weeks, 44 weeks, 45 weeks? Could you comment on subgroups of inducible versus the unripe cervix in management? How long can we afford to wait if the patient is ready for delivery? What is the advantage of the place of delivery in more appropriate management of the fetus, including endotracheal aspiration of meconium for better fetal outcome?

DR. CHANG Y. LEE, Detroit, Michigan. During discussion, questions have been raised about false-positive and false-negative results of the contraction stress test (CST) or the OCT. If you review the OCT tracings, you may observe baseline FHR reactivity with accelerations with fetal movements in the "false-positive" OCT cases. In a few cases we have observed that the active fetus

LIBRARY

recorded late decelerations in response to occasional Braxton-Hicks contractions while also recording FHR accelerations with active movements during the performance of fetal activity *acceleration* determination (FAD) or nonstress test. In two cases, we performed a CST to observe the fetal response to uterine contractions during the CST and the results were positive. Since the baseline was reactive in these cases, we classified them as "reactive-positive" and considered them as false-positive tests. Both patients were delivered vaginally in good condition. Internal FHR monitoring had not recorded FHR signs of fetal distress in these cases.

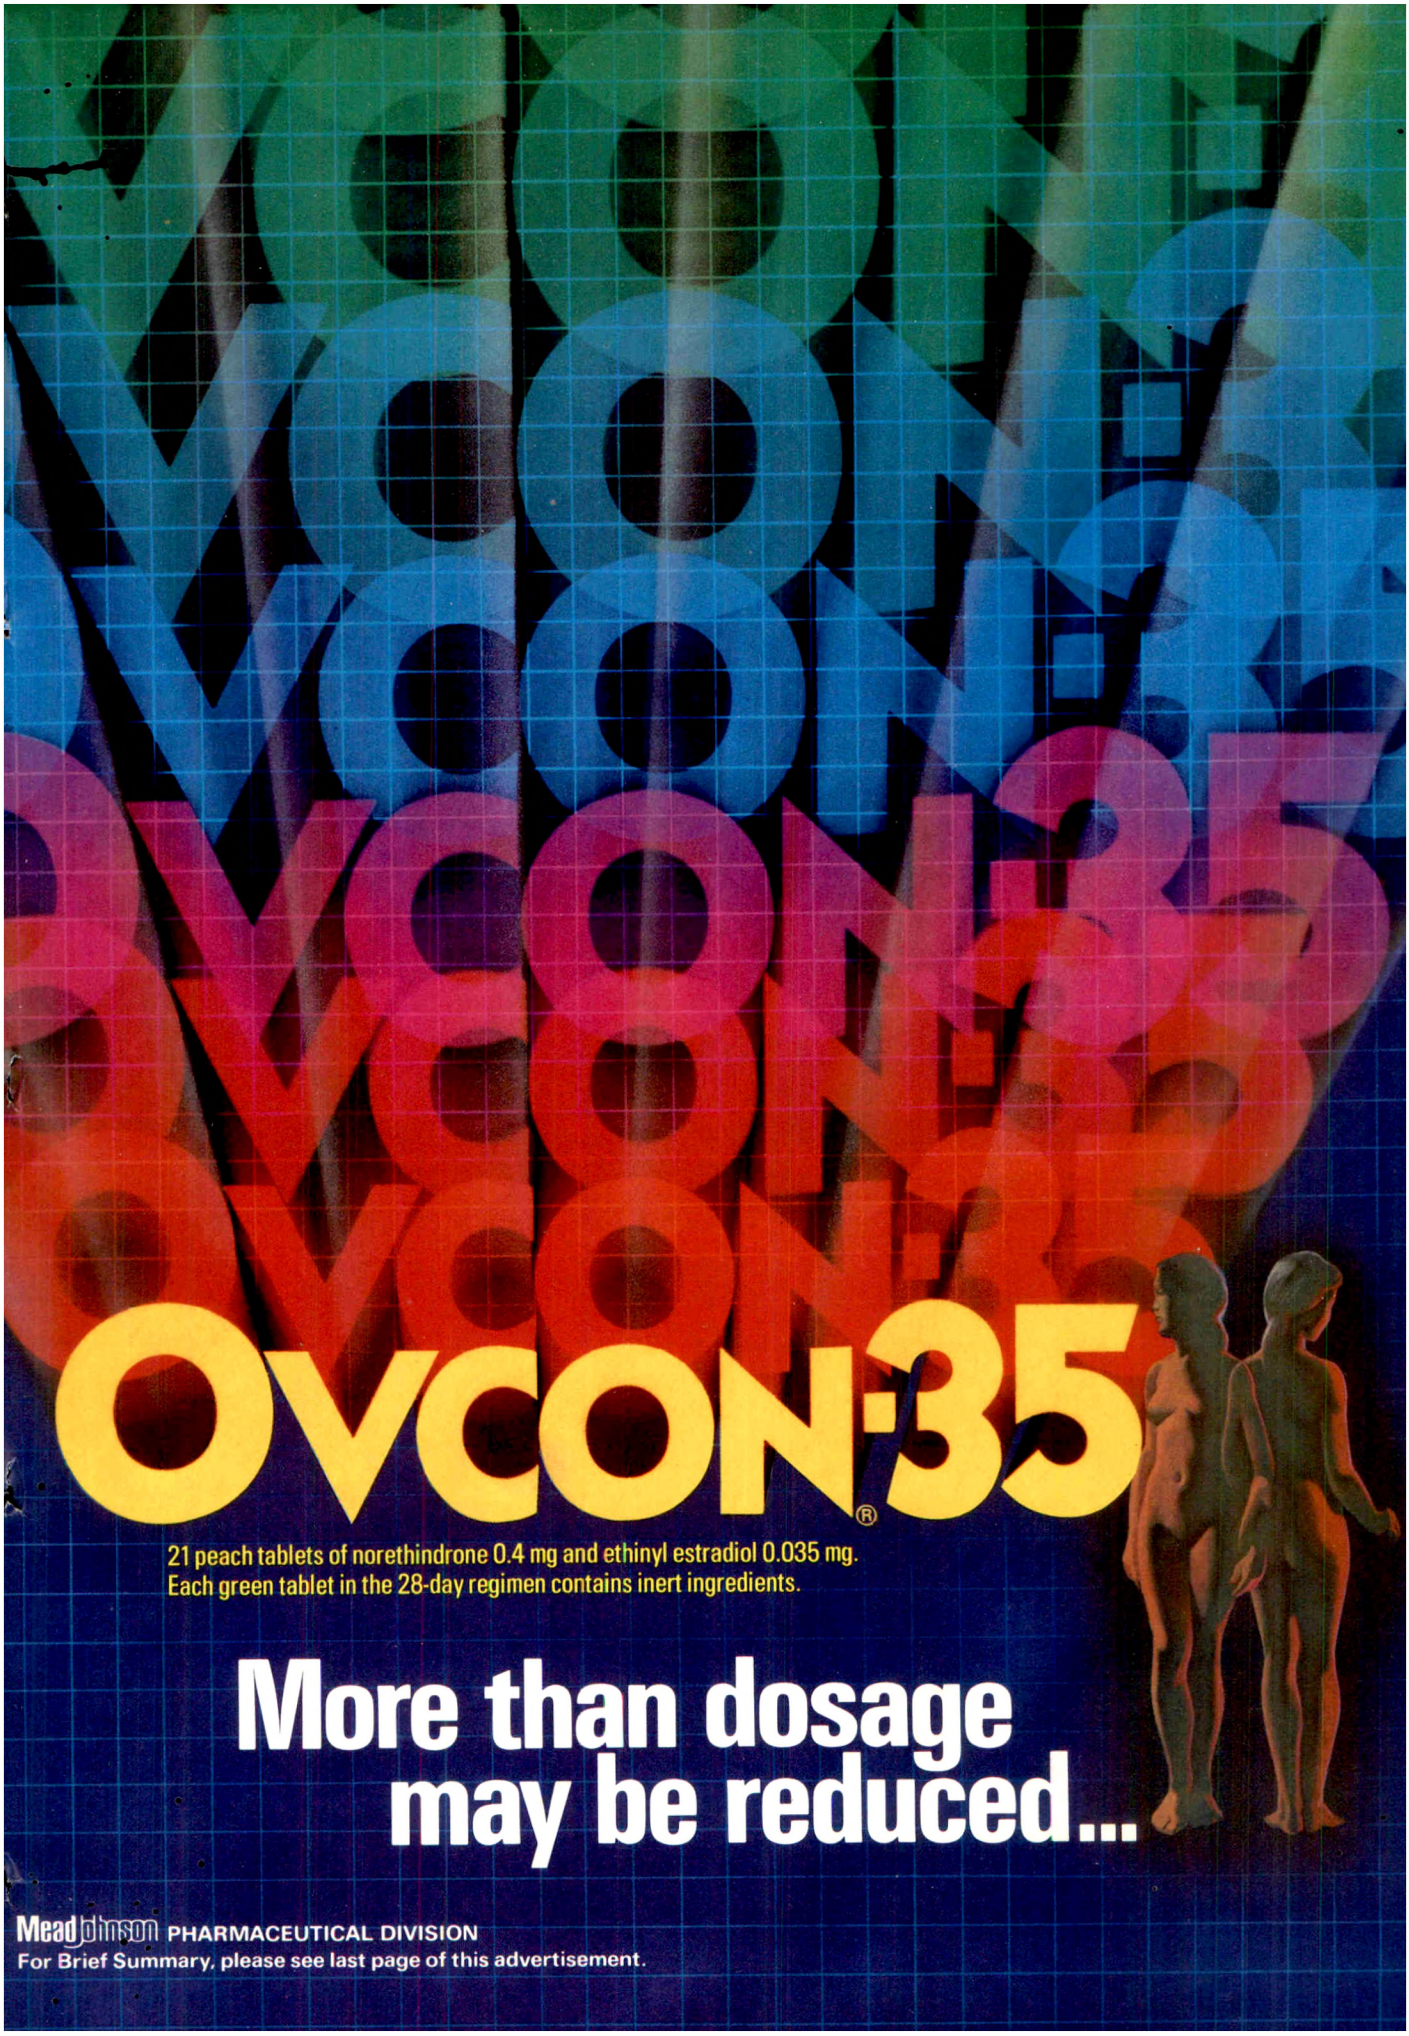
A nonreactive negative test, a negative CST without baseline reactivity, did not give us a solid negativity. A case with a nonreactive negative CST had recorded persistant late decelerations with mild tachycardia during labor.

If we include the baseline reactivity in the interpretation of the CST, I think that we can eliminate most of the false-positive or false-negative readings.

DR. KNOX (Closing). I would like to say at the outset that I agree with Dr. Kirschbaum. I think that what we have presented is a statement of relative risk or relative benefit. Viewed from the point of relative benefit, I guess the ultimate question becomes whether the clinician chooses to use an invasive or a noninvasive tool to monitor prolonged pregnancies. The data presented clearly suggest the comparability, if not the superiority, of the noninvasive test.

I also concur with Dr. Kirschbaum that the OCT itself has never been validated in the way that he suggests appropriate (prospective, randomized trial with a nonintervention control group). Be this as it may, what has happened is that enthusiasm for this test (OCT) like many other previously touted forms of fetal assessment (HPL, estriols, etc.), becomes so widespread that, when investigators go to a Human Use Committee and ask if they may compare an OCT versus nonintervention or expectant management, they are told, "No; by denying the patient this test you would be performing an unethical study." I would suggest, and I assume Dr. Kirschbaum would agree, that through this type of reasoning we are perhaps doing the unethical thing by introducing therapies into our practice prior to having them well validated by appropriate, controlled studies. At any rate, admitting the fact that the OCT has not been given that kind of prospective validation, then the rationale for the use of the OCT in this type of study hinges on its very low false-negative rate (approximately 1/1,000 tests performed). Given the dilemma of a Human Use Committee that says nonintervention is not an acceptable alternative, we chose instead to use a diagnostic modality that at least has a very, very low false-negative rate.

I think that the current statement of relative risk being equal, and with amniocentesis being invasive and the OCT being noninvasive, the next step involves comparing the OCT to other proposed forms of management in prolonged pregnancy. I would reiterate that the noninvasiveness and low false-negative rate make the OCT a good choice to be matched with other therapies (e.g., induction of labor) in future studies of this clinical entity.



Dr. Sebastian questioned the place of elective induction in this study. This was not taken into account. No inductions were done except for the indications that were given. Clearly a question that now needs to be asked is: What happens if you follow patients expectantly with OCT's versus inducing labor at 42 weeks, perhaps using a good Bishop score as a starting point for entry into the study? That study is currently being completed, but in the current study this was not done.

Elective induction of labor likewise addresses another issue: When the incidence of meconium doubles between time of entry into the study (42 weeks) and its final termination (at delivery), can you prevent some of the complications associated with meconium by elective induction? I believe this needs to be answered in a well-controlled prospective study.

There was no difference in outcome whether the patient was delivered at 42, 43, and, in a couple of instances, 44 weeks, but the numbers are so small (at 44 weeks) that a final statement in this regard is not possible.

The comment about the reactivity of the fetus during an OCT as a possible means of eliminating false-positive tests remains, at this point, a hypothesis that needs to be further scrutinized. I was fascinated by Dr. Messer's hypothesis. It is always easier to comment about hypotheses and interesting speculation than to attempt to answer a good critique as put forth by Dr. Kirschbaum. Thank you, Dr. Messer, for taking us off the hook a little. The questions concerning fetal distress in the group that had no meconium and were followed by amniocentesis can be answered as follows: There were no specific problems in that group, but one could speculate that given the fact that there are some potentially positive OCT's in the group, and that if a positive OCT is viewed as a criterion of fetal distress, then if enough patients were studied, fetal distress would probably be eventually found. However, in the current study, no differences were found.

I would like to close by saying that in the group of patients with a negative OCT and no meconium (over 50% of all patients with prolonged pregnancy), the risk of complications to baby and to mother is extraordinarily low; as low as in a normal delivery population. Because of the extraordinarily low risk in this subgroup among all patients who have prolonged pregnancy, the goal ought to be to define fetal well-being in the least invasive and least therapeutically invasive method possible.

21 peach tablets of norethindrone 0.4 mg and ethinyl estradiol 0.035 mg.
Each green tablet in the 28-day regimen contains inert ingredients.

More than dosage may be reduced...

Mead Johnson PHARMACEUTICAL DIVISION

For Brief Summary, please see last page of this advertisement.

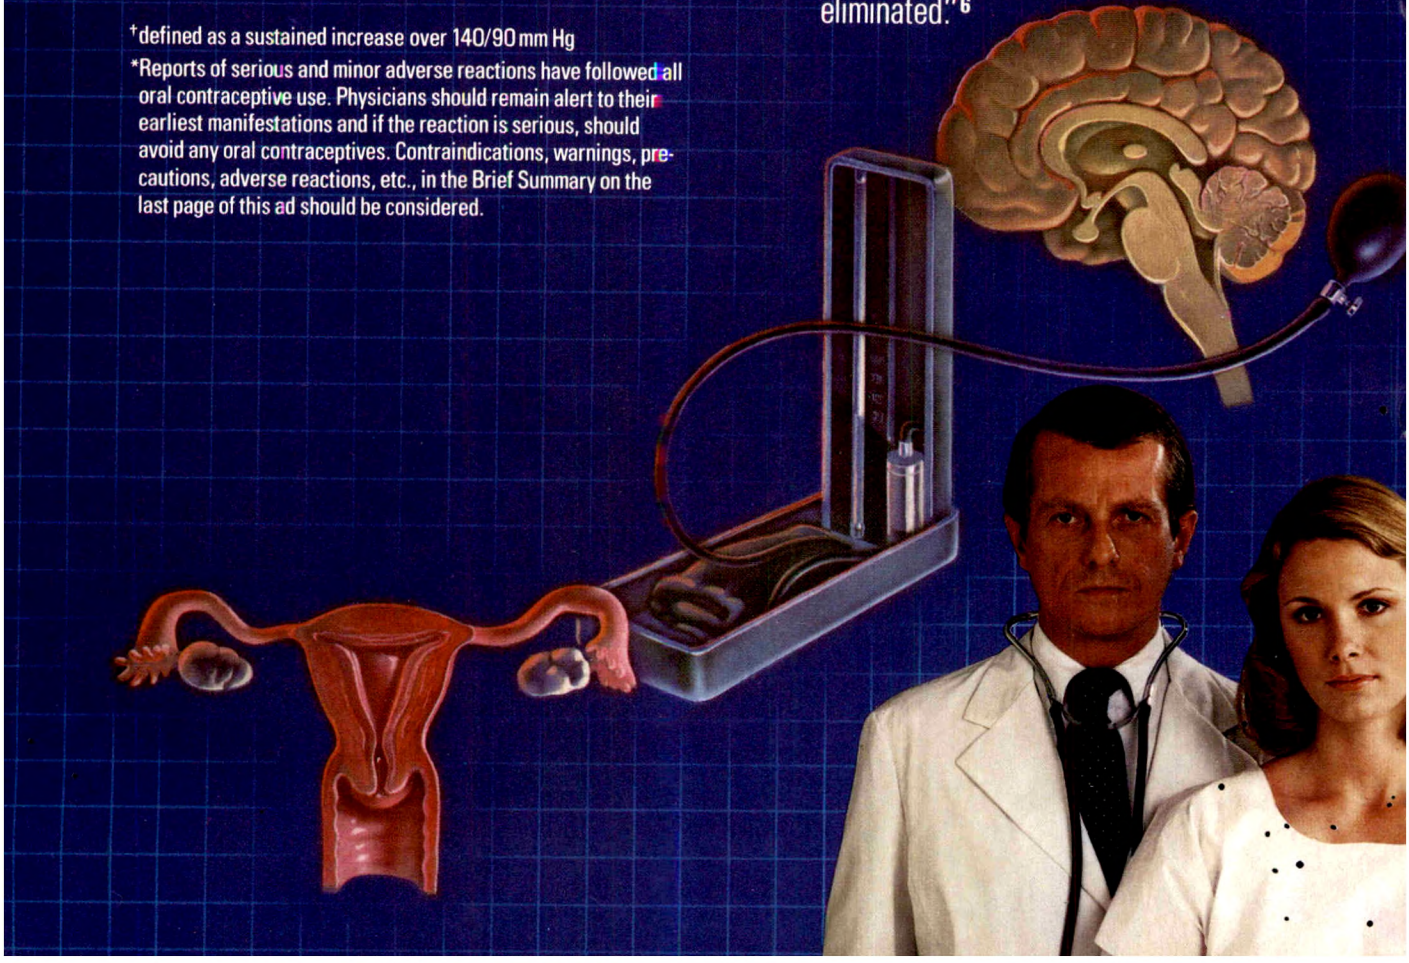
Research to date suggests that

reducing dosage may reduce risk*[1-3]

OVCON®-35 provides effectiveness

21 peach tablets of norethindrone 0.4 mg and ethinyl estradiol 0.035 mg.
Each green tablet in the 28-day regimen contains inert ingredients.

1 No hypertension†



- No hypertension developed in 564 normotensive women during 44 months of one study[5]
- No hypertension was observed in 1,925 of 1,970 women during original clinical experience[4]
- Blood pressure did not increase during 8–18 months of OVCON-35 therapy in four women who were initially hypertensive[5]
- Eighty-four women with histories of toxemia of pregnancy showed no significant differences in blood pressure from 480 women with normal pregnancy histories[5]
- Prevalence of hypertension increases with longer oral contraceptive use and age

†defined as a sustained increase over 140/90 mm Hg

*Reports of serious and minor adverse reactions have followed all oral contraceptive use. Physicians should remain alert to their earliest manifestations and if the reaction is serious, should avoid any oral contraceptives. Contraindications, warnings, precautions, adverse reactions, etc., in the Brief Summary on the last page of this ad should be considered.

2 No significant adverse changes in weight, plasma insulin levels, blood glucose values, or fasting triglyceride and cholesterol levels in a preliminary prospective study[6,7]

"Although these data are very preliminary in that they represent only a small number of women (seven) treated for only a short period of time (6 months), they are exciting, for they suggest that perhaps oral contraceptive development has reached a stage where some of the adverse effects have been greatly reduced or eliminated."[6]

and reduced dosage[4-6]

3 OVCON-35 appears to permit prompt return of endometrial function[5]

- In 125 randomly selected women, endometrial biopsies performed during the luteal phase of the first postcontraceptive cycle after up to 36 months of therapy, showed no inactive endometria
- No amenorrhea was seen, although mean cycle length for the first postcontraceptive cycle was slightly prolonged
- It cannot be assumed that amenorrhea will not occur in any patient population using oral contraceptives

4 Low incidence of breakthrough bleeding and spotting

- In one study with OVCON-35, the incidence of breakthrough bleeding was 9.1% and that of spotting was 4.7% during the first cycle of therapy; the incidence decreased to 3.2% and 1.9%, respectively, by cycle 39[5]
- Overall clinical experience with OVCON-35 (20, 230 cycles) shows an average combined incidence of breakthrough bleeding and spotting of 16.2%[4]

5 Provides "method effectiveness that does not differ from published method effectiveness rates of higher-dose products"[5]

- Pregnancy rate of 0.21 (Pearl Index, method effectiveness) in one study of 700 patients completing 17,294 cycles[5]
- Method effectiveness of 0.41 (Pearl Index) and a use-effectiveness of 1.36 (Pearl Index) in 20,230 cycles in original clinical trials[4]

OVCON-35®

Mead Johnson
PHARMACEUTICAL DIVISION

For Brief Summary, please see following page.

OVCON®-35

21 peach tablets of norethindrone 0.4 mg and ethinyl estradiol 0.035 mg. Each green tablet in the 28-day regimen contains inert ingredients. Available in both 21- and 28-day regimens

Indications and Usage: Ovcon is indicated for the prevention of pregnancy. Some combination products containing 35 mcg. or less of ethinyl estradiol report slightly higher pregnancy rates than are reported for the higher dose combination products.

Contraindications: Oral contraceptives should not be used in women with any of the following conditions: 1) Thrombophlebitis or thromboembolic disorders. 2) A past history of deep vein thrombophlebitis or thromboembolic disorders. 3) Cerebral vascular or coronary artery disease. 4) Known or suspected carcinoma of the breast. 5) Known or suspected estrogen dependent neoplasia. 6) Undiagnosed abnormal genital bleeding. 7) Known or suspected pregnancy.

Warnings:

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. Women who use oral contraceptives should be strongly advised not to smoke. Use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1) *Thromboembolic Disorders and Other Vascular Problems.* An increased risk of thromboembolic and thrombotic disease associated with use of oral contraceptives is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. In a study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater. An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported. Studies conducted in the United Kingdom found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction compared to nonusers who do not smoke. Oral contraceptive users who smoke have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. The amount of smoking is a very important factor. British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives: preparations containing 100 mcg. or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg. of estrogen. The relative risk of thromboembolic disease associated with progestin-only oral contraceptives has not been determined. Cases of thromboembolic disease have been reported in women using progestin-only products, and they should not be presumed to be risk-free. The overall excess mortality rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15-35: 5/100,000; ages 35-44: 33/100,000; ages 45-49: 140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. The highest risk was found in heavy cigarette smokers (15 or more cigarettes per day) who used oral contraceptives and were aged 40 or older. Women who smoke should be advised not to use oral contraceptives. The use of oral contraceptives in women over age 40 with other risk factors is not recommended. The mortality associated with all of the methods of birth control is low compared to the risk of childbirth, with the exception of oral contraceptive users who smoke and are over age 40. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and for myocardial infarction is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia, and especially by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. If feasible, oral contraceptives should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2) *Ocular Lesions.* There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue the medication if there is unexplained sudden or gradual partial or complete loss of vision; sudden onset of proptosis or diplopia; papilledema; or retinal vascular lesions, and institute appropriate diagnostic and therapeutic measures. 3) *Carcinoma.* Long term administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. In humans, one study investigated the first 21 cases of endometrial adenocarcinoma in women on oral contraceptives reported to a registry. Of those women without predisposing risk factors for this disease, nearly all occurred in women who had used a sequential oral contraceptive. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestin-only oral contraceptives. No increase in breast cancer in women taking oral contraceptives has been reported although one study reported an increased risk of breast cancer in subgroups of women treated using oral contraceptives with documented benign breast disease. There is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives. 4) *Hepatic Adenoma.* Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study reported a higher risk associated with oral contraceptive formulations with high hormonal potency. Although benign and rare, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short term as well as long term users of oral contraceptives. Two studies relate the risk with duration of contraceptive use, the risk being much greater after 4 or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass, or shock. A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time. 5) *Use in Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring.* Fetal abnormalities have been reported to occur in the offspring of women who have taken progestogens and/or estrogens during pregnancy. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. A high percentage of such exposed women (30% to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign it is not known whether th condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalitie of the urogenital tract. Similar data are not available with the use of other estrogens but it cannot b presumed that they would not induce similar changes. The data suggest that the risk of limb reductio defects in exposed fetuses is somewhat less than 1 in 1000 live births. In the past, female se hormones have been used during pregnancy in an attempt to treat threatened or ha[illegible]abortio There is considerable evidence that estrogens are ineffective for these indications and there is n evidence from well-controlled studies that progestins are effective for these uses. Increases i chromosomal aberrations have been reported in women who become pregnant soon after ceasin oral contraceptive therapy. Embryos with these anomalies are virtually always spontaneous aborted. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soo after stopping oral contraceptives is unknown. It is recommended that for any patient who ha missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptiv regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnanc should be considered at the time of the first missed period and further use of oral contraceptive should be withheld until pregnancy has been ruled out. If pregnancy is confirmed the patient shoul be apprised of the potential risks to the fetus and the advisability of pregnancy continuation should b discussed in light of these risks. It is also recommended that women who discontinue or contraceptives with the intent of becoming pregnant use an alternate form of contraception for period of time before attempting to conceive. Many clinicians recommend three months Administration of progestin-only or progestin-estrogen combinations to induce withdrawal bleedin should not be used as a test for pregnancy. 6) *Gall Bladder Disease.* Studies have reported a increased risk of surgically confirmed gallbladder disease appearing after one year of ora contraceptive use and doubling of the risk after 4 or 5 years of use. 7) *Carbohydrate and Lipi Metabolic Effects.* A decrease in glucose tolerance has been observed in a significant percentage o patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefull observed while receiving oral contraceptives. Increased serum levels of triglycerides and tota phospholipids have been observed in oral contraceptive users. The clinical significance of thi observation is unknown at this time. 8) *Elevated Blood Pressure.* An increase in blood pressure ha been reported in women receiving oral contraceptives. The prevalence of hypertension in ora contraceptive users may be no higher than nonusers in the first year of oral contraceptive use bu increases with longer exposure and in the fifth year of use is two and one-half to three times th reported prevalence in the first year. Women who previously had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. 9) *Headaches.* The onset or exacerbation of migraine or development of headache of a new pattern which is re current, persistent or severe, requires discontinuation of oral contraceptives and investigation of th cause. 10) *Bleeding Irregularities.* Breakthrough bleeding, spotting and amenorrhea are frequen reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases o irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only i necessary since this may increase the risk of thromboembolic disease. Women with a past history o oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. 11) *Ectopic Pregnancy.* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. However, in oral contraceptive failures, the ratio of ectopic to intrauterine pregnancies is higher than in women not using oral contraceptives since the drugs are more effective in preventing intrauterine rather than ectopic pregnancy. The higher ectopic-intrauterine ratio has been reported with both combination products and progestin-only oral contraceptives. 12) *Breast Feeding.* A small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The long-range effect to the nursing infant cannot be determined at this time.

Precautions: 1) A complete medical and family history should be taken prior to the initiation of ora contraceptives. Examination should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, ora contraceptives should not be prescribed for longer than 1 year without another physical examinatior being performed. 2) Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3) Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 4) Because oral contraceptives may cause some degree of fluid retention, conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, cardiac or renal insufficiency or asthma require careful observation. 5) Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6) Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7) Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8) Serum folate levels may be depressed by oral contraceptive therapy. This may complicate subsequent pregnancy with regard to folate deficiency. 9) The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. 10) Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T_4 by column, or T_4 by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting the elevated TBG, free T_4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient: Detailed Patient Labeling has been prepared for use by the patient and has been made available for distribution by the pharmacist.

Drug Interactions: Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium and ampicillin.

Adverse Reactions: An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see **Warnings**): Thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gall bladder disease, congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis; benign hepatomas; neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10% or less of patients during the first cycle (Other reactions, as a general rule, are seen much less frequently or only occasionally.); gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes (tenderness, enlargement, and secretion); change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome, intolerance to contact lenses, change in corneal curvature (steepening), cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, impaired renal function.

Acute Overdosage: Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Female sex hormone receptors and their importance in clinical practice

RONALD W. TAYLOR, M.D., F.R.C.O.G.
London, England

We now know a great deal about the early steps in the induction of a steroid hormone response at the cellular level. This helps to explain some of the observed clinical responses and also the development of some congenital anomalies. The importance of progesterone as a balance to the proliferative effects of estrogen both in hormone replacement therapy and in the hormone-sensitive tumors is clear. It is hoped that further studies will guide us to ways in which we might enhance these benefits. (AM. J. OBSTET. GYNECOL. 134:385, 1979.)

THERE ARE TWO broad categories of action of the steroid hormones. There is first a series of not very well defined nor easily measurable general effects upon the whole animal, often mediated by other hormones or enzyme systems. Such effects are seen in patients suffering from premenstrual depression[1] and it is through such general mechanisms that the beneficial effects of estradiol on the reticuloendothelial system are produced.[2, 3] Many of the problems attributed to the withdrawal of estrogen in the postmenopausal woman are attributed to loss of support for such general mechanisms.[4]

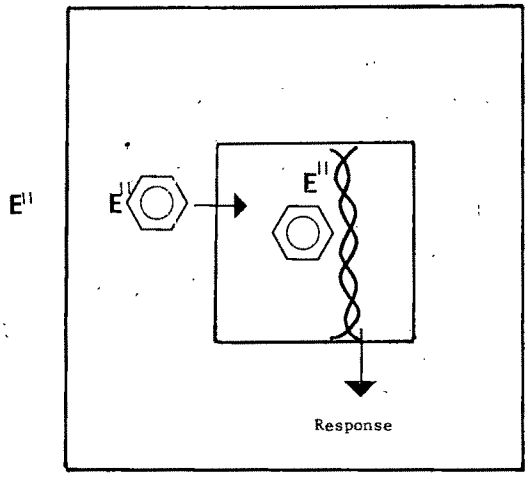
The second category is concerned with the highly specific and more easily measurable effect upon what are commonly called "target tissues." In the past a "target tissue" was defined as one that showed a clear, predictable, and often dramatic response to stimulation with the appropriate hormone. Today we can redefine this term because the presence of adequate amounts of highly specific receptor protein is in most cases mandatory if a cell is to be responsive to a steroid hormone.[5, 6] These data are so convincing that we can say with certain qualifications that if a particular steroid receptor is present in abundant amounts then that cell will respond to that steroid.

The qualifications relate to certain situations in which cells do contain soluble receptor but have defects in the machinery through which the receptor-steroid complex usually operates.

Blood plasma does contain specific, high-affinity, steroid-binding proteins which are of considerable importance in that they do bind appreciable amounts of steroid and make them physiologically inactive. However, these proteins have properties and functions which are noticeably different from the intracellular binding proteins with which we are at present concerned.

As gynecologists we are most concerned with the female sex steroids and, in fact, for practical reasons, most of the work on receptors has been done in relation to estrogen and progesterone. However, many of the general conclusions relate to the androgens, the glucocorticoids, and the mineralocorticoids as well.

Estrogen receptors



The concept of drug-receptor reaction was formulated at the turn of the century by Paul Ehrlich and it has since been modified to explain many of the actions of drugs and hormones.

Early attempts to test the validity of these ideas in relation to steroid hormones were unrewarding because pharmacologic doses of the hormone had to be administered to detect it at the cellular level by the methods then employed. The advent of tritium-labeled steroids enabled researchers to administer physiologic amounts of steroid, observe the way it behaved in body fluids, follow it into tissues, and detect its presence within various components of cells. This revolutionized experiments and led to the production by Jensen and Jacobsen[7] of a general model explaining the intracellular movement of estrogen within a responsive cell (Fig. 1).

Annual Guest Lecture presented at the Forty-sixth Annual Meeting of the Central Association of Obstetricians and Gynecologists, Kansas City, Missouri, October 13-15, 1978.

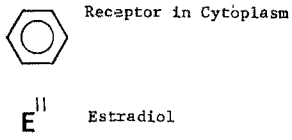

Fig. 1. Hypothetical model for estrogen interaction within the endometrial cell.

The steroid enters the cell and combines noncovalently with a limited number of specific receptor molecules of high affinity. This complex then enters the nucleus and elicits a response.[5] The response is determined by the nature of the reacting cell, not by the estrogen. Thus, whereas cells of the human endometrium respond to estrogen by proliferating, secretory cells of the endosalpinx respond by producing a characteristic fluid. We thus have the idea of an estrogen-receptor complex as a switch or amplifier.[8]

Every steroid receptor so far discovered is an oligomeric protein, the composition of which is dependent upon ionic strength. Changing salt concentration from 10 mM to 400 mM KCC changes the molecular weight of the receptor from about 2×10^5 (7 to 8 S) to 70,000 (4S). There is evidence that this change in size of the molecule also occurs when the receptor-steroid complex moves into the cell nucleus.[8] This led Jungblutt[9] to propose a refinement of Jensen and Jacobsen's model. He suggested that the primary receptor in the cytoplasm had two components (Fig. 2). One of these components (4S) with the steroid moved into the cell nucleus to constitute the nuclear receptor.

The number of cytoplasmic receptor molecules has been calculated to range from 1,000 to 9,000 per cell in the human endometrium and endosalpinx.[8] The number increases in response to estrogen stimulus.[10] The

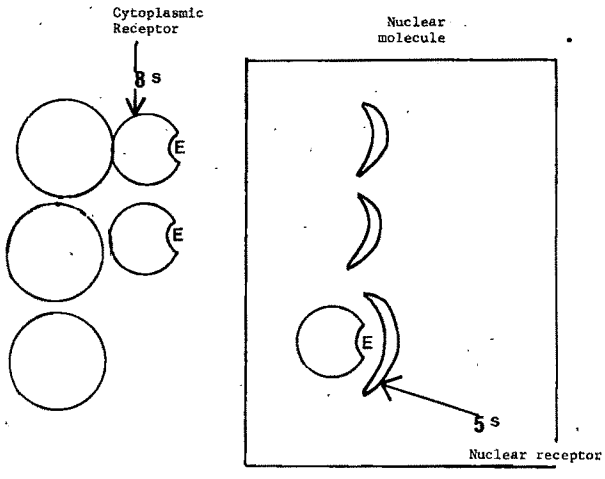

Fig. 2. Hypothetical model for estrogen transport into the nuclei of target cells. (Modeled after Jungblutt.[9]).

calculated binding constant (mean 3×10^{-13}) in both endometrium and endosalpinx indicates that the receptor molecules have a very high affinity for their respective steroids.[8] Comparatively minor changes in the steroid molecule decrease the binding affinity of the receptor. A change from estradiol-17β to estrone, for example, lowers the affinity by about 90%.[5]

The movement of the steroid-receptor complex to the nucleus results eventually in its attachment to chromatin. This over-all process is temperature dependent.[5] It is accepted that the steroid-receptor complex must be activated before becoming attached to chromatin but the nature of this process and the site at which it occurs are uncertain. Further, the identity of the nuclear acceptor for the steroid receptor remains a matter of dispute. It does appear that DNA-receptor interactions are physiologically important[11] but it is unlikely that such an interaction could explain all of the nuclear events. There is evidence that a specific nonhistone protein(s) is important in determining the number and tissue specificity of acceptor sites.[12, 13]

The picture is further confused by the possibility that the DNA sites so far measured represent comparatively low affinity binding and that there are a smaller number of very high affinity sites yet to be discovered. The exact location of the nuclear acceptor site is of more than academic interest because it may be expected to throw light on the issue of whether estrogen is a switch or an amplifier. If it acts as a switch the acceptor sites could be located in regions of inactive chromatin, but as amplifiers the acceptors might be found in more active regions of the chromatin. This is of some importance in clinical consideration of hormone-sensitive tumors. Both "switch" and "amplifier" processes may occur depending upon the tissue being considered.

Progesterone receptors

Cytoplasmic receptors specific for progesterone have been investigated by means of the same techniques as are employed in estrogen receptor studies. Much that has been said of estrogen receptors can be said for progesterone receptors also. Of greatest interest to the clinician is the interaction of the two steroids and their receptor complexes at the cellular level. While the number of estrogen receptors is autoregulated,[14] the number of progesterone receptors in many (though not all) progesterone-sensitive cells is determined by estrogen.[15] This serves to explain the synergistic effect of the two hormones. Equally relevant to the clinician is the observation that progesterone and certain progestational agents appear to affect the way in which the estrogen-receptor complex is translated to the nucleus of the target cell. It has been shown that while 80 to 90% of tritium-labeled estradiol-17β which enters the cell during the follicular phase of the menstrual cycle or in endometrium subject only to estrogen stimulation becomes associated with cell nucleus, only 20 to 30% becomes similarly associated during the luteal phase of the cycle or when the endometrium is subject also to progesterone or progestational agents.[8, 15] The mechanism by which this shift in the intracellular distribution of administered estradiol is brought about is not known, but progesterone has been shown to bring about changes in the lipid layers which surround the nucleus. These may be important in determining the ease with which the estrogen-receptor complex reaches the nucleus.[16]

Androgen receptors

Again, much that has previously been said can be applied to androgen receptors. They too are autoregulated,[17] which perhaps explains the sensitivity to low blood levels of androgen seen in patients treated and "cured" in the polycystic ovary syndrome. Apart from the uncommon virilizing syndromes, the chief interest of the gynecologist in androgens and their receptors is in the field of normal sexual development. In utero, the fetus with an XY chromosome pattern shows regression of the müllerian duct and the development of the wolffian duct into vas deferens, epididymis, and seminal vesicle. The external genital anlage develops into the prostate gland and the external genitalia. Virilization of the wolffian duct is achieved by testosterone in the absence of dihydrotestosterone (DHT) but normal development of the external genitalia requires the presence of DHT, not testosterone. These processes require the presence of androgen receptors.[18] In the autosomal recessive mutation in which 5α-reductase activity is low in the precursors of the external genitalia, external masculinization does not occur because no DHT is formed. As normal amounts of testosterone circulate, structures derived from the wolffian duct are formed normally. Other mutations are known in which the absence of androgen receptors results in failure of both müllerian and wolffian structures despite an XY genotype and normal levels of blood testosterone. Female external genitalia develop and give rise to the condition we call testicular feminization.[18]

What significance does this steroid-receptor knowledge have for the clinician?

1. Understanding of the initial steps in the mechanism of hormone action has helped us to understand the way in which certain maldevelopments of the secondary sex organs is brought about, without enabling us to do anything to prevent abnormality at present. We need to look further to find the cause of the enzyme defects which are responsible for such failure of normal hormone conversion as we see in testicular feminization.

2. The fact that we visualize estrogen as operating a "switch" or "amplifier" mechanism means, I think, that we should not regard estrogen as a substance causing malignant mutations but as one promoting growth in tumors which remain hormone sensitive. Not all receptor-positive tumor cells are hormone responsive,[11, 20] but the presence of receptors remains a very strong indication of responsiveness. The presence of receptors always indicates that the cells concerned are derived from responsive antecedents. This can be useful in determining the origin of tumors when the histologic examination is unhelpful (e.g., ovary vs. endometrium).

3. The distinction between a carcinogen and a tumor-promoting substance may at present be academic. Estrogen therapy after the menopause can be expected to give rise to an increased incidence of clinical malignancy in the endometrium in either case. In practice, the observations of the effect of progesterone on estrogen-sensitized cells (as well as the histologic evidence) should suggest that progesterone can protect against clinical malignancy when estrogen is given in the treatment of postmenopausal women. Clearly the hormones should be given cyclically to imitate the normal pattern of ovarian steroid production, since progesterone receptors appear in significant amounts only when the responsive cell is prestimulated by estrogen.

4. The fact that estrogen functions by forming a local complex in "target" cells should indicate that local application of the steroid would produce its effects. This is true, for local applications of estrogen-cream

bring about maturation of vaginal epithelium atrophied after the menopause. There is evidence (Taylor and Brush: Unpublished) that local application of estrogen—approximately 1/100 part of the normally recommended dose—can produce local maturation of vaginal epithelium without spilling over into the general circulation to cause unwanted effects such as cystic glandular hyperplasia.

5. Although the presence of minute amounts of receptor in target cells is genetically determined, the amount increases only slowly to the high levels seen in the reproductive years. Once present, it never completely disappears, although it diminishes as hormone stimulation ceases. This explains the relatively slow development of the secondary sex organs at puberty and the potential for hormone response that remains after the menopause. Radiation does not interfere with the presence of cytoplasmic receptors[8] and there is therefore the prospect that both radiation and hormone therapy can be applied with benefit in the treatment of hormone-dependent malignancy.

6. I was particularly asked not to dwell upon the use of hormone receptor studies in relation to cancer, but no review of their value to the clinician would be complete without mention of this. In the uterus and fallopian tube, where receptor protein abounds, malignancy is virtually always hormone sensitive. In the ovarian adenocarcinoma, where it is absent, no benefit is obtained from hormone treatment of any sort. Endometrial carcinoma always responds to estrogen deprivation which follows oophorectomy by showing a slower rate of growth and often, too, the shrinkage of secondary deposits. More important practically is the positive response seen in such tumors and secondaries following administration of progestational agents.[20, 21] The tumor cells pass from a proliferative to a secretory phase histologically and the proportion of administered estradiol reaching the cell nucleus falls from 80% to 30%. These responses are best seen in premenopausal women with normal levels of circulating estrogen, as one would expect from knowledge of the behavior of progesterone receptor. This has led some units, such as my own, to try to induce a similarly enhanced response in postmenopausal women, whose progesterone receptors are comparatively inactive, by administration of estrogen before the progestational agent. Insufficient data are at present available to encourage this form of approach but it is clear that progestational agents are an adjunct to surgery and radiotherapy and in my view should be given from the time the diagnosis is made until at least 3 months after it is thought that treatment is complete.

In breast cancer the results of receptor studies have not been as clearcut as in endometrial cancer. In view of the pleomorphic nature of the breast tumors this is not surprising. However, the premise that receptor assays would predict the response of the tumor to endocrine therapy has partially stood the test of time. Tumors having low or undetectable levels of receptor have less than a 10% chance of responding to endocrine treatment. However, only 50 to 60% of tumors with good amounts of receptor respond well to endocrine treatment, perhaps because there are abnormalities in the response machinery beyond the receptor stage. It is clear that patients with receptor-negative primary breast tumors develop recurrent disease at about twice the rate of their receptor-positive counterparts. This may simply reflect the greater maturity of the latter cells, but studies of the possibility of inducing receptor in receptor-negative tumors would seem to be appropriate.

Autonomic hyperreflexia in pregnancy and labor: A case report

MAHENDRA NATH, M.B., B.S., M.S.
JOHN M. VIVIAN, M.D.
WALTER B. CHERNY, M.D., C.M.
Phoenix, Arizona

The course of pregnancy and labor in a 36-year-old quadriplegic primipara is described. The associated problem of autonomic hyperreflexia and its management is discussed.
(AM. J. OBSTET. GYNECOL. 134:390, 1979.)

AS THE NUMBERS of automobile accidents and other diverse injuries from trauma increase there is now a rising incidence of severe spinal cord damage. The improved acute and long-term care of these individuals has led to greater longevity and transformation in their outlook from an inevitable hopelessness to that of an expectation of a near-normal and productive life. There is no longer any reason to discourage young spinal-injured women from either marriage or motherhood. Experience has shown that they are able successfully to continue pregnancy to term.[7, 11, 15] Obstetricians, therefore, should be aware of the peculiar problems and definite hazards to the mother and to the fetus.[4, 6] Guttmann, Frankel, and Paeslack[7] have called attention to the danger of pressure sores, anemia, and urinary tract infections during pregnancy, but special attention is directed to the problem of autonomic hyperreflexia, which may be more serious and can be life threatening, particularly during the third trimester and delivery, unless recognized promptly and managed correctly.

The syndrome of autonomic hyperreflexia, dysreflexia, or spinal poikilopoiesis[12] was first recognized by Head and Riddoch[10] in 1916 as a serious problem in the management of patients with spinal cord injuries. The potential for vital danger to the injured patient has been stressed by various authors.[1, 2, 8] Severity ranges from symptomatic annoyance to hypertensive encephalopathy,[18] cerebrovascular accidents, and death. Primarily affected are patients with a cord injury at the level of the sixth thoracic vertebra and above, that is, above the level of the splanchnic outflow, who lose hypothalamic control over their sympathetic spinal reflexes. It occurs only in patients with viable distal cord segments below the level of the disruption and may also be observed with incomplete lesion.[2] Generally, starting within a few months after the spinal shock recedes, the storm is produced in susceptible patients by any of several noxious stimuli below the level of the lesion. Afferent stimuli arising in the bladder, bowel, and genital areas ascend in the spinothalamic tracts and posterior columns. Reflex motor outflow through neurons originating in the lateral horns causes vasoconstriction and consequent hypertension. The patient experiences severe pounding headaches, has blood pressure elevations ranging as high as 250 mm Hg systolic and 150 mm Hg diastolic, bradycardia, flushing, sweating, tingling, and nasal stuffiness. The characteristically intense pounding headaches come from the stretch of the intracranial pial arteries because of the increased blood pressure at a time when supraspinal regulation to reduce blood pressure is impossible since the efferent pathways are interrupted.[17] Flushing (above the level of the lesion), sweating, bradycardia, and nasal stuffiness have been interpreted as adaptive mechanisms.[8] Bors and Comarr[2] have observed that these manifestations are more sustained and prolonged following bladder stimulation than with rectal stimulation. They tend to diminish as the stimulus is withdrawn. The following case is reported to illustrate hyperreflexia in a tetraplegic pregnant woman.

Case presentation

A Navajo Indian woman had become tetraplegic (complete loss below the level of the sixth cervical vertebra) following an automobile accident at 16 years of age. She was successfully rehabilitated and gainfully employed as a switchboard operator. At 35 years of age she married, then soon conceived after she and her husband obtained detailed advice from her physicians of the physical and sexual aspects of the marriage, and encouragement and support in the advisability of having a child. The prenatal course was normal until the thirtieth week. The hemograms remained stable and pulmonary function studies were normal within predictable tetraplegic parameters. Bladder management was meticulous. An indwelling urethral catheter was changed weekly; methenamine mandelate (Mandelamine) 1 gm q.i.d. and ascorbic acid 1 gm q.i.d. were given for urinary antisepsis. There were no episodes of clinical urinary tract infection. Normal bowel function was managed by anal sphincter dilatation and suppositories.

At 30 weeks' gestation the patient complained of mild headaches which were relieved by changing the plugged catheter. Because of increased frequency of micturition and a rise in blood pressure to 180/100 mm Hg, the patient was treated with oxybutinin chloride (Ditropan) 5 mg t.i.d., and triple anesthesia (topical anesthesia of the urethral, rectal, and vesical mucosa) during anal dilatation and catheter changes. This suppressed the headaches and the blood pressure stabilized at around 100/70 mm Hg.

At 36 weeks the frequency of headaches increased and the blood pressure rose again. She was hospitalized for observation and stabilization until delivery. An episode of urinary tract infection was successfully treated with intravenous carbenicillin. At this time the slightest manipulation of the catheter or a routine pelvic examination led to pounding headaches, sweating, flushing, and a sudden rise in blood pressure. The oxybutinin chloride and triple anesthesia were continued and guanethidine 25 mg daily was instituted. For the next 10 days the cervix had effaced somewhat, but the blood pressure remained labile, and the episodes of headache, though controlled in severity, kept increasing in frequency. Consequently, in week 38 of gestation it was decided to evacuate the uterus. Continuous epidural anesthesia was instituted; amniotomy was performed and intravenous infusion of Pitocin was begun. Though good uterine contractions developed, the autonomic hyperreflexia became quite intense; the diastolic blood pressure regularly reached 120 mm Hg. The hyperreflexia remained nonresponsive despite repeated injections for the epidural anesthesia. In the time intervals between contractions the blood pressure returned to normal. After 8 hours and only minimal progress the infant was delivered by primary cesarean section. Spinal anesthesia produced an immediate reduction in blood pressure to normal and complete remission of the physiologic turbulence. A living female infant, weight 3,352 grams, with Apgar score 9, was born. The puerperium was uneventful and the patient was discharged to her home after a week.

Comment

The relationship between autonomic hyperreflexia and uterine contraction was postulated by Guttmann and has been reported by several authors.[7, 15, 16] Comarr[4] suggested that the hypertension assoicated with this syndrome differed in etiology from that of preeclampsia, and should be managed differently. It has been observed that the symptoms of autonomic hyperreflexia are clearly related to the uterine contractions and decrease or even disappear during uterine diastole, the resting period between contractions.[15] They disappear completely at the end of the third stage of labor, as illustrated above. Signs of autonomic hyperreflexia during bladder and bowel contractions in pregnancy should be expected to become exacerbated in the course of labor and delivery. The physician should be alert to recognize this and provide management to either prevent or minimize the effects. Continuous monitoring of blood pressure is essential and vigorous efforts should be maintained to control it, preferably below 160/90 mm Hg. Elimination of bladder infection and bowel impaction is important in decreasing the nociceptive stimuli from the pelvic viscera and thus reducing the risk of crisis. It should be remembered that such a simple manipulation as a catheter change may provoke autonomic hyperreflexia. Topical anesthesia of the urethral, rectal, and vesical mucosa is usually sufficient to avoid such an episode.[2] Ganglionic blocking drugs such as hexamethonium and guanethidine have been found to be helpful in suppressing the autonomic hyperreflexia.[19, 20] Low spinal or epidural anesthesia is generally sufficient to block the impulses from pelvic structures and to prevent their occurrence entirely.[2] The continued autonomic hyperreflexia after the injection of epidural anesthesia in this patient was perhaps due to the technical difficulty encountered. Cesarean section in a spinal cord–injured woman is not mandatory; rather, a normal delivery should be expected.[13, 16] Seventeen patients in our institution have now been delivered at term over the past 8 years. In these only two cesarean sections were done; the other was necessitated by an obstetrical complication (bleeding). However, if autonomic hyperreflexia becomes acute during labor and cannot be controlled, prompt delivery by cesarean section is the most expedient method of management.

Cesarean hysterectomy: A twenty-five–year review

DOUGLAS M. HAYNES, M.D.
BENJAMIN J. MARTIN, JR., M.D.
Louisville, Kentucky

This article analyzes cesarean hysterectomies performed at Louisville General Hospital on clinic patients for the 25 year period 1953 through 1977. During this time there were 63,259 deliveries, of which 2417 were cesarean sections and 149 were cesarean hysterectomies. Twenty-six of the latter were classified as emergency operations done for urgent medical indications; in the remaining 123 patients the indications were elective to some degree. Operative and postoperative complications and morbidity are discussed, and changing trends regarding the place of cesarean hysterectomy in obstetrics over the years are evaluated. (AM. J. OBSTET. GYNECOL. 134:393, 1979.)

IT WAS IN 1876 that Porro[1] proposed a method for amputating the recently gravid uterus immediately after delivery by cesarean section in order to reduce the considerable death rate from the classical form of that operation. Since Porro's time, elective hysterectomy at the time of cesarean section has been a controversial procedure in obstetrics.

When cesarean hysterectomy is performed on an elective rather than an emergency indication, it has been denounced by many authors on the grounds that it is an unduly radical operation, particularly as regards blood loss. On the other hand, there have been some proponents of the viewpoint that cesarean hysterectomy can be an acceptable method for sterilization under certain circumstances. In a classic paper, Prystowsky and Eastman[2] concluded that the hazards of all sterilization procedures in grand multiparas were far less than those imposed by further pregnancy episodes. Haynes and Wolfe[3] reported a 2% failure rate of tubal ligation; 36% of the medically indigent patients in their series required gynecologic operations later on.

Significant recent reports on this subject are those of Barclay and associates[4] and O'Leary.[5] Review of the English language literature since 1953, excluding articles reporting fewer than 30 cesarean hysterectomies, indicates that: (1) From 1953 to 1977, there were 2,844 elective and 1,519 indicated cesarean hysterectomies reported, with a maternal mortality rate of 0.6%[8–26]; (2) Barclay has had more experience with this procedure than any other author[4]; (3) the subject was extensively debated in the latter half of the 1960's; (4) there is a significant though debatably acceptable low maternal mortality rate associated with the operation.

Material and methods

This report reviews 149 cesarean hysterectomies performed at Louisville General Hospital from 1953 through 1977. During those years there were 63,259 deliveries, of which 2,417 were cesarean sections (3%). Of these cesarean sections, 149 were cesarean hysterectomies (6.2% of the cesarean sections or 0.23% of all the deliveries).

In this series, each cesarean hysterectomy was classified as either an elective or an indicated procedure. *Elective* operations were performed for purposes other than immediate salvage of life, e.g., sterilization, functional uterine disorders, and myomas (see Table I). *Indicated* operations were those performed primarily as life-saving procedures in such acute emergencies as ruptured uterus with massive bleeding, amnionitis, and severe abruptio placentae (see Table II). Of the 123 "elective" cesarean hysterectomies, 119 were total hysterectomies and 2 were subtotal. Twenty-six "indicated" operations were performed; of these, all were total hysterectomies except for two subtotal operations.

The average parity of the patients in the "elective" category was 3; in the "indicated" category it was 4.

With respect to age, in the "elective" series the youngest patient was 18 years of age and the oldest was 41, with an average age of 29. In the "indicated" series,

Table I. Indications in 123 elective cases

	No.
Previous section (s)	
And multiparity or request for sterilization	100
And hypertension	4
And fetal death *in utero*	2
And myomata	3
And uterine prolapse	1
Hypertension, diabetes, myomas, and Rh immunization	10
CPD, malpresentation and mental deficiency	3

Table II. Indications in 26 indicated cases

	No.
Amnionitis	9
Ruptured uterus	6
Impending uterine rupture	2
Failed induction of obligation	1
Severe abruptio placentae (Couvelaire uterus and dysplasia)	3
Long-ruptured membranes, inertia, myomas, low implantation of placenta	1
Coagulopathy	2
Carcinoma in situ of cervix	1
Old uterine perforation with defect	1

Table III. Complications and morbidity

	No.
Anemia without fever	15
Cuff cellulitis or abscess	11
Iatrogenic cystotomy	10
Urinary tract infections	9
Atelectasis	7
Wound infections	6
Pneumonia	5
Ileus	4
Pelvic abscess	4
Broad ligament hematoma	4
Pulmonary embolus	2
Pyelonephritis	2
Laryngeal edema	1
Parametritis	1
Wound dehiscence with evisceration	1
Internal iliac vein laceration	1
Intestinal obstruction	1
Rectovaginal fistula	1
Ureterovaginal fistula	1
Hemoperitoneum	1

the youngest patient was 25 and the oldest was 44, the average age being 32.

Among the 26 "indicated" operations, amnionitis was the most common indication (nine cases), with uterine rupture the next in frequency (six cases). Among the 123 "elective" operations, multiparity or request for sterilization by patients who had been delivered by cesarean section in one or more previous pregnancies were the most prevalent indications.

The majority of the 149 operations were performed under general anesthesia, with spinal anesthesia next in frequency.

Of the 149 cesarean hysterectomies, 132 were performed by the senior resident in training as principal operator under staff supervision. The remaining 15 operations were carried out by a member of the attending staff as principal operator.

Results and comment

Some critics of cesarean hysterectomy have emphasized that it is a lengthy operation, entailing excessive operative morbidity as compared with cesarean section and tubal ligation.

In the 149 cesarean hysterectomies of this series, the average operating time was 132 minutes. The longest time required was 417 minutes and the shortest operating time was 42 minutes.

The patient requiring the shortest operating time was a 40-year-old woman, gravida 15, para 14, who had premature rupture of the membranes and failed induction of labor. Ironically, hers was the only postoperative death in the series; she died following a massive pulmonary embolus on the third postoperative day.

The patient with the longest operating time was a 37-year-old woman, gravida 4, para 3, with a complete placenta previa, who had undergone two previous cesarean sections. The operation was complicated by an intraoperative accidental laceration of the right internal iliac vein. The resulting hemorrhage was ultimately controlled, but necessitated 11 units of blood replacement. The combination of the central placenta previa and the iliac vein laceration occasioned the inordinately long operating time in this patient, who, incidentally, was operated on by an attending staff member rather than a resident as principal surgeon.

This case calls to mind a commonly cited disadvantage of cesarean hysterectomy, namely, the excessive blood loss reported with the procedure. Certainly the operation is attended by a more formidable blood loss than is abdominal hysterectomy in the nonpregnant woman. However, in this series, 32 of the patients required no transfusion of blood and 40 others received only one unit each, suggesting that transfusion was superfluous in those instances. Eleven patients required 5 or more units of blood; 10 of these patients had either severe abruptio placentae or placenta previa. All 11 were complicated by coagulopathy. One patient received 21 units of blood replacement. She was a 29-year-old woman, gravida 7, at 36 weeks' gestation, who had sustained extensive blunt trauma to the abdomen involving a laceration of the liver which required ligation of the right and medial segmental hepatic arteries.

Cesarean section was done because of evidence of fetal distress, and post-section hemorrhage secondary to coagulopathy made hysterectomy mandatory. The patient ultimately recovered.

Ancillary operations at the time of cesarean hysterectomy in the series reported included 19 incidental appendectomies, 15 salpingo-oophorectomies, and 10 repairs of iatrogenic cystotomy incisions.

Complications and morbidity encountered in this series of patients undergoing cesarean hysterectomy are summarized in Table III. In consonance with most published reports was the occurrence of 10 instances of bladder injury, which thus constituted the most common operative complication. Postoperative cuff cellulitis or abscess, observed in 11 patients, was the most frequent cause of febrile morbidity. Four patients developed broad-ligament hematomas; two of these required unilateral salpingo-oophorectomy and one hypogastric artery ligation.

Postoperative febrile morbidity occurred in 51 patients. There were 15 patients with postoperative anemia unassociated with febrile episodes. Two patients suffered pulmonary emboli, one of which accounted for the only maternal death.

The average hospital stay per patient was 9 days, or about 2 days longer than that of most patients undergoing abdominal hysterectomy and 4 days longer than the average for cesarean section. The longest stay was 21 days and the shortest was 4 days.

With regard to fetal outcome, 13 of the 149 infants were stillborn (8.8%); the other 136 infants were healthy and survived. Clinical circumstances associated with the 13 stillbirths included three instances of amnionitis, three ruptured uteri, and three cases of abruptio placentae. There were two unexplained deaths in utero, one secondary to an umbilical cord wrapped four times around the neck and one death in an anencephalic infant.

Follow-up studies on the 149 patients treated by cesarean hysterectomy showed that 36 of the patients were lost to follow-up. Seventy-six patients were known to have been living and well for up to 1 year following operation. Fifteen patients were alive more than 1 year later, with unrelated illnesses. Two of the latter had hypertensive cardiovascular disease. One patient who had a diagnosed ureterovaginal fistula refused reparative operation. Another patient who developed a rectovaginal fistula had a successful repair 2 years later.

In reviewing the data from this series, it is noteworthy that during the period 1962 to 1970 there was a striking increase in the number of cesarean hysterectomies performed at Louisville General Hospital as compared with previous years, whereas in subsequent

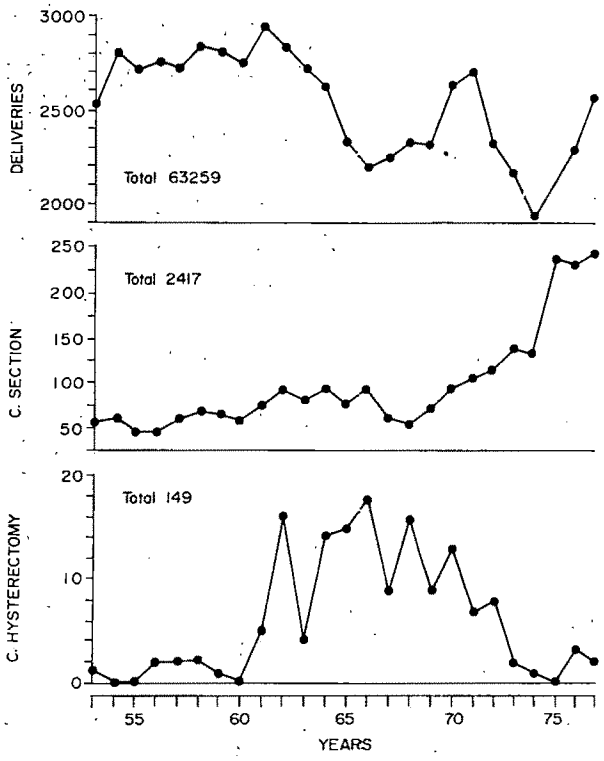

Fig. 1. Cesarean hysterectomies at Louisville General Hospital, 1953 to 1977.

years the operation was performed with greatly diminished frequency. Fig. 1 illustrates the distribution of cesarean hysterectomies during the years in question. The trends illustrated resulted from the adoption in 1962 of a liberalized attitude toward elective as opposed to emergency indications for the procedure, reflecting the nationwide interest in re-evaluating this point at that time. It was thought that it might be worthwhile to document the results that could be obtained in a single institution in which most of the operations would be performed by residents in training under appropriate staff supervision to test the point, so frequently made in the pertinent literature, that a key feature of satisfactory outcome in elective cesarean hysterectomy is the experience of the operator. It should, of course, be understood that resident education per se was in no way the underlying motivation for liberalizing the indications for the operation.

The dramatic decrease in the number of cesarean hysterectomies since 1970 reflects changes in departmental policy resulting in part from accumulated experience and in part from changing philosophy with regard to the elective performance of the operation.

From operative experiences and postoperative sequelae a few general conclusions seem warranted regarding the liberal use of "elective" cesarean hysterec-

tomy. The operation is greatly complicated by the presence of a complete placenta previa. There should be in each case an acceptable obstetric indication for abdominal delivery. Blood loss is not invariably excessive, nor is operating time necessarily greatly prolonged in the average case. Occasionally it may be justifiable to perform the subtotal rather than the total operation, but this modification is probably more appropriate in complicated emergency situations than it would be in less urgent circumstances. Operative and postoperative morbidity is a significant consideration.

In conclusion, while cesarean hysterectomy should remain in the obstetrician's repertoire for use in appropriate situations, our experience suggests that it may be relatively inadvisable to employ this procedure for strictly elective indications.

Discussion

DR. CLARENCE F. WEBB, Grand Rapids, Michigan. Many years ago, Dr. Ralph Reis discussed the problem of comparing elective and indicated cases of cesarean hysterectomies as similar to that of comparing apples and oranges. Unfortunately, this problem exists in most of the papers that are presented on cesarean hysterectomy, as it is hard to assemble a series large enough to become significant for either group.

Dr. Haynes is correct in saying that they have deemphasized the procedure at a time when cesarean section is increasing. They have tripled their cesarean section rate. It might be assumed that the number of cesarean hysterectomies would increase; however, they performed only 10 in the last 5 years. It is assumed that, in a teaching service with this low volume, there would be no residents being trained in more than a casual familiarity with the procedure. I wonder if this indicates a trend that, in the future, will be comparable to some residents' training in delivering a primigravida with breech presentation.

The authors quote Prystowsky and Eastman as saying that the hazards of sterilization procedure were less than those imposed by pregnancy. Actually, those authors concluded that grand multiparity did not constitute a true medical indication for sterilization. The Johns Hopkins University had previously published a report advocating tubal ligation for grand multiparity. However, the paper quoted had been written to refute this earlier report because of the high failure rate and the ectopic pregnancies that occurred after a tubal li-

gation. This made it a rather unprecedented article, reversing an earlier position.

I still feel that there are valid reasons to do an elective cesarean hysterectomy in preference to a tubal ligation at the time of a repeat cesarean section.[1] The ideal patient is not obese and has a hemoglobin of 12 gm or more. The main advantages to the patient are that she is assured of sterilization and further uterine disease is markedly decreased. Therefore, any risk of future surgical procedures is decreased in the patient. Each patient, however, has to be individually considered before a choice of procedure is made. In private practice, the patients that have cesarean hysterectomy are well satisfied with the end results.

The procedure should be comparable to an abdominal hysterectomy in ideal circumstances. It is the combination of the cesarean section alone, such as bladder injury, plus the obstetric complications, that tends to make the obstetric operator become concerned about performing a cesarean hysterectomy. Barclay's large series has indicated that in an institution similar to Louisville, where primarily residents are doing the surgery, it is possible for residents to gain adequate experience, so that morbidity rates can be reduced and transfusions decreased to acceptable minimums. Then, faced with an obstetric emergency, a resident can safely accomplish a cesarean hysterectomy.

It is noted that four of the patients in Dr. Haynes' series had a subtotal hysterectomy. This is one situation in which residents in training might do well to do a few subtotal hysterectomies to familiarize themselves with the technique as a teaching mechanism. However, the patient must be continually followed and the cervix observed. Follow-up may be a problem in some cases.

1. Webb, C. F., and Gibbs, J. V.: Cesarean Hysterectomy, Gynecology and Obstetrics, Hagerstown, Md., 1978, Harper & Row, vol. 2, chap. 85.

DR. SAM P. PATTERSON, Memphis, Tennessee. Cesarean hysterectomy was once my favorite operation, when I was a resident and subsequently on the full-time faculty. I also had the privilege of presenting a paper on the subject to this association in 1969. At that time, I reviewed 327 cesarean hysterectomies performed over a 14 year period at the University of Tennessee in Memphis. Its popularity has waned there also, not only because of its morbidity rate but also probably because elective sterilization is now so frequently performed for young women. Most authors have agreed that its associated morbidity rate is a deterrent to elective cesarean hysterectomy. The complications reported by Dr. Haynes are similar to those of others. He reports, however, a rather high incidence of iatrogenic cystotomy, 10 in 149 cesarean hysterectomies, whereas we had only three in 327 cases, nearly all of which also were performed by residents. Dr. Haynes' classification of repair of iatrogenic cystotomy as an ancillary operation such as appendectomy is a new designation. He may also have a "first" with the reported rectovaginal fistula. I should like to ask how this occurred.

Dr. Haynes mentioned four subtotal hysterectomies. Since nearly all bladder injuries occur in patients who have had previous cesarean section, I continue to suggest that subtotal hysterectomy is frequently better than total hysterectomy if there is the slightest difficulty in advancing the bladder. Adherence of the bladder to the cervix after previous low cervical cesarean section allows easy perforation. I should like to ask Dr. Haynes if any of his subtotal operations were done because of previous cesarean section. I also suggest that varicosities beneath the bladder are a contraindication to total cesarean hysterectomy. The bladder must be advanced with extreme gentleness, and for this operation I suggest using a moist gloved finger rather than scissors that cut vessels or rough sponges that tear veins. In addition, this operation should be performed only by obstetricians with surgical assistants who are all clearly aware of the tremendous vascularity of the puerperal pelvis.

Dr. Haynes has reported four broad ligament hematomas, emphasizing the frequency of this complication. Venous plexi in the pelvis are extremely large and easily torn in the multipara at term. The broad ligament must be handled very gently.

Dr. Webb has lauded the simplicity of cesarean hysterectomy and its paucity of complications, saying that cesarean hysterectomy is preferable to cesarean section and tubal ligation. I wonder what his thoughts are about the morbidity in this series, especially the two fistulas. I hasten to say that both his and my series included one urinary tract fistula each. The mortality rate reported by most authors emphasizes that there must be an obstetric indication for cesarean section before cesarean hysterectomy is contemplated, unless it is done for preinvasive cancer of the cervix. If cesarean hysterectomy is decided, then total or subtotal must be considered, since nearly all urinary tract injuries occur with total hysterectomy. There should be no embarrassment for subtotal cesarean hysterectomy, the opinion of Blue Cross notwithstanding. The risk of total cesarean hysterectomy may not always be justified. Lastly, I would comment that a comparison of morbidity might be more appropriately made with cesarean section rather than simple total abdominal hysterectomy.

DR. THOMAS W. MCELIN, Evanston, Illinois. To debate with a classicist such as Douglas Haynes is indeed treading in very deep water. However, I think it is time that the name of Dr. Porro in primary association with this operation should be put aside.

Irving,[1] in his charming book entitled *Safe Deliverance,* makes it very clear that the operation was first performed by Horatio R. Storer of Boston approxi-

mately 8 years (1868) before Dr. Porro. Perhaps, because the name of Dr. Eduardo Porro of Milan has been so long associated with cesarean hysterectomy, the eponym of the Storer-Porro operation might be substituted for the Porro eponym.

REFERENCE

1. Irving, F. C.: Safe Deliverance, Boston, 1942, Houghton Mifflin Company.

DR. BROOKS RANNEY, Yankton, South Dakota. The point has been made several times that there is an increased morbidity rate in association with cesarean hysterectomy. However, we have observed factors relating to a cesarean hysterectomy that also decrease the morbidity rate. These result from the removal of the uterus and the placental site.

Removal of a grossly infected uterus, a severely hemorrhaging uterus, or one containing large, degenerating myomas will be of immediate benefit to the patient. Postoperative ileus is less following cesarean hysterectomy than it is after cesarean section. A patient with pregnancy toxemia recuperates more rapidly after removal of the uterus. Cesarean hysterectomy eliminates the phenomenon of involution of the decidua and myometrium, which would otherwise cause fever and an abnormally elevated blood urea nitrogen by the third and fourth postpartum days.

In our hands most patients feel better and heal better, sooner, following cesarean hysterectomy, than they would following cesarean section, despite the unusual obstetric complications which produced the rare indications for cesarean hysterectomy.

DR. JOSEPH A. LUCCI, JR., Houston, Texas. Reference has been made to the technical difficulties which cause the blood loss and broad ligament hematomas.

I think one factor which predisposes to blood loss in a patient who has been in labor is the difficulty of identifying where the cervix ends and the vagina begins. Such patients can present a difficult technical surgical problem which may predispose to additional bleeding or hematoma formation.

DR. HAYNES (Closing). Dr. Webb, the reason for the policy change that resulted in a great diminution of the number of cesarean hysterectomies in our series was not only a change in policy but also a change in department chairmen, and a consequent change in philosophy which was reflected in other institutions as well.

During the years that we did this operation more or less electively I had hoped to continue the trend of liberalized indications as long as it seemed to be feasible from the point of view of safety of the patients. Indeed, during those years, I think we did have as a serendipity an excellent training program for residents to learn the procedure. The diminishing incidence of cesarean hysterectomies was not confined to our institution, but reflected a national trend that still continues.

Dr. Patterson questioned the classification of iatrogenic cystotomy as an ancillary operation. This is merely a matter of semantics. We expected a certain amount of bladder injury because of the nature of the procedure. I will note that there were no serious sequelae of the iatrogenic cystotomies in our series. Our one ureterovaginal fistula was not associated with recognized bladder injury.

Dr. Patterson asked how we happened to get a rectovaginal fistula. This was a surprise to us also. In that particular patient we were not conscious of having encountered any problems around the rectum, but the patient did end up with a rectovaginal fistula which we had to repair.

As far as the subtotal operations are concerned, I agree that there should be no absolute rule that a subtotal operation is never to be performed under any circumstances. Two of our subtotal operations were done in emergency situations in which a great deal of hemorrhage and a great deal of trauma were present, and we wanted to get the operation done as quickly as possible. Two of them had extensive adhesions and scar tissue formation because of previous cesarean sections, and it was thought at the time by the staff member in attendance at the operation that it would probably be safer in that situation to do a subtotal operation.

Dr. McElin rightly puts me in my place about Eduardo Porro. However, Prof. Porro's classic description of the *taglio cesareo demolitore* was the one that popularized the procedure in the world literature. I did not mean to imply that Porro was necessarily the first to perform it, but he appears to have been the first to publicize it so that it became a well-known procedure.

I appreciated Dr. Ranney's remarks, and also those of Dr. Lucci, who suggested that perhaps complications are more likely if this operation is done prior to the formation of a well-defined, thinned-out lower uterine segment. This has been our experience also. On the other hand, I feel that sometimes it would not be particularly desirable, particularly in cases of previous cesarean section, to await thinning of the lower uterine segment in view of the risk of uterine rupture.

A controlled trial of the differential effects of intrapartum fetal monitoring

ALBERT D. HAVERKAMP, M.D., F.A.C.O.G.

HORACE E. THOMPSON, M.D., F.A.C.O.G.
Denver, Colorado

A controlled prospective study of the differential effects of intrapartum fetal monitoring on mothers and infants has been conducted at Denver General Hospital, Denver, Colorado. A total of 690 high-risk obstetric patients in labor were randomly assigned to one of three monitoring groups—auscultation, electronic fetal monitoring alone, or electronic monitoring with the option to scalp sample. There were no differences in immediate infant outcomes in any measured category (Apgar scores, cord blood gases, neonatal death, neonatal morbidity, nursery course) among the three groups. There were no differences in rates of infant or maternal infections. The cesarean section rate was markedly increased in the electronically monitored groups, especially in the electronically monitored alone (18%) as compared with the auscultated (6%) ($P < 0.005$). In this controlled trial electronic monitoring did not improve neonatal outcomes and the mothers were at increased risk of cesarean section. (AM. J. OBSTET. GYNECOL. 134:399, 1979.)

DURING THE PAST DECADE, intrapartum electronic fetal monitoring has become increasingly widespread in clinical obstetrics[1–5] and is thought to improve perinatal outcome, especially among high-risk obstetric patients.[6–13] This paper reports an effort to assess clinical effectiveness of three methods of clinical intrapartum fetal monitoring presently used in this country: auscultation, electronic fetal heart rate monitoring, and electronic fetal heart rate monitoring combined with fetal scalp sampling. A randomized prospective clinical trial was used to evaluate these techniques.

Reprint requests: Dr. Albert D. Haverkamp, Department of Obstetrics and Gynecology, Denver General Hospital, Denver, Colorado 80204.

A previous study, from 1973 to 1975, at Denver General Hospital in Denver, Colorado, examined the effects of electronic fetal heart rate monitoring and careful auscultation on a group of 483 high-risk patients.[14] There were no significant differences in infant outcomes between the monitored and auscultated groups. The results of this study were contrary to our expectations. A new study was begun in July, 1975, with a similar study design which included additional measures of infant status at birth and at 9 months of age.

Study design

The specific objectives of the new study were to assess, by means of a randomized controlled trial, the differential effects of continuous electronic monitoring and fetal pH scalp sampling on high-risk mothers and their offspring, as compared with outcomes among auscultated mothers. The basic question asked by this research is whether or not electronic monitoring significantly improves a variety of outcomes for mothers and infants.

Method

The obstetric part of the study ran from July, 1975, to July, 1977, and consisted of a group of 690 high-risk mothers in labor. There were five sets of twins so the total number of infants was 695.

Mothers were admitted to the study either on the basis of their over-all risk status and/or if they developed certain labor abnormalities that most authorities consider high risk per se. Assignment of risk was based on a system developed by Goodwin, Dunne, and Thomas.[15] Two points could be subtracted in any of five categories: past medical history, past obstetric history, current prenatal course, present labor evaluation, and estimated gestational age. A low-risk patient would have no points subtracted and thus have a score of 10. Patients with scores of 6 or less were considered high risk. Women were also admitted to the study if they had meconium-stained amniotic fluid, abnormal fetal heart tones by auscultation, an arrested labor, or significant pre-eclampsia, or if they required oxytocin. Because of the difficulties in evaluating neonatal outcomes between markedly premature and term infants, mothers whose fetuses were estimated to be less than 34 weeks' gestational age or less than 2,000 grams were not admitted to the study.

When a mother was determined to be high risk she was, with her consent, randomly assigned to one of three fetal monitoring groups: auscultation alone (Aus), electronic monitoring alone (EM), or electronic monitoring with option to obtain fetal scalp pH (EM + SS). All the patients were allotted a sealed envelope to remove any antenatal bias. This envelope contained a slip of paper marked A for auscultation, B for electronic monitoring alone, and C for electronic monitoring with option to scalp sample. The EM groups had internal monitoring (Hewlett Packard Cardiotocograph)—(scalp electrode and pressure catheter) applied as soon as this was feasible during labor. Until such time, the patients were followed by external monitoring with an ultrasonic transducer and a tocodynamometer.

All mothers were attended by individual study nurses who insured that the quality of care and the time spent with the patient were the same in each study group. The study nurses notified the labor area doctor and the staff doctor as to abnormalities of fetal heart rate for both auscultated and electronically monitored patients. Final decisions regarding cesarean sections were made by the staff physicians.

The Aus group of patients had fetal heart tones auscultated and recorded 30 seconds after a contraction at least every 15 minutes in the first stage of labor and every 5 minutes in the second stage. Fetal distress (or ominous fetal heart rates) was defined in this auscultated group as fetal heart tones of less than 100 bpm after three or more consecutive contractions despite such corrective measures as changes in position, oxygen administration, correction of hypotension, etc. Such patients were delivered as quickly as possible. "Nonreassuring" fetal heart rates included fetal tachycardia, bradycardia between 100 and 120 bpm, and irregular heart rate.

In the Em group, fetal distress ("ominous" patterns) was defined as late decelerations, severe variable decelerations, tachycardia with total loss of short-term variability, or marked bradycardia that was not relieved by corrective measures within 15 to 30 minutes. Such patients were delivered immediately. Fetal heart rate patterns that were "nonreassuring" but not "ominous," as the preceding, included tachycardia with good variability, moderate bradycardia, diminished and absent short-term variability with a normal baseline, moderate variable decelerations, variable decelerations with late return to baseline, or patterns that were difficult to interpret. Patients with nonreassuring tracings were allowed to continue labor unless there were other clinical indications for its termination. The criteria developed by Kubli and associates[16] were employed to evaluate the decelerations. All tracings were reviewed at the con-

clusion of the study by an outside independent reviewer.

The infants of mothers in the EM + SS group were scalp sampled after 3 to 4 cm cervical dilatation had been reached when patterns were ominous or nonreassuring. A maternal venous sample was also obtained. A pH value of 7.20 to 7.25 was considered problematic and that of less than 7.20 was considered to be a sign of acidosis and an indication for immediate action if this value was at least 0.15 units less than that of the mother. Determinations were repeated every 20 minutes if the fetal heart rate pattern continued to be ominous or nonreassuring.

Infant outcomes were measured by Apgar scores at 1 and 5 minutes, cord blood gases at birth, Brazelton neonatal assessment at 2 to 3 days, neonatal death, neonatal morbidity (incidence of seizures, etc.), comprehensive pediatric physical examination at 9 months, and infant neurologic development as measured by the Bayley and Milani-Comparetti tests at 9 months of age. The last two, as mentioned, are not yet complete and, together with the Brazelton assessments, will be the subject of another report.

Results

Analysis of data. The data were computerized and analyzed by the Biometrics Department of the University of Colorado Medical Center. Chi-square analyses and analysis of variance were used where appropriate. The p values presented in the accompanying tables were determined by chi-square discrete (count) data and one-way analysis of variance for continuous (mean and S.E.M.) data.

Mothers' sociodemographic characteristics. The study population might be characterized as being at higher socioeconomic risk than one would find in most communities, but it is typical of that cared for by many city-county hospitals. Almost all mothers came from households where the heads were semi- or unskilled laborers. More than one third were single. Many were from minority backgrounds, with close to half of the total being Spanish-American. Relevant to this investigation, there were no significant differences among the three study groups with respect to maternal age, race, marital status, educational level achieved, or occupation of head of household (Tables I to V).

Risk status of mothers. The risk system used to admit mothers to the study guaranteed the appropriateness of their entry, but not that the major categories of risk would have similar distributions within the three study groups. With respect to over-all risk criteria upon entrance to the study (Table VI), somewhat over half of all patients were admitted to the study because of a score of 6 or less, 37% because of disturbing events

Table VI. Reasons for entry into study

*LGA = Large for gestational age; AGA = appropriate for gestational age; SGA = small for gestational age. p = 0.5 (NS) This value refers to the major categories: preterm, term, and postterm.

during labor, and the remaining 11% because they had both a score of 6 or less as well as high-risk factors uncovered during labor. There was no significant difference in the distribution of these among the three groups.

A summary of a number of maternal and infant characteristics, which are known to be important clinical determinants of infant outcome, is presented in Table VII. There were no significant differences among the three study groups in the means of maternal age, parity, over-all risk score on admission to the study, weeks' gestation, or birth weight.

Gestational ages of the infants at birth and whether they were average, small, or large for gestational age are shown in Table VIII. Most were average for gestational age. These did not differ significantly among the three groups.

As mentioned, certain abnormal developments encountered during labor were tabulated (Table IX). Pre-eclampsia was further subdivided into mild and severe cases according to the method of Pritchard and MacDonald.[23] The distribution of arrested labors requiring oxytocin, presence of meconium, presence of pre-eclampsia, and the development of amnionitis among the study groups was not significantly different.

Outcomes. Fetal heart rate patterns and their distributions are displayed in Tables XA, XB, and XC. Because of the capacity of the electronic monitor to identify certain patterns (i.e., variability, late decelerations) with far greater accuracy than is possible by ausculta-

tion, "reassuring" patterns are reported more frequently in the auscultated group. The distribution of various electronically monitored patterns is presented in Table XI. Independent obstetric review of these patterns was in agreement 90% of the time. In the electronic monitoring plus scalp sample group, scalp pH sampling was done on 44 patients.

Routes of delivery are presented in Table XII and modes of delivery in Table XIII. Here, monitored alone patients had a significantly higher cesarean section rate than did auscultated patients (18% vs. 6%). This applied to both the number of cesarean sections done for fetal distress as well as to sections done for other reasons, of which cephalopelvic disproportion or failure to progress were the most common indications. This incidence was lower in those mothers in whom scalp sampling was optional but the difference is not significant. There was also no significant difference in the total number of cesarean sections among electronically monitored patients with option to scalp sample and among auscultated patients. The use of general anesthesia was also higher in both of the monitored groups (Table XIV). This reflected the higher incidence of cesarean section in these patients.

Tables XVA and XVB present two types of data: the administration of antibiotics and the presence or absence of infection. The latter data are more appropriately regarded as outcomes in that they reflect maternal morbidity following delivery. Table XVA presents the rates of postpartum infections in vaginal deliveries. There were no differences in postpartum infections among the three groups. Table XVB gives the rates of infection among the three groups when cesarean sections were done. There were no differences. At Denver General Hospital, prophylactic antibiotics are routinely given to patients in labor undergoing cesarean sections.

There were excellent perinatal outcomes in all groups, with no intrapartum deaths and three neonatal deaths, none of which was related to monitoring techniques. Of these three neonatal deaths, two were in the EM group and one was in the EM + SS group. In the EM group, one infant died at birth from a massive intracranial hemorrhage which was found at autopsy to have occurred prior to the onset of fetal monitoring. The second infant died 30 hours after repair of a diaphragmatic hernia. The infant in the EM + SS group had an uneventful nursery course, was discharged from the hospital at 3 days of age, and died at age 3 weeks from overwhelming sepsis. The perinatal mortality rate was 4.3 per thousand.

Table XA. Fetal heart rate patterns during early first stage of labor

	Aus (N = 160)	*EM (N = 157)*	*EM + SS (N = 140)*
Reassuring	152 (95%)	134 (85%)	109 (78%)
Nonreassuring	8 (5%)	8 (5%)	18 (13%)
Ominous	0	15 (10%)	13 (9%)
	100%	100%	100%

$p < 0.005$ (sig). Early first stage of labor ≤5 cm.

Table XB. Fetal heart rate patterns during late first stage of labor

	Aus (N = 221)	*EM (N = 226)*	*EM + SS (N = 219)*
Reassuring	204 (92%)	183 (81%)	172 (78%)

	100%	99%	99%

$p < 0.005$ (sig). Second stage = complete dilation to delivery.

The condition of the infants following delivery was appraised at 1 and 5 minutes by means of the Apgar method. Mean scores are presented in Table XVI, showing no differences, nor were there significant differences in the distribution of scores (Table XVII).

The biochemical status of the infants at birth was assessed. Venous and arterial cord blood pH values were analyzed since they are indicators of intrauterine hypoxia and fetal acidosis. There were no differences in the mean pH and blood gas values in the three groups (Table XVIII) except for the venous Pco_2. A venous pH of 7.25 or less and an arterial pH of ≤7.20 or less were considered to be problematic. There were

no differences in the distribution of these low scores (Table XIX).

Neonatal morbidity was recorded along with various clinical judgments as to the need for more than ordinary care. The data are displayed in Table XX. There were very few serious problems and the number of infants who were affected is smaller than the number of reported events since sometimes sick infants had more than one illness. There were no significant differences among the three study groups with respect to neonatal morbidity.

Comment

Two primary conclusions emerge from this investigation on the differential effects of fetal monitoring: (1) electronic fetal monitoring with or without scalp sampling did not improve perinatal outcomes over that achieved by auscultation alone; (2) the cesarean section rate was much higher among electronically monitored patients.

While confident these conclusions are justified by our study results, we do not wish to imply that they are to be generalized to other populations in other institutional settings. For example, very premature or low-birth-weight infants (less than 2,000 grams or less than 34 weeks' gestation) were excluded from this study. The neurologic status of these infants could not be assessed by the Brazelton test. Gross prematurity is, at present, the overwhelming risk factor associated with neonatal death and morbidity. Retrospective studies have repeatedly indicated statistically significant improvements in the outcomes among less than 1,500 grams premature infants.[9, 10, 17] However, as yet no prospective controlled studies have been done in these weight and gestational age ranges.

There are many studies that strongly suggest the efficacy of electronic fetal monitoring in improving perinatal outcomes. Most of the past studies of fetal monitoring have been retrospective or, when prospective, have not included comparable control groups.[6, 8–10] In the controlled clinical trials reported to date, three have studied high-risk patients—Haverkamp[14] and Renou[7] and their co-workers and the present report—and one—Kelso and associates[24]—studied low-risk patients. The two Denver studies, which excluded grossly premature infants, showed no differ-

Table XIII. Modes of delivery

Prophylactic antibiotics, infection	1 (0.5%)	2 (1%)	2 (2%)
Treated documented infection	6 (3%)	8 (4%)	5 (2%)

ences in perinatal outcomes. Renou's controlled study did show differences in perinatal outcomes, especially improved neurologic status in the electronically monitored infants, but the range of gestational ages is unclear. The controlled trial by Kelso and associates[24] of low-risk obstetric patients showed no difference in perinatal outcome in 504 patients between auscultation and monitoring.

We are impressed that good prenatal care combined with good clinical intrapartum obstetric care, regardless of exact fetal monitoring techniques, results in excellent perinatal outcomes. Although we studied the patients with the highest risk status in a hospital with a high-risk population, the fact that the grossly premature infants were excluded reduces the morbidity and mortality rates to very low levels. Indeed, Neutra and associates[25] noted in their recent paper, remarking on neonatal death of term-size infants: "one of the striking findings of this study is that the majority of babies have a risk of neonatal death at or below one per thousand."

Table XVB. Postpartum infections among mothers having cesarean sections

	Aus (*N = 13*)	*EM* (*N = 41*)	*EM + SS* (*N = 26*)
No antibiotics, no infection	0 (0%)	1 (2%)	3 (12%)
Prophylactic antibiotics, no infection	12 (92%)	35 (85%)	18 (69%)
Prophylactic antibiotics, infection	1 (8%)	5 (12%)	4 (15%)
Treated documented infection	0 (0%)	0 (0%)	1 (4%)

Combining the two controlled trials in Denver totals almost one thousand patients who were followed clinically in labor by either electronic monitoring (475) or auscultation (473). Perinatal outcomes were the same in all measured categories and included no intrapartum deaths. There were five neonatal deaths, one in the auscultated and four in the electronically monitored groups. To attempt to show a beneficial effect of moni-

Table XVI. Mean Apgar scores + SEM*

toring under the conditions of these two studies would epidemiologically require an enormous number of term high-risk patients, as the adverse events or end points being used seem to be very infrequent. Furthermore, since no differences in outcome were found in these studies among high-risk patients, it would seem very unlikely that a low-risk term patient experiencing a normal labor would benefit from monitoring if she is properly auscultated.

The method of delivery was affected by the manner of intrapartum monitoring. There were distinct differences in the rates of cesarean section, especially between the Aus (6%) and the EM groups (18%). This followed an increased diagnosis of both fetal distress and failure to progress (e.g., cephalopelvic disproportion) in the EM patients. Thus, it appears that the EM laboring patient is at greater risk for cesarean section. The option of scalp sampling with electronic monitoring also had a significantly higher cesarean section rate for fetal distress, when compared to auscultation (3% vs. 0.4%). There was a similar trend for other indications (8% vs. 5%) but this did not achieve statistical significance. Note that in all categories, the cesarean section rate for those monitored with scalp sampling was lower than for those with electronic monitoring alone. This apparent difference did not achieve statistical significance. However, other investigators have previously noted the high rate of false-positive diagnosis of fetal distress with ominous patterns. Only 20 to 40% of ominous patterns will be associated with fetal pH values that are considered acidotic. It is for this reason that Beard,[18] James,[19] Quilligan,[20] and others have argued for scalp sampling as an integral part of any program of electronic fetal monitoring. If one relies on the fetal monitor, fetal scalp sampling may be required in order to more carefully distinguish stress from distress.

Paradoxically, the perception of the need to intervene during labor and to deliver the fetus by cesarean section was reduced by having less information about the auscultated patients. The difference in the rate of cesarean section for both fetal distress and failure to progress (CPD) is statistically significant between the EM and the Aus patients. We are left with the impression that nurses auscultate with a different perspective since the advent of the electronic monitor, which has provided much more information about fetal heart rate patterns. This may explain the divergence of our findings from those of the study published by Benson and associates[21] in 1968, which noted a poor correlation between auscultation and fetal outcome.

A perplexing observation was the significant increase in cesarean sections performed for reasons other than fetal distress among electronically monitored patients as compared to auscultated ones. Most of these were done because of CPD or failure to progress in labor. Why this is so is unclear. However, in the two other controlled trials of electronic monitoring, investigations showed somewhat similar findings. Kelso and associates[24] found a significantly increased rate of cesarean section in the electronically monitored versus auscultated patients for reasons other than fetal distress in their low-risk patients. Renou and associates[7] noted that cesarean sections for reasons of CPD or failure to progress were more common among patients being followed by monitoring and scalp sampling than among auscultated patients, but the difference was not significant.

There have been concerns about maternal postpartum infections, infant infections, and sepsis related to direct fetal heart rate monitoring. Among the three groups of women delivered vaginally, there were no differences in the rate of postpartum infections, all being approximately 3%. Having an internal monitor prior to vaginal delivery did not increase postpartum infections. The infants showed no differences among the three groups in the rate of neonatal sepsis with the actual number, two (both viral), so low that sepsis in relatively term-size internally monitored patients does not appear to be a significant problem.

Because of the high rates of postpartum infection in laboring patients undergoing cesarean sections at Denver General Hospital, most of the patients were given prophylactic antibiotics. There were no differences be-

Required antibiotics	15	15	20	50

tween the postpartum infection rates with or without internal monitoring when prophylactic antibiotics were used.

A nurse was assigned to each mother in the study, whether electronically monitored or auscultated, in order to assure the quality and uniformity of patient care as well as the accuracy of data collection. This type of one-to-one nurse-to-patient ratio may be impractical and is impossible in many clinical situations. The effectiveness of less rigidly auscultating and recording FHT's is an unknown. However, the laboring patient needs more nursing care than can be provided by an electronic monitor. It must be realized that considerable time is spent by nurses in setting up machines, checking on monitors' functioning, and in their own inservice training for this task. The feeling that monitoring reduces the cost of nursing care has not been carefully studied from total cost, time, benefit, or training perspectives.

Fetal monitors are now receiving almost universal use in obstetric practice. When 68 hospitals were surveyed by the Senate Subcommittee on Health, which is studying obstetric practice, it was found that all the hospitals used monitors. Sixty-four percent used monitors on almost all labors.[22] This use creates a number of problems with respect to interactions between patient, physician, and institutions. For example, what does the doctor or hospital do if a patient refuses monitoring? What does the patient do if the doctor or hospital insists upon monitoring?

Clearly, more controlled, well-designed perinatal studies (including long-term follow-up) are needed to evaluate the proper clinical role of electronic fetal monitoring. It has never been more important to separate the needed technology from the extraneous technology. More information and more sophisticated techniques do not necessarily improve outcomes. The support of both the public and the medical community is needed for more randomized prospective controlled studies to provide evidence which will allow both the physician and the patient to make informed, reasoned decisions on the effectiveness of various medical interventions.

Discussion

DR. PRESTON V. DILTS, JR., Memphis, Tennessee. In their continued, difficult study, the authors have concluded: (1) electronic fetal monitoring and monitoring plus scalp pH sampling do not improve fetal outcome as compared to standard auscultation; (2) the cesarean section rate is several times higher in patients with electronic monitoring but not in patients with scalp sampling.

These conclusions are specifically limited to patients (1) at term, (2) with high-risk pregnancy, and (3) in a city-county hospital.

There are several problems. In their previous paper, Haverkamp and associates[1] found a difference in the incidence of abnormal heart rate tracings between the auscultated and monitored groups. Dr. Morton Stenchever discussed this, suggesting that the groups were not similar. There also was a higher cesarean section rate in the monitored group for reasons other than distress. No attempt is made to answer these questions now nor were they mentioned in the review of literature.

The authors ruptured membranes as early as possible in the monitored patients. This may increase the incidence of heart rate abnormalities and may influence the course of labor. Scalp pH definitely is lower with early rupture of the membranes.

The reasons for which patients were classed as high risk are not given. The number and degree of severity of the patients with diabetes, hypertension, and other illnesses must be presented and discussed.

Scalp sampling was done on 44 of the patients. No data or discussion are presented. In the tables presenting nonreassuring and ominous heart rate tracings, abnormalities increase as labor advances. The scalp sampling group had the highest rate of abnormality, with the monitored group second. However, the cesarean section rate is lower in the scalp sampling group. Is this because of scalp pH or some other reason?

The types of heart rate abnormality are presented in a very involved table. An outside observer agreed 90% of the time. A 10% change in the numbers in any group might distinctly bias the outcome.

There was a 5% cesarean section rate for CPD or failure to progress in the auscultated group without fetal distress. This rose to 11% in the monitored group and 8% with scalp sampling. The difference is difficult to explain. The increased incidence of fetal distress in the monitored group as opposed to the scalp sampling and auscultation groups is apparently because the monitor picks up variations in heart rate which may appear ominous and because scalp sampling reassures, avoiding cesarean section. However, data are not presented to support this position.

Finally, in the discussion, the authors add the numbers in this report with those in their previous paper. This is adding apples and oranges to pears and comparing them to grapefruit. I am sure the authors are aware of the vast differences in the two studies.

My conclusions, based on the data in the manuscript, are: (1) Scalp sampling reduces the incidence of cesarean section to that found with auscultation. It is implied that the level of confidence in that decision is greater with monitoring plus scalp sampling than with auscul-

tation alone. (2) There are no differences in immediate outcome between the scalp sampled and the auscultated groups or the monitored group. However, long-term results are needed and the paper is not complete until they are available. (3) There are many unanswered questions. Why is the cesarean section rate higher with monitoring and somewhat lower with scalp sampling for reasons other than fetal distress? Our impression is that CPD is diagnosed more often with monitoring because monitoring indicates that labor is "adequate." In the "old days" we waited at least 4 hours before deciding there was failure to progress. Second, does early rupture of the membranes lead to fetal distress and/or cephalopelvic disproportion? Caldeyro-Barcia and others[2] felt that membranes should not be ruptured unless there is need for a scalp electrode. If this is the case, why the improvement with scalp sampling? Finally, the conclusions apply only to high-risk patients at term in a city-county hospital.

The authors are again to be congratulated. They have begun the long process of trying to figure out what the value of monitoring is. However, their study has deficiences which must be answered.

Hellegers[3] has proposed that a study of cesarean section may be the correct approach. After all, cesarean section is the ultimate treatment of the abnormalities discovered by monitoring. He suggested alternate vaginal and abdominal delivery for high-risk patients with or without a trial of monitoring. The issue of prematurity also needs to be approached. Finally, given the level of nursing expertise and staffing patterns in most OB units, how does this transpose to the real world? Is not monitoring better and less expensive than sporadic auscultation?

I hope both the proponents and opponents will refrain from debating or presenting publicly until a scientifically sound study of enough patients can be conducted to provide valid conclusions. As an example, it was reported in the January 1, 1978, issue of *OB GYN News* that Dr. Haverkamp had presented some of these data before the American Public Health Association some time in 1977.

DR. ROBERT A. MUNSICK, Indianapolis, Indiana. In 1959 Walker[1] reported a prospective study from South Africa on operative versus conservative management of fetal distress. Among his most notable findings was the fact that operative intervention for fetal distress did not improve the perinatal mortality rate unless other obstetric complications such as disproportion were extant. In his editorial discussion of this study, Eastman[2] stated, ". . . the author reviews the widely divergent opinions of various authorities on the significance of the supposed signs of fetal distress; and, on the basis of this and other evidence, it is clear that we need much more information on this important question than we now possess. It seems probable that prolonged electronic monitoring of fetal heart rates, when correlated with meconium stained fluid, fetal outlook and other circumstances, may provide some portion at least of the detailed, precise information we should like to have. Several such studies are now under way and let us hope that they serve this end."

Just as it is a sad commentary on our specialty that it has taken nearly a score of years to produce four objective prospective studies to answer Eastman's suggestion, we can be proud of the fact that these studies have been done, that those from the Denver General Hospital have both been presented to this Association, and that each by Haverkamp and associates has been masterfully designed and is among the best clinical investigations performed in obstetrics.

From the data so far reported, it appears clear that EM does not improve fetal or neonatal survival or immediate performance. Long-range data are still wanting. In this study reported to us today by Dr. McFee, the group has objectively answered the critics of the first study. I have some questions to ask, mostly for clarification:

(1) In the first study, ultimate management decisions were made by three staff members with very similar approaches to obstetrics. Was this the case in the current study? (2) Previously, febrile morbidity was reported, not infections. Do these equate and what were the particular infections? (3) What were the types of abnormal labor in each of the three groups? (4) What were the indications for oxytocin in each of the three groups? (5) Among labors induced or stimulated with oxytocin, was EM of significant advantage to the fetuses? (6) What were the total hospital days and costs for the mothers and babies of each group? (7) Were gravidas with prior cesarean sections admitted to any groups and, if so, did their presence influence the rate of cesarean section? (8) What, exactly, were the indications other than fetal distress for the cesarean sections in each group? (9) From the last question, do the authors have a hypothesis to explain the high cesarean section rate with EM? (10) Will the authors now or in their subsequent papers better define "high-risk" status? The system of Goodwin, Dunne, and Thomas, to which they refer, does not include parturition and has a 0 for least, 10 for greatest risk score. In the current study, many patients were quite properly included

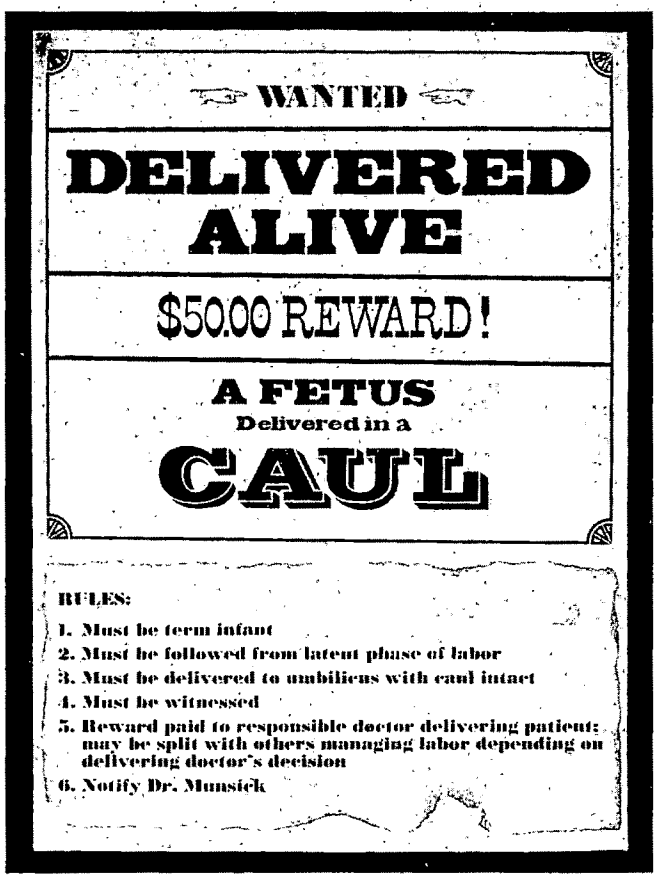

Fig. 1. "Wanted" notice posted in residents' lounge.

because of labor abnormalities, but these should be defined, and the scoring system goes 10 for least, 0 for greatest risk. (11) Finally, will Dr. McFee not attempt to make a recommendation concerning the use of EM? What system of monitoring is now being used at Denver General Hospital?

Unless EM is shown incontrovertibly to benefit the neonate, my experience with it leads me to recommend against its frequent use. It has had pervasive negative effects on obstetric practice and training. What effects are these?

External monitoring restrains patients in bed in early labor. It encourages assumption of the supine position. Competent abdominal examination is made impossible and few are those who will even temporarily remove the straps once they are applied. Nurses and physicians regularly misinterpret external tocographs as showing uterine tonus and contractile amplitude. They tend not to or cannot palpate uterine contractions with straps in place.

With internal EM, pelvic examinations are less than competently done for fear of dislodging electrodes or catheters. Adequate assessments of fetal position, presentation, and pelvic architecture are less often sought.

Early amniotomy becomes a routine reflex; how else can the scalp electrode be placed? For many patients, this practice then requires oxytocin for augmentation or even for induction of labor. Attempts by me through entreaty, counseling, and even cajolery failed to influence this practice. What finally worked for a while is shown in Fig. 1. Incredible as it may seem, four infants were delivered in caul within 10 days of posting this notice!

Perhaps worst of all, EM has dehumanized obstetrics. We cannot divert our eyes or ears from EM's alluring LED's, beeps, and stylus-chattering graphs. We no longer listen to, talk with, gaze upon, or touch our patient. We will deny her analgesia to protect the graph from a loss of variability.

Is there evidence of this growing dehumanization, evidence other than the public push for home deliveries? I would like you to entertain a hypothesis which will explain on the basis of dehumanization with EM the increased rates of both fetal distress and cesarean section. We begin by restraining a woman early in her labor. We allow her to see the EM's chattering stylus and its winks; often we even torture her unnecessarily with hours of its staccato sounds at 150 beeps per minute and we watch the monitor and not her. She dare not interrupt our silent vigil. Anxiety gives way

to fright and anger. Something—possibly catecholamines—causes her to have abnormal contractions and these in turn cause arrest of labor and sometimes diminished uteroplacental blood flow. The supine position aggravates the latter. And we then apply the modern-day obstetric panacea—cesarean section. If you doubt that internal fetal monitoring can influence labor, see Fig. 1 of the paper by Sokol, Zador, and Rosen.[3]

This explanation may be incorrect, but there can be no doubt that the cesarean section rate doubles in association with, if not because of, EM. If Neutra and associates (Ref. 25 of the paper under discussion) are correct in estimating that EM may save 1 in 1,500 or more infants, let's extrapolate these data in terms of what is seldom mentioned in this enormously important controversy—*maternal death.* The cesarean section mortality rate is at least 1 in 1,000 operations.[4] In 1975, there were 3,150,000 live U. S. births. If EM saves 1 in 1,500, it would have saved 2,000 babies in 1975 if applied to all laboring patients. Assuming an 8% over-all cesarean rate without EM, 240,000 cesarean deliveries would have occurred in 1975 with 240 maternal deaths. Doubling the cesarean rate with EM would then kill 480 women. For 2,000 babies saved we sacrificed 240 women—one woman for eight babies. Should not this information be provided to gravidas before obtaining their informed consent for EM? Indeed, should not informed consent be obtained before instituting EM?

This issue is so important that our Association and the A.C.O.G. through the N.I.H. should begin at once a massive, prospective, collaborative study to settle the question: For whom is EM beneficial? Only through such a large study can the question of whether or not to monitor premature fetuses be answered.

Dr. Stephen L. Bloom, Waterloo, Iowa. How soon after observing abnormalities with monitoring was action instituted to evaluate the abnormality?

In reviews of monitoring at some institutions there can be a lag time, depending on how busy the staff is between the time an abnormality is picked up and the time it is evaluated. If there is a lag time, then I think that knocks down the ultimate result and quality to the level of the unmonitored patients.

The next comment that I have is in relation to the last discussant. I do not feel that electronic fetal monitoring is a cause of physician insensitivity in dealing with patients, nor is electronic fetal monitoring a cause of inept pelvic examinations. I do not see any cause-and-effect relationship. I do not think monitoring has anything to do with treating patients impersonally and improperly.

Dr. Frank H. Boehm, Nashville, Tennessee. While we are going through the years of arguments and discussions on fetal monitoring, I hope that we do not lose sight of the fact that the monitor is an instrument that gives us information pertaining, in part, to fetal well being. Those who would not support its use, in my opinion, are arguing against quality information with a very low risk-benefit ratio.

We put a lot of emphasis on fetal heart rate, yet few individuals address themselves to the very important information that comes from the uterine activity line: the ability to make a more accurate diagnosis of CPD or to monitor patients who are being given oxytocin infusion to stimulate labor or drugs to stop labor are important parameters of fetal monitoring and clearly an aid to optimal care.

In most institutions where routine fetal monitoring has been instituted, the fetal death rate in labor has been reduced to close to zero. This is certainly a significant improvement from the two to four per thousand fetal deaths in labor that have occurred in other studies without fetal monitoring.

The Cesarean section rate, in my opinion, goes up because we have not educated our medical personnel on the proper interpretation of the data. Our cesarean section rate at Vanderbilt has been the same in the last 4 years despite the fact that we have monitored all of our patients on a continuous basis.

Patients who are monitored in our institution are given quality, considerate, and kind care by our nurses. The monitor does not nor should it ever replace that kind of care.

Despite this paper's results, I still believe that fetal monitoring is an extremely important device to reduce maternal and fetal death and morbidity.

Dr. Warren M. Crosby, Oklahoma City, Oklahoma. While this paper suggests that fetal monitoring does bad things and the absence of the fetal monitor does good things, I submit that Drs. McFee and Haverkamp really believe in fetal monitoring. Else why would they hire a nurse and plug her in to the patient to listen to the fetal heart rate every 5 minutes? You cannot do that on the usual hospital labor ward without hiring a special nurse and having a special setup for each individual patient; that can be accomplished only in a study like this. So the fetal monitor in this case is human rather than electronic.

Anyone who looks at hours of fetal monitor strips will see many horrible-looking fetal cardiac deceleration patterns, acceleration patterns, and occasionally lack of beat-to-beat variability. In many of these the

baby is well, but in a few the baby is sick. My point here is that the fetal monitor does not tell you when the fetus should be delivered abdominally, it merely is a screening device that tells the physician when the fetal cardiac response to labor is no longer proceeding normally. When this occurs, the physician should re-evaluate the situation to find out whether a maternal problem has developed. Then he must evaluate the degree of fetal compromise by scalp blood gas analysis if the alarming fetal distress pattern continues on the monitor. With fetal scalp blood pH it is possible to select the acidotic fetus from the one with an overreactive cardiovascular system. This then enables the obstetrician to perform cesarean section only on those fetuses that are in jeopardy of dying before labor could be expected to terminate naturally or by forceps delivery. This paper does not negate the usefulness of fetal monitoring, as the authors suggest. Their results indicate that if you monitor the fetus carefully enough—by nurse or by machine—and evaluate those fetuses in potential jeopardy, intrapartum death can be essentially eliminated. The key phrase here is "monitor the fetus carefully enough." In most hospitals that can be accomplished only by an electronic fetal monitor.

DR. G. ERIC KNOX, Minneapolis, Minnesota. I have a question regarding statistical analysis. Assuming that the issues raised by Dr. Dilts regarding the comparability in general, and of obstetric risk in particular, between the groups is satisfactorily addressed, this study may still not answer the question it was designed to. As Dr. Munsick pointed out, and as was pointed out in the recent publication from Boston, approximately 1,100 term babies need to be monitored to demonstrate an effect on the mortality rate. Therefore, even though the current study is impressive with regard to the number of patients that have already been enrolled, I am wondering from a statistical point of view whether the numbers needed to actually demonstrate an effect or lack of effect of monitoring on mortality can ever be achieved in any study, simply because they are so high.

DR. MCFEE (Closing). Why there was a higher cesarean section rate for reasons not due to fetal distress in the monitored groups over that auscultated I do not know. At least two other studies on fetal monitoring from other parts of the world have shown essentially the same thing. I think Dr. Munsick's hypothesis may very well play a role here. I am convinced that the presence of a monitor and the events which ensue do indeed frighten a considerable number of women, especially among the indigent and the uneducated. This may, in turn, contribute to uterine inertia and failure to progress normally in labor.

Dr. Dilts noted that we have left out many specific diagnoses in our list of reasons why patients were deemed high risk. We did not tabulate these as they include a multitude of conditions, most of which are so small in number that they probably would not make any difference anyhow. One thing to remember in doing a randomized study of this sort is that it is impossible to make the three groups totally equal in all respects and still remain randomized. We have shown things this morning which indicate that the three groups on retrospect were equal in many respects.

I agree that combining the results of our two studies is probably not a good comparison. However, when one get down to the basics, there was a considerable difference in the number of cesarean sections between monitored and auscultated patients.

As for Dr. Bloom's question about how soon after abnormal patterns was something done, I would say this was immediately because the nurses were with the patient on a one-to-one basis.

I agree with all the comments of Dr. Boehm regarding the many things about which the monitor can inform the physician.

With respect to Dr. Crosby's comments, I would like to correct one misinterpretation: Perinatal outcomes of auscultated mothers were not better than those of monitored patients; they were equal. I think this is important. I agree with him that it is virtually impossible in most institutions to obtain this kind of nursing care on a one-to-one basis throughout all labors. This brings up the necessity of investigating costs when we are considering both the use of fetal monitoring and the use of nurses for intrapartum surveillance.

Another important question is how many patients we really need to show a difference between monitoring, monitoring with scalp sampling, and auscultation. This is particularly relevant among low-risk patients.

To answer Dr. Munsick's question on my feelings about the use of monitoring, I believe electronic monitoring is an easy, useful tool for the observation of labor. This is especially true in conjunction with scalp sampling and also in our high-risk units, which have a heavy volume of patients and often a relative lack of physicians and nurses to care for them. However, the feeling currently being expressed in many quarters that *all* labors must be monitored or, to put it medicolegally, that it is malpractice *not* to monitor given labor, is simply not justified. That auscultation can do as good a job has important implications for the small rural hospital which may not have the monies to buy and maintain monitoring equipment or be able to give correct interpretation to the tracings. This may also have some importance for some of our larger hospitals which deal primarily with a low-risk, term pregnant population. In short, universal electronic fetal monitoring is currently being advocated before its usefulness in all labors for both the mother and fetus and cost-benefit relationships have been adequately assessed.

Lastly, I would like to re-emphasize one of Dr. Munsick's comments that in recent years we have perhaps overemphasized the well being of the fetus and have largely pushed the mother into the back of our minds. I think this needs to be corrected.

Perinatal deaths in twin pregnancy

A five-year analysis of statewide statistics in Missouri

ARNOLD L. MEDEARIS, M.D.
HARRY S. JONAS, M.D.
JOSEPH W. STOCKBAUER, M.A.
HERBERT R. DOMKE, M.D., PH.D.
Kansas City and Jefferson City, Missouri

Analysis of computer-stored State of Missouri birth and death records over a 5 year period revealed 3,594 twin pregnancies (1.02% of all pregnancies), which accounted for 10.1% of the perinatal deaths. The mean birth weight according to weeks of gestation was computed for the pregnancies with no complications noted prior to labor and the perinatal mortality rate was determined. Complications of pregnancy were evaluated. Low birth weight appears to be the major factor in the elevated perinatal death rate in twin pregnancy, with a significant elevation of the perinatal death rate noted with labor prior to 36 weeks, any episode of hemorrhage, or premature rupture of membranes. A more liberal use of cesarean section currently shows no effect in altering the perinatal mortality rate. Programs are suggested to increase early detection and appropriate consultation and referral of multiple pregnancies in a statewide comprehensive effort to decrease the perinatal mortality rate in twin pregnancy. (AM. J. OBSTET. GYNECOL. 134:413, 1979.)

LEGISLATION established in Missouri in 1974, a high-risk maternal and child care program under House Bill No. 1686. The program's intent was to ensure that pregnant women and infants at high risk for developing mental retardation would not be denied needed health care because of inadequate funds. Thus, the program was conceived as an attempt to prevent mental retardation. As part of this over-all plan, computerization of birth certificate data in Missouri and analysis of various conditions contributing to increased perinatal and neonatal risk were performed by the Missouri Division of Health to gain a better statistical understanding of the problem of health care delivery in Missouri.

Most computer research previously done has been on singleton pregnancies. Because of the difficulty of data management in multiple pregnancies, it was felt that this initial statistical analysis would aid in establishing computer analysis of other high-risk pregnancies. In addition, multiple pregnancy is one of the major areas of perinatal death within this state.

From the Department of Obstetrics and Gynecology, University of Missouri–Kansas City School of Medicine, and the Missouri Division of Health.

Presented at the Forty-sixth Annual Meeting of the Central Association of Obstetricians and Gynecologists, Kansas City, Missouri, October 13-15, 1978.

Method

Data for this study were acquired from the official vital statistics of Missouri. It is believed that over 99% of all births are recorded at the time of occurrence and more than 98% of recorded births in Missouri occur in hospitals. An extensive program of editing and querying data of birth and of fetal and infant death certificates has been in existence since 1974. In 1974 work was begun on matching birth with infant death certificates and now an ongoing file exists, starting with the 1972 calendar year.

In conjunction with this an ongoing file of births and fetal deaths exists, starting with the 1972 calendar year. The present study uses both the matched birth–infant death file and the birth–fetal death file to create a cohort file on twins. To select out and match twins, the following method was used. If the number born equalled two, the following items were matched by computer: last name of child and parents, date of birth,

and state and county of recording. For those records where the number born was unknown, or the column for the date of the previous live born or previous fetal death is blank or not of the same date of delivery, the born number is assigned as one. A manual check was performed to make sure that there was no evidence of their being twins.

The birth order was assigned on the basis of considering the twin with the lowest birth–fetal death certificate number as first born. Where a certificate noted that another twin was a fetal death but no certificate existed, matching certificates were made for the fetal deaths. Where a certificate noted that the other twin was a live birth but no certificate existed, dummy live birth certificates were made. The data for the dummy certificates were acquired by using variables obtained from the existing certificate.

The computer-stored data were then analyzed from January, 1972, through December, 1976, with regard to no complications noted before labor, weeks of gestation, total pregnancies, percent of pregnancies, percent of cesarean sections, percent of abnormal presentations (at least one twin breech or transverse), the mean birth weight and the percentage under 1,500 grams, between 1,500 and 2,500 grams, and greater than 2,500 grams, stillbirths, neonatal deaths, and the combined perinatal mortality rate were all evaluated. The data were then further analyzed with regard to complications noted before labor in a hierarchical form. These included abruptio placentae, placenta previa, other episodes of hemorrhage, diabetes mellitus, premature rupture of membranes, toxemia, major medical complications of pregnancy, miscellaneous complications of pregnancy, Rh incompatibility, obesity, abnormal pelvis–cephalopelvic disproportion–fetal distress (ACF), previous cesarean section, total complications category, total without complications prior to labor, and a page total. Risk ratio was calculated according to a formula of the percent of all perinatal deaths divided by the percent of all pregnancies.

Tests for the significance of difference between two rates were performed for comparison of the significant values utilized during the analysis of data. In an effort to evaluate the use of a hierarchical form of ranking complications, nonhierarchical analysis of complications noted before birth was performed and in all cases statistical analysis was not altered. There were also certain complications noted before labor in the groups of major medical and miscellaneous complications of pregnancy which, while having significant N values, contained such a wide diversity of factors that analysis was not performed in these categories; however, they were added into the total complications.

Results

Demographic data. During the 5 year period there were 3,594 pairs of twins born, a total incidence of 1.05% of the pregnancies in the state. These pregnancies accounted for 7.06% of all stillbirths, 13.03% of neonatal deaths, and 10.10% of all perinatal deaths during this period of time.

The mean birth weight was 2,349 grams, with a standard deviation of 677 grams, and 57.7% were less than 2,500 grams. Complications noted before labor were present in 21.2% of all twin pregnancies with premature rupture of membranes accounting for 5.0% and toxemia of pregnancy 4.9%, followed by previous cesarean section 2.1%, ACF 2.0%, and abruptio placentae 1.5%. The over-all stillborn rate was 40 per thousand, with a neonatal death rate of 76 per thousand and a perinatal death rate of 116 per thousand (Table I).

Birth weight, gestational age, with complications noted prior to labor. The analysis was performed in a hierarchical manner; abruptio placentae, placenta previa, other episodes of hemorrhage, diabetes, premature rupture of membranes, toxemia, Rh incom-

patibility, obesity, ACF, previous cesarean section, and complication total were recorded in Table II. These perinatal death rates were compared with the total values for the noncomplicated patient and statistically significant P levels of <0.001 were found for abruptio placentae, placenta previa, other hemorrhage, premature rupture of membranes, and total complications. Toxemia and ACF were not significant for perinatal death and the N was insufficient to evaluate on the other entities.

Neonatal death rate showed a significant level of $P < 0.001$ for three forms of hemorrhage, premature rupture of membranes, and total complications, with an insignificant level for toxemia; the remainder of the values were insufficient to evaluate.

Fetal death rate showed a significant level of $P < 0.001$ for abruptio placentae, other hemorrhage, premature rupture of membranes, and total complications. Toxemia was insignificant; the remainder of the values were insufficient to evaluate.

When the perinatal death rate was compared to birth weight with regard to complications or no complications (Table III), there was a statistically significant incidence of low-birth-weight infants (less than 1,500 grams) in association with abruptio placentae, placenta previa, other hemorrhage, premature rupture of membranes, and total complications (P level <0.001). There was no statistically significant incidence of low-birth-weight infants (<1,500 grams) in association with toxemia, ACF, and previous cesarean section. The majority of infants in the category of ACF demonstrated a statistically significant birth weight greater than 2,500 grams.

The highest number of perinatal mortality complications occurred in the miscellaneous complications of pregnancy and there was a significantly lower mean birth weight of 1,423 grams, with 72.2% under 1,500 grams and 18.8% between 1,500 and 2,500 grams, which is a statistically significant $P < 0.001$ for comparison with noncomplications, total, and low-birth weight infants.

Route of delivery. An analysis was performed to de-

Table IV. Twins: Significance of the difference between complications and no complications for cesarean section rates

	No. with cesarean section	*% with cesarean section*	*Significance level*
No complications	229	8.1

Other hemorrhage	4	21.0	
Diabetes	3	42.8	
PROM	56	31.1	0.001
Toxemia	69	38.5	0.001
Rh incompatible	1	5.2	
Obesity	1	20.0	
ACF	66	89.1	0.001
Previous cesarean	74	97.3	0.001
Complications—total	332	43.5	0.001

termine the significance of the difference between complications and no complications for rates of cesarean section and was found to be significant at the P of <0.001 for abruptio placentae, placenta previa, premature rupture of membranes, toxemia, ACF, previous cesarean section, and total complications. These results are tabulated in Table IV.

Breakdown of the percentage of live births in comparison to the percentage of twins delivered by cesarean section in Missouri shows a statistically significant increase (P level of <0.001) in the percentage of cesarean sections utilized in the delivery of singleton and twin pregnancies over the years 1972 to 1976. Results are given in Table V.

Abnormalities of presentation. Analysis of pregnancies where at least one of the fetuses was either breech or transverse showed 30.1% of the uncomplicated patients to have an abnormal presentation and 24.2% of the complicated patients to have abnormal presentation noted for a total of 28.8%.

Further analysis of perinatal death with regard to birth order and presentation is in progress.

Effect of race, gravidity, and educational level on perinatal death and perinatal risk. The perinatal death rate by race, year, and complication showed no statistically significant data between race and presence or absence of complications (Table VI).

Risk ratios were calculated for white and nonwhite patients based on gravidity and educational level. The results of this are shown in Table VII. While this table would appear to show increased risk in white patients with less education and low gravidity, the over-all comparison of singleton and twin perinatal mortality rates, 1972 to 1976 (Table VIII), has an equally poor prognosis in twin pregnancy in white and nonwhite patients.

Comment

Approximately 1% of the pregnancies in Missouri have a marked effect on the state perinatal mortality rate by accounting for 10.10% of all the perinatal deaths in the state. This relatively infrequent occurrence (twinning) shows no difference in perinatal mortality rate with regard to race and is of significant importance to require the physicians of the state to make a concerted effort to decrease the perinatal mortality rate associated with twins. Increased patient years of education as well as increases in gravidity have a favorable predictive value for the patient with twin pregnancy; however, these still do not exclude such patients from a significant perinatal risk.

The percentage of perinatal deaths for the whole state is similar to the percentages of perinatal deaths presented in a number of other previous articles on twin pregnancy in North America, which have ranged from 9.2 to 28.6%,[1–18] with the majority accounting for 10 to 15% of perinatal deaths. Despite this fact, the occurrence of twins does not appear to significantly alarm many physicians practicing obstetrics in Missouri. The incidence of referral to major obstetric and neonatal units is low.

Complications noted prior to labor increase the perinatal mortality rate. The specific reason appears to be related to the delivery of the low-birth-weight infant in patients with premature rupture of membranes and all episodes of hemorrhage. Premature labor still accounts for the major complications, with 21.4% of patients

Table VII. Risk ratio—perinatal

Total			9.51			12.1	9.90

being delivered at a gestational age of less than 36 weeks and below a mean weight of less than 2,101 grams. The delivery of the low-birth-weight infant has been felt to be the major cause of increased mortality rates in a number of other studies.[9, 12, 14–16, 18–28] The incidence of toxemia (4.9%) was less than expected in this study compared to reported ranges in several twin studies showing an incidence of 15 to 20%.[2, 5–7, 11, 13–17] It is also noted that there was no statistically significant increase in the perinatal mortality rate when toxemia was noted prior to labor. If patients who went into labor prior to 36 weeks had been excluded from the no complications analysis, however, toxemia would have shown a significant perinatal mortality rate. The perinatal birth weight for toxemia was higher than the birth weight for complications of hemorrhage, premature rupture of membranes, and premature labor, and probably accounts for the decrease in perinatal mortality rate. Those with previous cesarean section and ACF all had larger infants, with a subsequent decrease in the perinatal mortality rate.

The rising incidence of cesarean section for delivery does not appear to be decreasing the statewide perinatal mortality rate for twins. It cannot be concluded, however, that the increasing incidence of cesarean section is inappropriate. More data are needed to analyze the indications for cesarean section and the related outcome in twin pregnancy.

The major educational effort in Missouri should be directed toward the importance of twins as a major contributor to the state's perinatal mortality rate. Such education should serve to increase the early diagnosis of twin pregnancy and to facilitate consultation and referral.

Various figures have been reported in the literature with regard to the accuracy of detection of twins, varying from 50 to 95%, depending on the degree of clinical suspicion.[5–7, 22, 23, 26, 27, 30] Ultrasonic detection of early pregnancy is greater than 95% accurate[31, 32, 33] and in Sweden the use of human placental lactogen has also been reported as an effective screening method for detecting twin pregnancy.[34, 35]

The institution of a routine ultrasound screening program throughout the state available to all pregnant patients would be one of the initial steps in improving early detection. Also, aid in the evaluation of twin pregnancies at serial times for the early, attempted identification of conditions of increased risk such as mono- or diamniotic twins, abnormalities of cord insertion,[36] and dissimilar twin growth, which may lead to severe intrauterine growth retardation and preterm fetal death, is needed.[31, 37, 38] The use of serial antepartum fetal monitoring techniques should aid in the identification of these patients at increased risk for antepartum stillbirth and help clarify indications for earlier intervention.

Table VIII. Perinatal deaths/1,000 by race and number born—Missouri resident data, 1972 to 1976

	Singleton	*Twin*	*Total*
White	19.4	112.2	21.4
Black	34.4	136.9	37.3
Total	21.8	117.0	24.0

The effect of bedrest on gestational age and birth weight in multiple pregnancy has not been clearly established.[39] However, it is used by many obstetricians[4, 9, 10, 26, 27, 30] and it has been shown to increase uterine blood flow in the singleton pregnancy.[40] A recent report[33] showed a reduction in the rate of premature twin births from 48 to 27% under conditions of complete bedrest and tocolysis with a beta-mimetic if instituted between weeks 32 to 37 of pregnancy. In an effort to increase gestational age and birth weight, the state of Missouri should consider appropriate financial support to facilitate bedrest for these patients between 28 and 36 weeks, in either a home or hospital environment.

Because of intrapartum problems even in the uncomplicated cases of low-birth-weight infants, these pregnancies are best handled in select high-risk centers which have the capability of electronic fetal monitoring of both fetuses, rapid surgical intervention when indicated, and sufficient volume to be experienced in current methods of management. A perinatal review

committee should be established to evaluate perinatal death secondary to twins. The lack of referral of multiple gestations appears to be a frequent problem which contributes to the perinatal mortality rate within the state.

Conclusion

Twin gestation is a significant cause of perinatal death in Missouri. In these patients, the perinatal mortality rate is increased with the complications of premature labor, premature rupture of membranes, and episodes of hemorrhage. An educational program directed to the severity of this problem and the importance of early detection of twin pregnancy is much needed. Ultrasound detection programs and antepartum monitoring units, especially for twin pregnancy, are now being established in Missouri. Efforts to increase the birth weight and gestational age in all multiple pregnancies by establishing aid to mothers who have this diagnosis and setting up appropriate areas of delivery where physicians have sufficient experience and volume to adequately handle the obstetric and neonatal complications that occur in multiple pregnancy are indicated. A perinatal committee on twin pregnancies needs to be established to stimulate the development of referral patterns for the management of such patients.

The occurrence of multiple pregnancy has often been regarded as a rarity and a condition which physicians have often not viewed seriously. The information gained from this study on the high percentage of perinatal deaths generated from a relatively low number of twin births should call attention to the seriousness of this problem. Twin pregnancy demands a concentrated effort with new approaches in an attempt to lessen the potential fetal wastage from such a condition.

Discussion

DR. CHARLES E. GIBBS, San Antonio, Texas. An organized attack on perinatal death must begin with accurate information about those factors associated with death as well as specific causes of death in the population to be cared for. For example, multiple gestation is a factor associated with an increased perinatal mortality rate and the deaths are usually due to RDS, labor hypoxia, intrauterine fetal transfusion, etc. Dr. Medearis and his group have presented us with data regarding perinatal death associated in a general way with twinning. Naeye and associates[1] recently published some material regarding the probable causes of death in a large number of twins. Both approaches are useful.

The role that multiple gestation plays in perinatal death varies from population to population. The authors found that rates did not vary with race and this is somewhat surprising with the increased frequency of fraternal twinning in black women. This might be explained by the finding of Naeye and associates that monozygotic twins suffered a mortality rate 2.7 times that of the dizygotic infants. In our hospital, in a recent 5 year period, multiple gestation was associated with only 6% of the perinatal deaths, whereas Drs. Medearis and Jonas and their group reports a 10% figure. One possible reason for the difference might be that all of our liveborn infants were managed by neonatologists in a very good Level III nursery as contrasted to the Missouri experience, which includes all types of care. Dr. Naeye reported that Addis Ababa twins had 2.5 times the mortality rate of a study group in the United States. The causes of death were similar but more deaths from intrauterine infection and abruptio placentae were noted. It is my impression that in the United States RDS is the leading cause of death associated with multiple gestation. Dr. Jonas indicated that multiple gestation requires early diagnosis and good prenatal care followed by an experienced and sophisticated environment for delivery. We agree and believe that with such care a realistic goal for a perinatal mortality rate associated with multiple gestation is 50/1,000 births and that these deaths would make up less than 5% of the total perinatal deaths.

I was interested in the information that abruptio placentae was associated with 49 of the 835 deaths, an involvement rate of 0.6%. It was surprising that more of these deaths were neonatal (28) than were fetal (21). It is probably safe to say that RDS was the killer and that the foregoing premature birth was triggered by the abruptio placentae. If this is true, one could expect a reduction in perinatal loss associated with abruptio placentae through improved neonatal care, even before the cause and prevention of the condition are identified.

Finally, I would like to comment on data derived from birth certificates, fetal death certificates, and death certificates. One has only to consider how carelessly and quickly these documents are completed by many of us to begin to question their accuracy. In Texas (and, I think, elsewhere) it is very likely that much of the clinical information (cause of death, duration and complications of pregnancy, month beginning prenatal care, etc.) is inaccurate and therefore unreliable for any scientific purpose. On the other hand, the demographic information (place of residence, place of birth, birth order, sex and birth weight, education and occupation of parents) is usually correct and therefore useful. If regional planning by Health Systems Agencies continues these data will be very helpful for planning and evaluation.

DR. HOWARD G. MCQUARRIE, Salt Lake City, Utah. Drs. Medearis and Jonas and their associates, utilizing retrospective computer analysis of information gleaned from birth certificates, have addressed the incidence and perinatal outcome of twinning in Missouri, comparing the study results with an appropriate array of published material.

The paper reflects a sincere effort to unmask the elusive key to improvement of perinatal outcome in twin pregnancy by the computer study of vital statistics. The paper did not unveil new or innovative ideas but did reinforce the importance of early diagnosis and the ominous complications possible in twin pregnancy, and offered regional planning, consultation, and referral as logical steps to improve the outcome.

The study's documented references, plus the contribution by Harris and Gibbs,[1] does suggest that early diagnosis of twinning is essential and may be possible by simple clinical measurement of the uterine growth or more sophisticatedly by ultrasound or x-ray.

Early diagnosis allows timely inventory of resources available to assess and treat predictably the problems of twinning. The simple availability of an extra pair of trained hands on site at delivery has improved the outcome of the delivery process in our practice.

Whether or not it is practical in a known twin pregnancy to change the environment of the mother to a regional center to enhance rest and give nutritional and educational counseling away from her home exposes a current controversy that will be worthy of exploration.

This observer senses that the patient who is at bed rest opposes centralization of care, subspecialization, and the resulting fragmentation of care with the end result of depersonalization so much that house calls for prenatal management of twins are in vogue in our practice.

Twinning, by all styles of analysis, presents the obstetrician with unique problems, difficult decisions, and often clinically nonpredictable challenges that are worsened by "Surprise! It's twins!"

REFERENCE

1. Harris, R. E. and Gibbs, C. W.: Early diagnosis and management of multiple gestations, Virginia Med. Month. 97:696, 1970.

DR. JOHN F. HUDDLESTON, Birmingham, Alabama. I am certainly a proponent of the regionalization of perinatal care. However, residing in a rural state with considerable distances between primary care and referral facilities, I question whether maternal transfer will prove to be of great value in avoiding perinatal deaths associated with twinning.

In the first place, as Dr. Jonas has pointed out, the perinatal deaths are primarily due to prematurity associated with premature labor and with antepartum hemorrhage. The active phase of premature labor is notoriously rapid. Intravenous tocolytic agents probably cannot be safely administered inside an emergency vehicle speeding down the highway. A gravida with an actively bleeding placenta previa is likewise hardly a candidate for safe transfer over any great distance.

Second, even if we become proficient at the early identification of twin pregnancies, their prophylactic referral during the third trimester for observation and domiciliary care is of questionable benefit,[1] is quite expensive, and may cause considerable family turmoil.

Taken together, these factors cast some doubts on the ability of in utero referrals to have significant impact on the perinatal mortality rate in twin pregnancy.

REFERENCE

1. Jeffrey, R. L., Bowes, W. A., and Delaney, J. J.: Role of bed rest in twin gestation, Obstet. Gynecol. 43:822, 1974.

DR. WILLIAM B. STROMME, Edina, Minnesota. As late as 25 years ago Prof. Will Nixon of the University of London established a policy there of bed rest from 32 to 36 weeks of multiple pregnancy and felt that this was a principal factor in reducing the perinatal mortality rate.

Also, because of the concerns of premature delivery in multiple pregnancy, we should be mindful of the fact that many of these people have silent incompetent cervix. This should be looked for and corrected when found.

DR. DONALD L. CLINE, Indianapolis, Indiana. I feel that with the increasing use of Clomid and Pergonal we are going to encounter more frequent multiple gestations.

I would like to offer two suggestions for consideration: (1) the prophylactic use of cervical circlage in multiple gestations could be considered if the multiple pregnancy is diagnosed early and (2) the prophylactic use of beta-methasone at an appropriate time in a multiple gestation may be indicated. These two factors may very well reduce prematurity as a result of silent cervical dilatation and, if a premature delivery does occur, the survival rate might be increased with the use of beta-methasone.

DR. WILLIAM P. GIDEON, Tulsa, Oklahoma. In light of the decrease in the perinatal mortality rate in domiciliary type institutions, this might be an opportune time in light of the current controversy on overbedding in many of our hospitals to start a drive to establish long-term care units at a reduced price per diem. It is my understanding that in certain cities in the Southwest now, specifically Dallas, there is a program where the average daily cost for a bed is around $35 or $37 a day. This would be much more economical than the cost in a neonatal intensive-care unit.

DR. GERALD B. HOLZMAN, East Lansing, Michigan. Although I agree with the authors that it is desirable to make the diagnosis of a twin pregnancy early, the employment of ultrasound in every pregnancy seems a bit excessive. Most of us do not have units in our office and the hospital charge for this procedure is not insignificant. Twinning does increase with advanced maternal age. Thus, one might consider these women to be sufficiently at risk to justify an ultrasound examination, particularly since many of them will consent to an early midtrimester diagnostic amniocentesis to rule out a chromosomal abnormality.

DR. MEDEARIS (Closing). Dr. Gibbs' comment on the difference of race in our study is reflected by the percentage incidence of pregnancies in black patients in Missouri, and by the fact that the perinatal mortality rate in nonwhite patients has markedly decreased over

a 2 year period of time. This probably is related to the availability of abortions to this patient population, and this occurrence toward the end of our 5 year period alters our statistics regarding black patients. It will be interesting to see if recent funding decisions on abortion influence our perinatal mortality rate in the nonwhite patients.

I agree with the problems of data collection from birth certificates; in many cases we had to further hand sort and inquire to complete our files. One of the areas that was particularly frustrating was presentation. Physicians tend in twin pregnancies to list either vertex-vertex, breech-breech, or transverse-transverse. It would seem, from looking over all the data, they do not accurately describe the presentation of the twins. This is a major problem in pursuing data. I would like to encourage people to fill out these forms accurately.

With regard to Dr. McQuarrie's comments, we really had not advocated that the patient necessarily be away from home. We have encouraged the state to offer aid to these patients so that they might be allowed to stay at bed rest or reduced activity at home. We have been interested in comparing one group in a domiciliary facility as opposed to a group that is at bed rest at home.

Last, I would like to comment on the question of referral of multiple pregnancy. The problem in the state appears to be not necessarily the referral and transfer to a high-risk facility of a patient who is unstable but, in many cases of a known diagnosis of multiple pregnancy, the insistence of physicians on keeping this pregnant patient in their community.

I would cite a recent episode where a physician whose patient was known to have a set of triplets had consulted one of the obstetric staff and a neonatologist at one of the referral centers approximately a month prior, and told them of his awareness of multiple pregnancy. He then proceeded, when this patient was in early labor, at approximately 28 to 30 weeks, to deliver her at his institution because triplets had never been born in that town, and he desired to deliver them there. At the time the neonatologist arrived, rather hurriedly, after approximately 50 to 60 miles by ambulance, he found all infants intubated, two in the esophagus, all being ventilated with adult equipment. All three fetuses have now been born, and are now buried in that town. I think that is one of our major concerns about multiple pregnancy.

Information for authors

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. Therefore, all manuscripts must be accompanied by the following written statement, signed by one author: "The undersigned author transfers all copyright ownership of the manuscript (title of article) to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. Ultrasonic evaluation of the fetal heart

A report of experience and anatomic correlation

DEAN T. YAMAGUCHI, M.D., PH.D.
FREDERICK Y. L. LEE, M.D., F.A.C.O.G.
New Orleans, Louisiana

Identification of fetal intracardiac structures in utero is accomplished with B-scan, gray-scale ultrasonography. Sagittal and transverse ultrasonographs of the interventricular septum, aortic root, tricuspid, and mitral valves are presented. These structures are characterized with respect to their relations to each other, atrial and ventricular chambers, and acoustic appearances. Correlation of these cardiac structures is made with gross anatomic fetal specimens sectioned in longitudinal and transverse planes. Recognition of fetal intracardiac detail may be of aid in future noninvasive investigations of human fetal cardiovascular dynamics. (AM. J. OBSTET. GYNECOL. 134:422, 1979.)

PULSE-ECHO A-mode, time-motion (T-M) mode and Doppler ultrasound techniques have been used in obstetrics to detect the presence of fetal heart activity in confirming fetal viability.[1-6] However, few studies have been reported with B-scan techniques to study the anatomy of the fetal heart in utero. Early B-scan studies of fetal cardiac anatomy have been performed with bistable technique. Some fetal intracardiac details may not be generated by bistable technique if their reflected echo intensities are lower than the threshold echo intensities detected by the given ultrasound system.

Such bistable scans have revealed that the cardiac interventricular septum can be identified within a circular transonic structure within the fetal thorax.[7, 8] The ultrasonic representation of atrioventricular valves was also reported.[9] In a report by Egeblad, Bang, and Nonheved,[10] bistable imaging of a fetal intracardiac structure identified as the "atrioventricular septum" was made. They stated that such a septum includes the area of the tricuspid and mitral valves and their immediate supporting structures. Egeblad and associates also tentatively identified fetal atria, ventricles, interventricular and interatrial septa, pulmonary conus and artery, aortic root, and superior and inferior venae cavae on the basis of their relationships to the "atrioventricular septum."

Recent ultrasound tomographic studies of fetal anatomy have used gray-scale techniques. Kossoff[11] reported that fetal heart chambers may be delineated from myocardium. Flanigan and Buttny,[12] using a slow, single-pass technique in obtaining gray-scale B-scans of the fetal heart, reported the interventricular septum as a wavy structure within a transonic area in the center of the fetal thorax. In March, 1975,[13] we reported on the sonographic appearance of a fetal cardiovascular sonographic image display which we believe to be the fetal aortic root as it exists from the left ventricle and ascending aorta.

The present communication is a report of the continuation of work on the sonographic imaging of the fetal cardiovascular system by B-scanning, gray-scale techniques with the tentative identification of other fetal intracardiac structures.

Materials and methods

A Unirad Sonograf II with Greatone Zoom Display capability was used in the investigation. This diagnostic pulse-echo unit was equipped with simultaneous A-and B-mode display modules and T-M mode capability. An electronic caliper module to measure quickly fetal biparietal diameters was also available.

A 2.25 MHz multipurpose long-focus transducer of

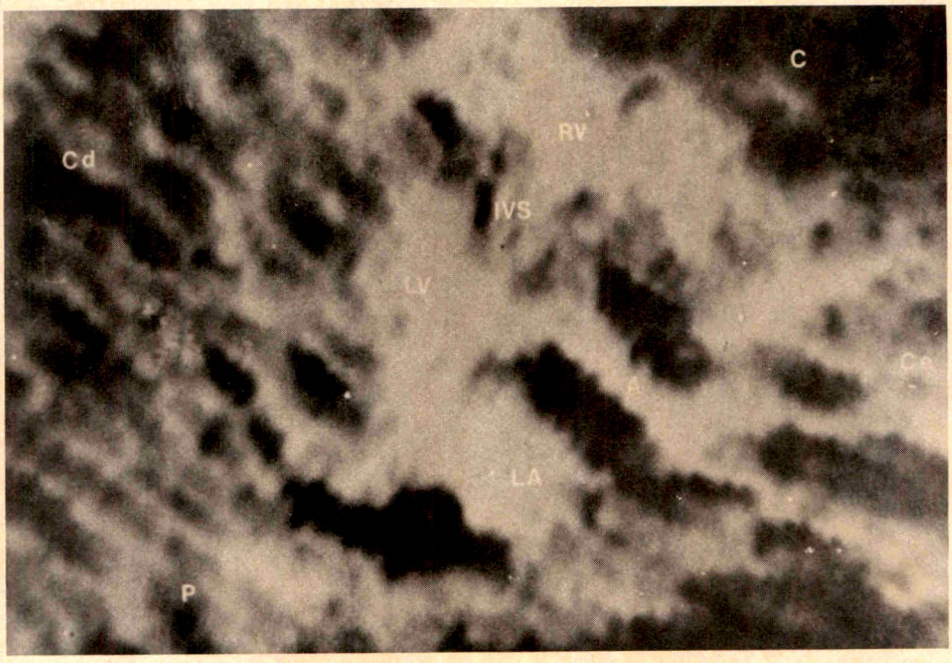

Fig. 1. Sagittal B-scan of the heart in a fetus at 40 weeks of gestation. The walls of the aortic root *(A)* appear as two dark, parallel echoes. The anterior wall of the aortic root is continuous with a lighter gray band of echoes which divides the sonolucent cavity into two chambers. This lighter gray band of echoes is the interventricular septum *(IVS)*. The sonolucent chamber anterior to the interventricular septum is the right ventricle *(RV)*. The sonolucent chamber posterior to the interventricular septum is the left ventricle *(LV)*. A small gray echo appears as an appendage to the posterior wall of the aortic root. This echo may be part of the anterior leaflet of the mitral valve. Hence the left atrium *(LA)* can be identified. Cephalad *(Ce)*, caudad (Cd), fetal anterior chest wall *(C)*, posterior aspect of the fetus *(P)*.

13 mm diameter and a 3.5 MHz 19 mm diameter transducer focused at 7 to 11 cm were used.

Mineral oil or aqueous gel was used as a coupling agent between the transducer and abdominal skin for optimal sound transmission.

Fresh-frozen and formalin-fixed anatomic specimens for correlative study were obtained from the embryologic collection of the Department of Pathology, Charity Hospital of Louisiana at New Orleans. Longitudinal and transverse sections of these fetal specimens were made with a band saw or a brain knife.

Patients in their third trimester referred for obstetric ultrasound were examined for determination of fetal intrauterine attitude, estimation of gestational age by biparietal diameter, and placental localization. Fetal heart examinations were accomplished after the routine obstetric ultrasonic examination and required approximately 30 extra minutes of scanning time.

The position and presentation of the fetus were ascertained by B-scan to localize the fetal thorax and heart. Fetal heart activity was then confirmed by A-mode and/or T-M mode. The fetal heart was serially examined by longitudinal and transverse scans in 0.5 to 1.0 cm sections. A slow, single pass of the transducer over the area of the fetal heart was used to demonstrate any oscillations within the fetal heart space. In some patients the position of the fetus was such that it was difficult to locate the fetal heart with B- and A-modes alone. A Doppler unit was then found to be helpful in audibly identifying the fetal heart. Such a maneuver enabled one to reposition the B-scanning transducer for correct angulation in order to obtain the required longitudinal or transverse sections of the fetal heart. All B-mode ultrasonographs were recorded on 35 mm and/or Polaroid film.

Results

Approximate sagittal ultrasonographic sections of an in utero fetus at 40 weeks' gestational age are presented in Figs. 1 and 2. The dark gray to black areas in the ultrasonographs represent sonic interfaces. The lighter areas or sonolucent parts of the ultrasonographs represent homogeneous fluid areas. Two dark, parallel sonic interfaces appear to arise from a sonolucent saccular area caudal to these interfaces. Generally, a zigzag image of the parallel interfaces can be seen. An inter-

Am. J. Obstet. Gynecol.

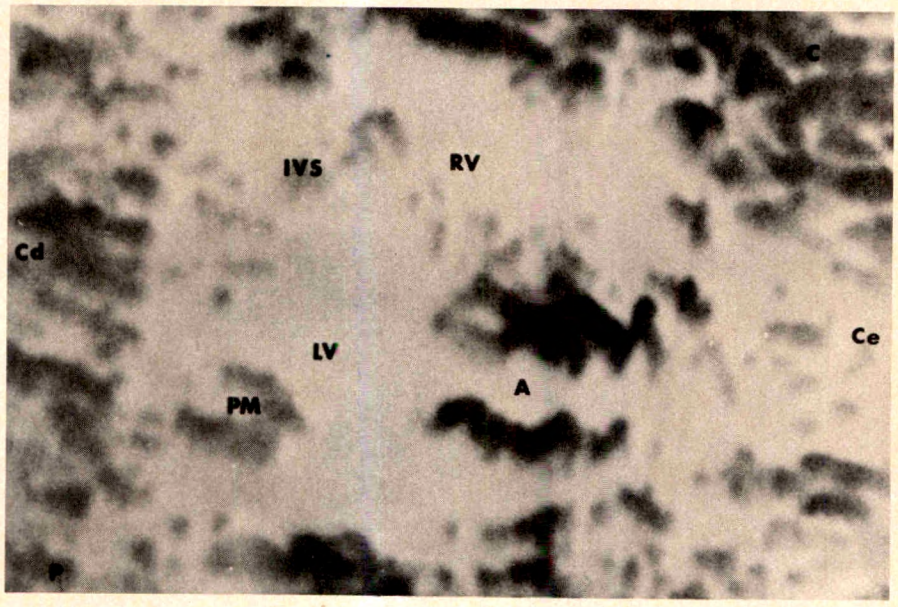

Fig. 2. Sagittal B-scan of the heart in a fetus at 40 weeks of gestation. The walls of the aortic root *(A)* are apparent as two dark, parallel echoes. The anterior wall of the aortic root is continuous with the interventricular septum *(IVS)*, which appears as a set of lighter gray echoes with a wavy appearance. A gray echo seems to jut into the sonolucent space posterior to the interventricular septum. This echo may represent a papillary muscle *(PM)*. The right ventricle *(RV)* and left ventricle *(LV)* are identified. Cephalad *(Ce)*, caudad *(Cd)*, fetal anterior chest wall *(C)*, posterior aspect of fetus *(P)*.

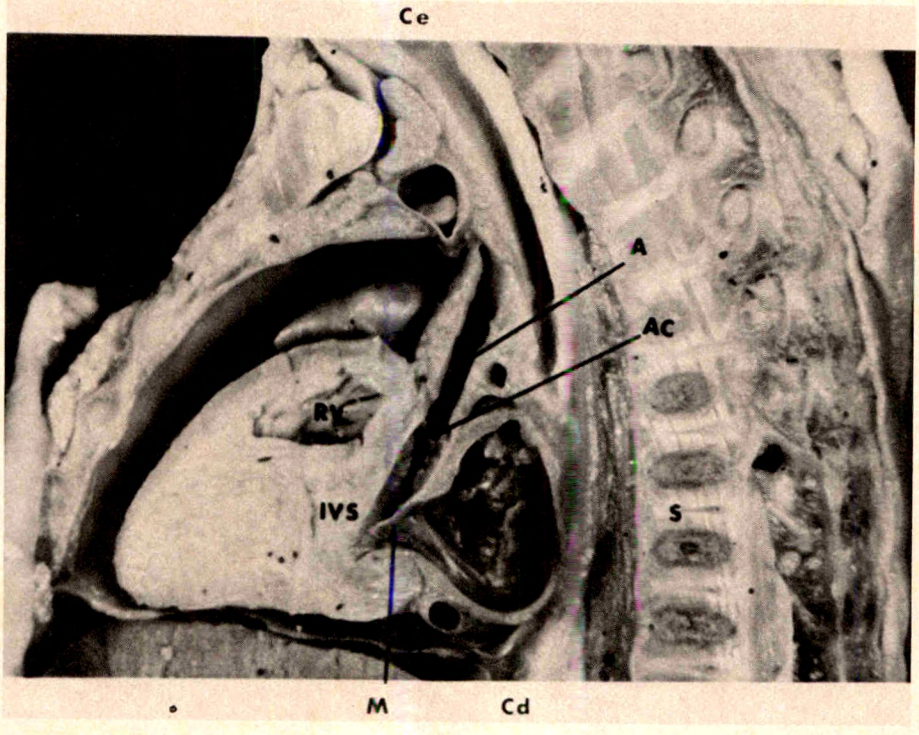

Fig. 3. Sagittal section through the heart in a morbid fetus at approximately 19 weeks of gestation. The aortic root *(A)* is clearly visualized. Part of the aortic valve is also apparent *(AC)*. The interventricular septum *(IVS)* is continuous with the anterior wall of the aorta. The anterior leaflet of the mitral valve *(M)* is continuous with the posterior wall of the aortic root. The right ventricle *(RV)* and the left atrium *(LA)* are apparent. The left ventricle has been cut away in this section. Cephalad *(Ce)*, caudad *(Cd)*, fetal anterior chest wall *(C)*, fetal spine *(S)*.

face that is lighter in appearance than these parallel interfaces is continuous with the more anterior of the two parallel interfaces and continues to the caudal extent of the sonolucent cavity to divide the cavity into anterior and posterior chambers. The waviness of such an interface imparts the impression of motion. Another gray interface can be seen as a small appendage to the caudal extent of the more posterior of the two dark, parallel interfaces in Figs. 1 and 2.

Correlation of the anatomic source of the interfaces represented on the ultrasonographs was done from morbid fetuses sectioned slightly oblique to the sagittal plane. Fig. 3 shows a 19-week-old fetus sectioned in approximately the same plane in which the ultrasonographs in Figs. 1 and 2 were made. The two dark, parallel interfaces present in the ultrasonographs appear to originate from the anterior and posterior aortic root wall/blood interfaces. The gray interface continuous with the anterior aortic root wall may represent the interventricular septum. The appendicular interface continuous with the posterior aortic root wall may represent parts of the anterior leaflet of the mitral valve. Once the basic landmarks of aorta, interventricular septum, and mitral valve are identified, the left ventricle, right ventricle, and left atrial cavities can also be identified as shown in Figs. 1 and 2. In Fig. 2 a gray interface appears to jut into the left ventricular cavity and is continuous with the echoes from the posterior left ventricular wall. Such an interface may be a papillary muscle. Fig. 4 shows the orientation of the heart in the fetal thorax, and the intracardiac structures identified can be compared with those shown in Figs. 1 and 2.

Fig. 5 is an approximate sagittal B-scan of an in utero fetal heart at 37 weeks' gestational age. Oscillations are present within the sonolucent fetal heart cavity. Two dark, parallel interfaces are present and again these probably represent anterior and posterior aortic root wall/blood interfaces. The anterior aortic root wall appears to be continuous with a set of echoes stretching to the caudal extent of the fetal heart space. These echoes may originate from the interventricular septum/blood interface. Spiking oscillatory echoes appear to be either continuous or contiguous with the anterior aortic root wall. These probably arise from parts of the tricuspid valve. The posterior aortic root wall is continuous with another set of oscillatory echoes that extend into an echo-free cavity. It is likely that these echoes arise from the anterior leaflet of the mitral valve. Hence right and left ventricles may also be identified in Fig. 5. The structures identified in Fig. 5 can be compared with the intracardiac structures labeled in Fig. 6.

Fig. 7 is an approximate transverse or cross-sectional ultrasonograph of an in utero fetal heart at 40 weeks' gestational age. Two dark, parallel echoes appear in a more sonolucent space bordered by darker echoes. Grayer echoes originate from both parallel echoes. Correlation of the echo patterns with morbid fetal cross-sectional cardiac anatomy (Fig. 8) shows that the two dark, parallel echoes probably originate from the aortic root wall/blood interfaces. Echoes continuous with the left anterior portion of the aortic wall may arise from the interventricular septum and the zigzag echoes from the left posterior portion of the aortic root may arise from the anterior leaflet of the mitral valve. The sonolucent area anterior to the aortic root may be the right ventricular outflow tract and the sonolucent area behind the aortic root may be the left atrium. Hence the limits of the left ventricle may be delineated by the interventricular septum anteriorly and the mitral valve posteromedially, as shown in Fig. 7. The transverse section of the fetal heart shown in Fig. 9 can be compared with the ultrasonograph of the fetal heart in Fig. 7.

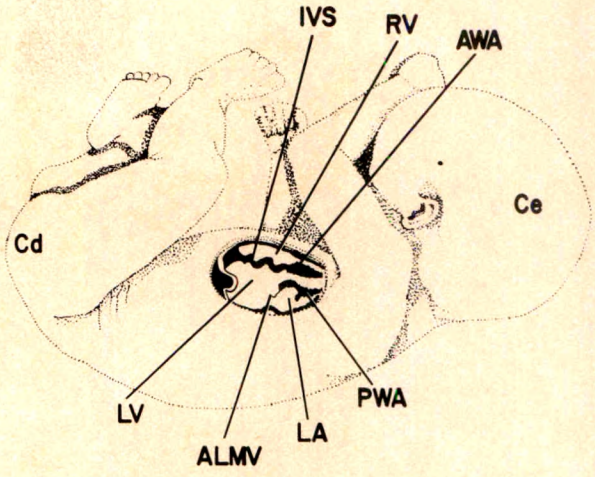

Fig. 4. Schematic representation of an approximate sagittal section of the fetal heart in the fetal thorax. The interventricular septum *(IVS)*, right ventricle *(RV)*, anterior wall of the aortic root *(AWA)*, posterior wall of the aortic root *(PWA)*, left atrium *(LA)*, anterior leaflet of the mitral valve *(ALMV)*, and the left ventricle *(LV)* are labeled. Cephalad *(Ce)*, caudad *(Cd)*.

Comment

The present B-scan gray-scale studies of fetal hearts in sagittal and transverse sections demonstrated that fetal intracardiac structures can be identified. Fetal heart visualization was best accomplished from approximately 35 weeks of gestation through term due to the large size of the fetal heart with respect to the fetal thorax and the minimal amount of positional change of the fetus. In general the basic intracardiac landmarks used to orient the examiner to the various cardiac chambers were the anterior and posterior walls of the

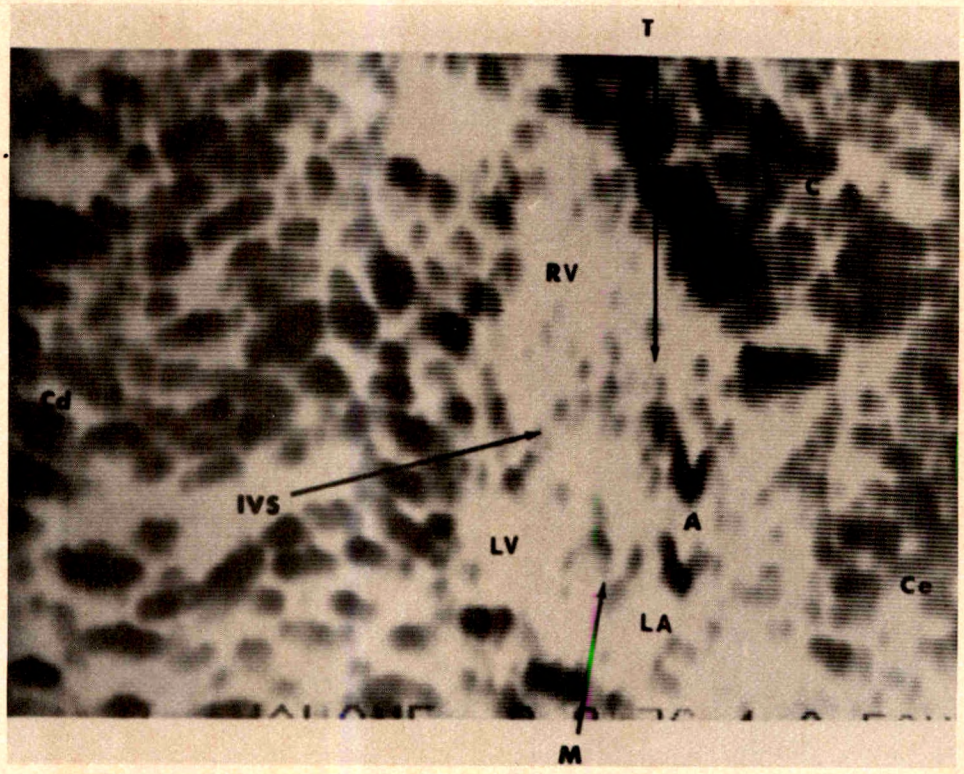

Fig. 5. Sagittal B-scan of heart in a fetus at 37 weeks of gestation. The walls of the aortic root *(A)* are apparent as two dark, parallel echoes. A lighter gray echo continuous with the anterior wall of the aortic root is the interventricular septum *(IVS)*. A lighter gray echo continuous with the posterior wall of the aortic root is the anterior leaflet of the mitral valve *(M)*. A tricuspid valve leaflet *(T)* appears as sharp spiked echoes contiguous with the anterior wall of the aortic root. The right ventricle *(RV)*, left ventricle *(LV)*, and left atrium *(LA)* are identified. Cephalad *(Ce)*, caudad *(Cd)*, anterior chest wall of fetus *(C)*.

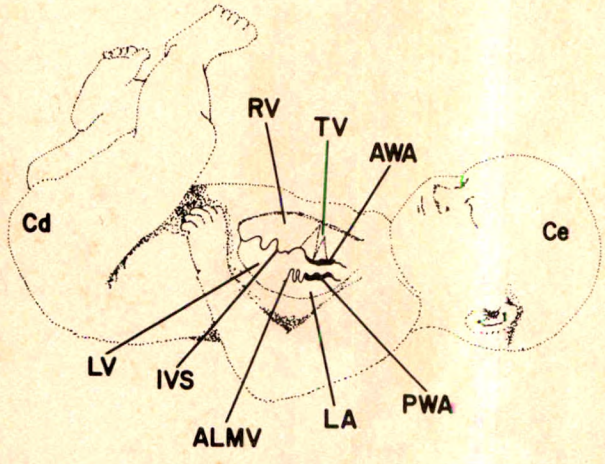

Fig. 6. Schematic representation of an approximate sagittal section of the fetal heart of the fetal thorax. The interventricular septum *(IVS)*, left ventricle *(LV)*, right ventricle *(RV)*, anterior leaflet of the mitral valve *(ALMV)*, left atrium *(LA)*, anterior wall of the aortic root *(AWA)*, and posterior wall of the aortic root *(PWA)* are labeled. Slight positional change of the fetus from that shown in Fig. 4 allows one to visualize parts of the tricuspid valve *(TV)*. Cephalad *(Ce)*, caudad *(Cd)*.

aortic root, the interventricular septum, the anterior leaflet of the mitral valve, and parts of the tricuspid valve. In this particular study, the walls of the aortic root were structures that tended to be characterized by high-intensity or darker interfaces, whereas the interventricular septum and atrioventricular valves were sonographically demonstrated as lower intensity or lighter gray echoes. Such differences in reflected echo intensities may be a function of the histologic composition of these cardiovascular structures, the angle of incidence of the pulsed ultrasonic beam to the interface being examined, or both of these factors.

The atrioventricular valves are thin and composed of delicate connective tissue with an acoustic impedance only slightly different from that of blood. Thus the atrioventricular valves may not reflect as much ultrasound as do the aortic walls, which are composed of denser elastic and fibrous connective tissues and smooth muscle. The acoustical impedance mismatch between the aortic walls and blood may be large enough to give the reflected ultrasound a higher in-

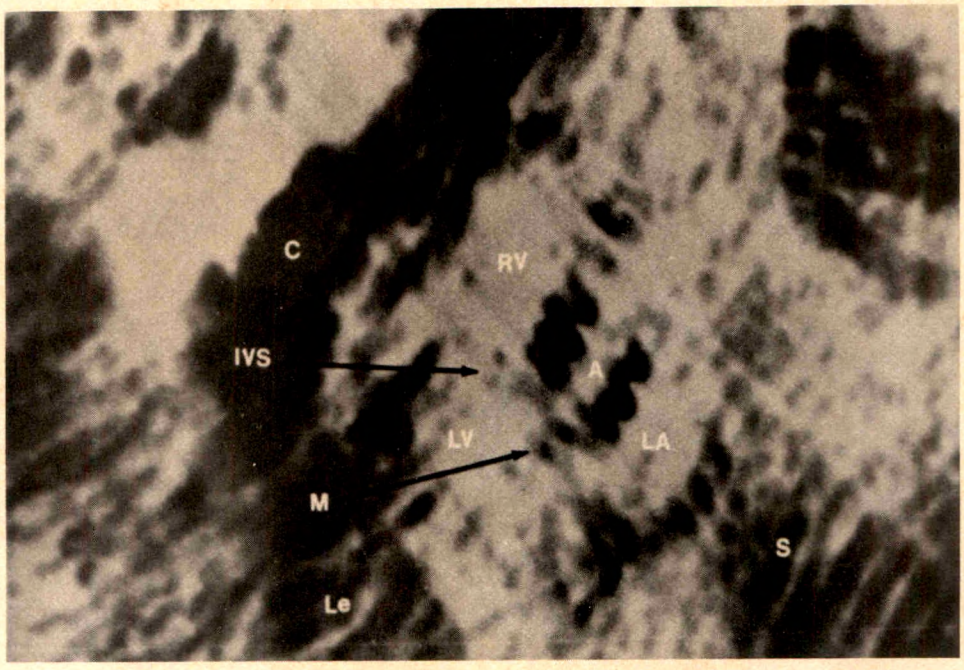

Fig. 7. Transverse B-scan of the heart in a fetus at 37.4 weeks of gestation: View of the aortic root. The walls of the aortic root *(A)* appear as two dark, parallel echoes within a sonolucent cavity. The anterior wall of the aortic root is continuous with lighter gray echoes of the interventricular septum *(IVS)*. The posterior wall of the aorta is continuous with lighter gray zigzag echoes from the anterior leaflet of the mitral valve *(M)*. The right ventricle *(RV)*, left ventricle *(LV)*, and left atrium *(LA)* are noted. Fetal anterior chest wall *(C)*, fetal spine *(S)*, left side of fetus *(Le)*.

tensity. Similarly, a well-vascularized muscular interventricular septum may present with an acoustical impedance slightly different from that of blood, the difference being due to the cardiac muscle of the interventricular septum. The membranous part of the interventricular septum may also tend to give a sonographic representation similar to that of the atrioventricular valves since it too is composed of connective tissue within an endothelial lining.

It is known that as the angle of incidence of the pulsed ultrasound to the tissue interface being studied approaches 90 degrees, the amount of reflected ultrasound detected by the ultrasonic receiver approaches a maximum.[14] Perhaps the anatomic position of the aortic root with respect to the movement of the transducer position was such that the aortic root generally presented a near normal interface to the incident ultrasonic beam of the transducer in which maximal reflected ultrasound could be detected. Conversely, the positions of the interventricular septum and atrioventricular valves may have presented a less favorable lie to the incident ultrasonic beam for the maximization of the reflected echoes from such interfaces. We feel that both of the above-mentioned factors play a role in the sonographic appearances of the described fetal cardiac structures.

Some problems in correlating B-scan fetal cardiac anatomy to the cardiac structures of the morbid fetal specimens were due to slight obliqueness of the ultrasonic tomographs of the fetal heart with respect to the sections cut in the morbid specimens. True sagittal or transverse sections were not easy to obtain in all fetuses studied. Slight obliqueness of the B-scans of the heart may add a degree of distortion that results in less commonly recognizable relationships of intracardiac structures and chambers. Also it must be noted that the hearts of the morbid specimens studied for correlation appeared to be fixed in ventricular systole so that ventricular chamber sizes could not be very well appreciated.

In general it was observed that B-scan cross-sections of the aortic root of the fetal heart did not appear circular but the walls appeared to be more or less parallel to each other. Usually the lateral margins of the aortic root did not fill in or show a wall/blood interface. This was probably due to the incident ultrasonic beam being parallel to the reflecting interface. This artifact may be corrected by angling the transducer so that the incident beam strikes all aspects of the aortic root wall/blood interface at an angle as close to 90 degrees as possible.

Added confirmation of the fetal cardiac structures

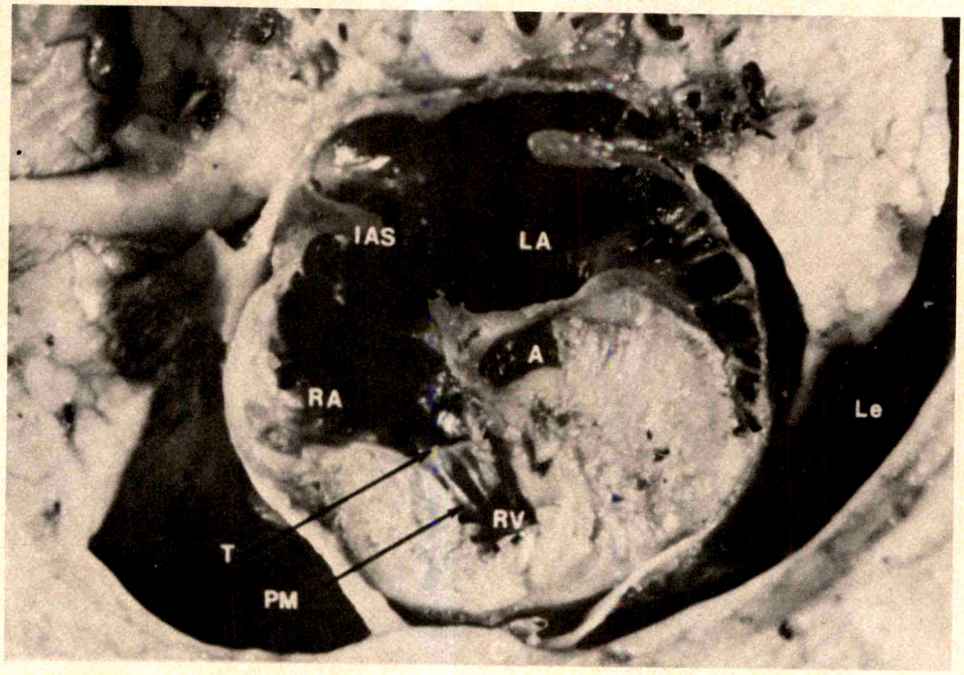

Fig. 8. Cross-section through the level of the heart in a morbid fetus at approximately 25 weeks of gestation. The right and left atria *(RA* and *LA*, respectively) appear quite prominent relative to the total area of the heart. The tricuspid valve *(T)* and attaching papillary muscles *(PM)* are apparent within the right ventricle *(RV)*. Part of the interventricular septum *(IVS)* and aortic root *(A)* are also visible. Part of the interatrial septum *(IAS)* has been torn away. Anterior chest wall *(C)*, posterior aspect of fetus *(P)*, left side of fetus *(Le)*.

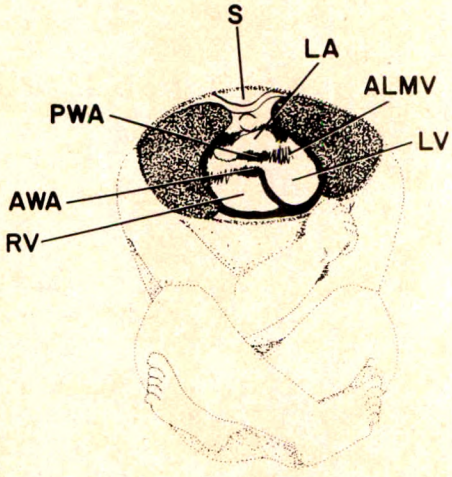

Fig. 9. Schematic representation of a transverse section of the fetal heart in the fetal thorax. The anterior wall of the aortic root *(AWA)*, posterior wall of the aortic root *(PWA)*, anterior leaflet of the mitral valve *(ALMV)*, left atrium *(LA)*, left ventricle *(LV)*, right ventricle *(RV)*, and interventricular septum *(IVS)* are labeled. Fetal spine *(S)*.

delineated by B-scan was accomplished by T-M mode scanning, as was done in our previous work[13] and that of Winsberg.[15] Such T-M mode fetal heart work will be the subject of a subsequent report.

In summary, we have expanded on our experience with ultrasonic visualization of fetal cardiovascular structure. Gray-scale ultrasound aids one's attempt to identify the various fetal intracardiac structures by both their echogenic properties and their anatomic relations. Identification of motion by such intracardiac structures can be of assistance in recognizing fetal viability with B-scan technique alone. Consistent recognition of fetal cardiovascular structures by both B-scans and T-M mode tracings may enhance the possibility for the assessment of fetal cardiovascular physiologic function by fetal echocardiography.

Present technologic advances in measuring blood velocity by a pulsed Doppler system has combined pulsed Doppler instrumentation with the real-time visualization of the vessels in which such blood velocity is measured in order to quantitate blood flow.[16] Pulsed Doppler ultrasound in combination with T-M mode echocardiography is also presently used to evaluate murmurs due to turbulent flow in congenitally malformed hearts in pediatric patients.[17]

Structural recognition of fetal intracardiac anatomy by B-scan is thus the initial step in investigations of fetal blood flow and cardiac output and may eventually prove to be of value in the diagnosis of congenital heart

disease in utero or in evaluating the cardiovascular status of the fetus in various pathologic processes in pregnancy, such as maternal diabetes and hypertensive disease.

Discussion

DR. JOSEPH C. SCOTT, JR., Omaha, Nebraska. This report of in utero identification of fetal cardiac structure is an extension of the authors' report presented before this Association in 1975. The reality of these studies ultimately will be a finer understanding of human in utero cardiac function, development, and anomalies.

Since the early development of clinical ultrasound, the technology has advanced at a steady pace. Pelvic sonography has proved itself as a useful adjunct clinically. Pulsed ultrasound, because it is noninvasive and considered safe, is forging new understandings of both placental and fetal development. As the technology continues to be refined, our generation will undoubtedly see ultrasound replace more invasive techniques for fetal and placental evaluation and the identification of anomalies.

Real-time scanning of the fetal heart presents a few challenges that adult heart scanning has not had as problem areas. Orientation of the fetal thorax and its contents varies with gestation and the fetal presentation. If there is motion, a change in orientation of the ultrasound plane occurs. The fetal heart is pumping at a greater pace than adult hearts and thus study of wall thickness and valve motion is more challenging. Superior camera, film, and/or videotape capability is a must to obtain good records. Also, simultaneous electrocardiogram tracings in conjunction with the TM mode ultrasound scanning may be of marked assistance in pinpointing valvular function in the fetus.

I would like to ask the authors to speculate the future directions of their studies and also would be interested in knowing what their experience has taught about the major equipment difficulties they have encountered.

DR. CHARLES C. BIRD, Evanston, Illinois. Ultrasound has been an extremely valuable diagnostic adjunct in the Department of Obstetrics and Gynecology at Evanston Hospital for several years, and with the addition of real-time ultrasonography the use of this test has expanded incredibly. We are so thrilled with it that it is actually hard to imagine in many instances practicing obstetrics without it. The portability, simplicity, and noninvasiveness of ultrasound allow the clinician to easily assess fetal age, position, and viability as well as placental location with minimal effort and virtually no patient risk. The enormous benefits are obvious.

As is true with any new technique, more and more refinements in technology lead to enhanced interpretation of results. The increased expertise of those who work with ultrasound can be no more clearly demonstrated than by the work of Yamaguchi and Lee. In 1975 at the annual meeting of the Central Association of Obstetricians and Gynecologists these authors[1] presented some preliminary data relating to the ultrasonographic identification and evaluation of the fetal heart, using a compound B-scan diagnostic unit with gray-scale processing. Today we have seen an impressive pictorial display clarifying, solidifying, and extending their efforts. Whereas their first report dealt with the identification of the fetal heart in general, i.e., the "fetal cardiac silhouette sign" and the aortic root, now their work has expanded to consistently demonstrate smaller and more subtle intracardiac structures. The

authors, using exquisite gross anatomic correlation with morbid fetal hearts, present convincing evidence that they can clearly delineate, using ultrasound, the fetal cardiac root, interventricular septum, and tricuspid and mitral valves.

The literature demonstrates that although in instances of congenital heart disease there is no significant increase in fetal distress in labor, no increase in the cesarean section rate, and no increase in maternal prenatal complications, antenatal detection of this fetal problem is very helpful in predicting small-for-dates infants.[2] The enormous pediatric benefit of foreknowledge of this complication, i.e., congenital heart disease in utero, is clear.

With only the data we have seen today, I can envision the in utero diagnosis of hypoplasia of the left ventricle, significant ventricular septal defects, aortic stenosis, tetralogy of Fallot, tricuspid atresia, and possibly coarctation of the aorta, to mention a few. The next logical step, of course, would be the transfer of mothers carrying fetuses afflicted with congenital heart disease to larger centers where appropriate postpartum neonatal management would be effected.

I have two principal questions to ask the authors: (1) Have any instances of congenital heart disease been discovered and, if so, was there, possibly, surgical confirmation of the ultrasonographic interpretation? (2) Is this a technique that can be reasonably easily reproduced by more inexperienced ultrasonographers or, in other words, at the present time, is this a practical procedure?

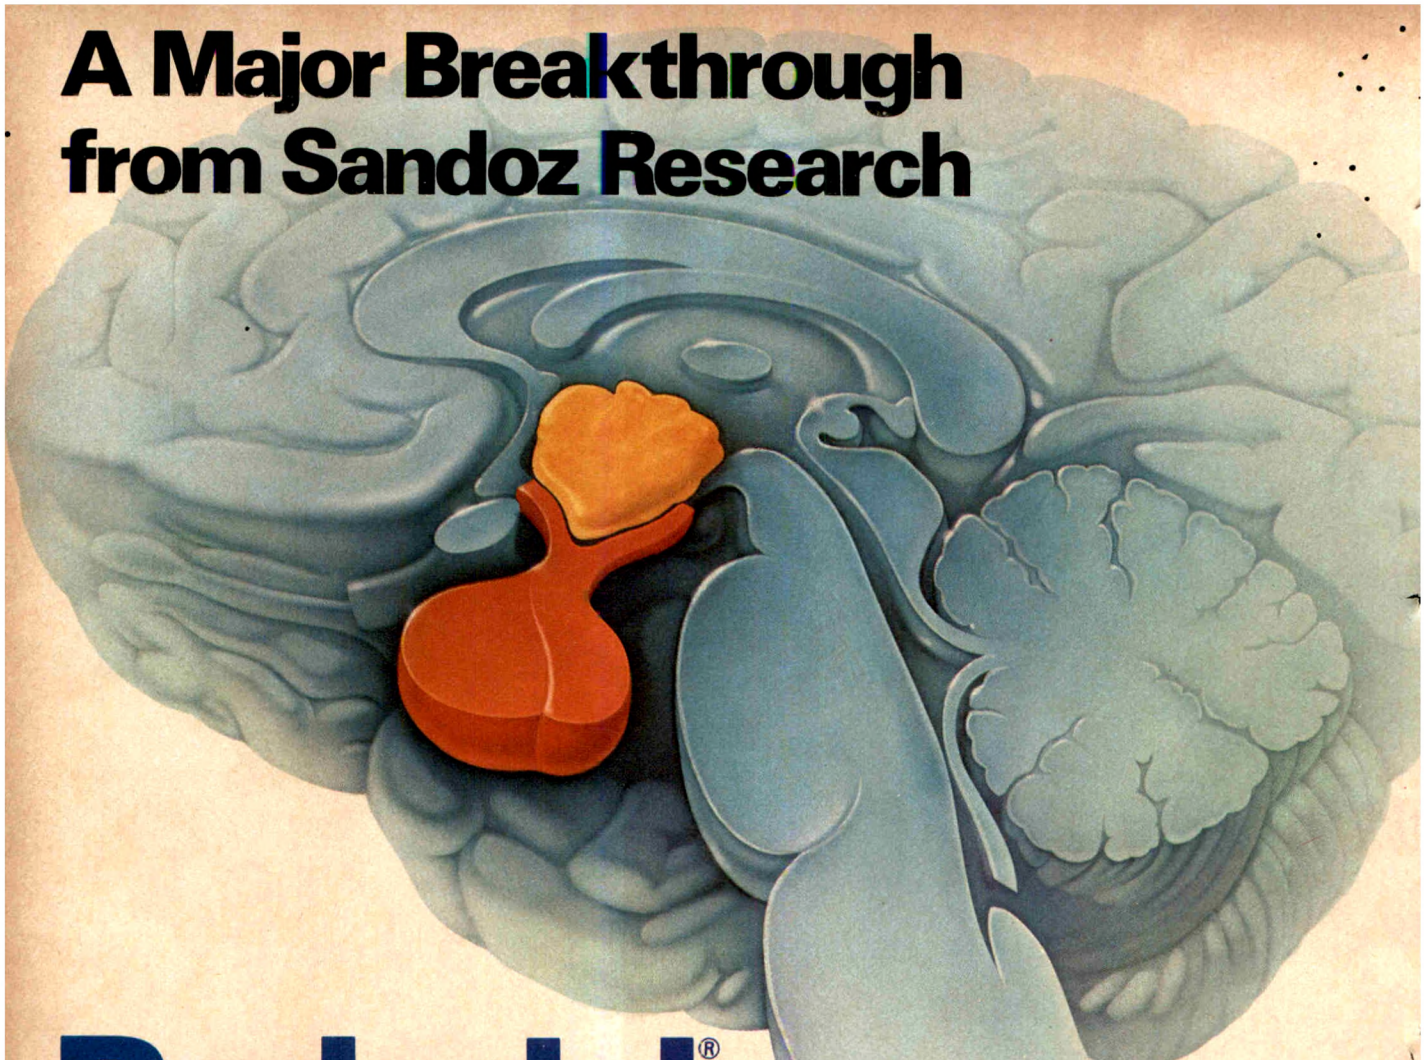
DR. YAMAGUCHI (Closing). With respect to Dr. Scott's question on the future direction of our laboratory, we do hope to present more studies relating to echocardiographic observations of the fetal heart at a later date. As has been evident from the literature, invasive studies on fetal cardiovascular physiology have been done solely on animal models such as sheep. Using the data derived from our present study of fetal cardiac anatomy and combining it with refined real-time ultrasonographic techniques to observe cardiac dynamics and the application of pulsed Doppler ultrasonography to measure blood flow, we hope that a comprehensive, noninvasive assessment of human fetal cardiovascular physiology in utero and later fetal cardiovascular pathophysiology may be developed.

As to Dr. Bird's question on the identification of congenital heart disease by the techniques that we have been using, we have not yet recognized any type of cardiovascular defects in those fetuses that were studied in detail for cardiovascular structure. However, this is not to say that such recognition of cardiac anomalies may not be made in the future.



We have found that over the past 4 years of studying fetal cardiovascular structure in utero, it has taken patience, perseverence, imagination, and a little serendipity.

BETTER THAN EVER... NATAFORT

A Major Breakthrough from Sandoz Research

Parlodel®
(bromocriptine mesylate)

TABLETS, 2.5 mg.

The first clinically useful dopamine receptor agonist

Dosage and Administration

- Start with one 2.5-mg tablet with the evening meal for three days; increase to one tablet with food in the morning and in the evening on the fourth day. The therapeutic dosage is one tablet two or three times daily with meals.
- If adverse effects occur, temporarily reduce dosage.
- Duration of treatment should not exceed six months.
- If pregnancy occurs, treatment should be discontinued immediately.
- For further details, including information on contraception and pregnancy tests, please see Brief Summary.

Contraindications: Sensitivity to any ergot alkaloids.
Warnings: Since hyperprolactinemia with amenorrhea/galactorrhea has been found in patients with pituitary tumors (Forbes-Albright syndrome), a complete evaluation of the sella turcica is advisable before treatment with Parlodel® (bromocriptine mesylate). Although Parlodel therapy will effectively lower plasma levels of prolactin in patients with pituitary tumors, this does not obviate the necessity of radiotherapy or surgical procedures where appropriate. If pregnancy occurs, treatment should be discontinued immediately; safe use has not been demonstrated in pregnancy. Should not be administered to nursing mothers. Safety and efficacy have not been established in children under age 15. Although the incidence of congenital malformations and spontaneous abortions reported in human studies does not exceed that generally reported for such occurrences in the population at large, the total number

- mimics the action of dopamine at the receptor sites
- potent inhibitor of prolactin secretion
- indicated in amenorrhea/galactorrhea associated with hyperprolactinemia*

Clinical effectiveness in amenorrhea/galactorrhea associated with hyperprolactinemia*

Parlodel therapy was studied in 210 patients with amenorrhea/galactorrhea associated with hyperprolactinemia;* of whom 187 were evaluated for efficacy. In light of the usual findings with previously available therapies, the response to Parlodel® (bromocriptine mesylate) was impressive.

- **CLINICAL IMPROVEMENT IN AMENORRHEA**
  Reinitiation of menses (or pregnancy without first having menses†) was reported by 80% of 187 patients after an average treatment time of 5.7 weeks.

- **CLINICAL IMPROVEMENT IN GALACTORRHEA**
  76% of 187 patients experienced clinically significant—75% or greater—reduction in galactorrhea, and 58% experienced complete cessation of milk secretion. The treatment time required for 75% reduction was 6.4 weeks, and that for complete cessation was 12.7 weeks.

- **OVERALL CLINICAL EFFECTIVENESS**
  63% of 187 patients experienced reinitiation of menses and at least 75% reduction in galactorrhea; 47% had both reinitiation of menses and complete cessation of milk secretion.

- **CORRELATION OF CLINICAL RESPONSE WITH REDUCTION IN PROLACTIN LEVELS**
  Improvement markedly correlated with reduction in serum prolactin levels. Maximum reduction of prolactin levels was achieved within the first four weeks of therapy, and reduced levels were maintained throughout therapy.

***in the absence of demonstrable pituitary tumor. Not indicated in patients with normal prolactin levels. Safe use in pregnancy not demonstrated. Thus, not indicated in the management of infertility.**
†Parlodel (bromocriptine mesylate) is not indicated in the management of infertility.

Stylized rendition of the hypothalamus and the pituitary

©1978 Sandoz, Inc.

of pregnancies reported is an insufficient sample in which to detect any given birth defect; extrapolation of these data to a greater patient population would be statistically invalid.
Precautions: Since treatment may result in restoration of fertility, patients should be required to use contraceptive measures, other than the oral contraceptives, during treatment; however, since patients often ignore this recommendation and since pregnancy may occur prior to reinitiation of menses, as an additional precaution, a pregnancy test is recommended at least every four weeks during the amenorrheic period and, once menses are reinitiated, every time a patient misses a menstrual period. Parlodel® (bromocriptine mesylate) therapy has been demonstrated to be effective in the short-term management of amenorrhea/galactorrhea only. Data are not available on the safety or effectiveness of its use in long-term continuous dosage, or in patients given repeated courses of treatment following recurrence of amenorrhea/galactorrhea after initial treatment. Recurrence rates are reportedly very high, ranging from 70% to 80% in domestic and foreign studies.
Adverse Reactions: The incidence of adverse effects is quite high (68%) but these are generally mild to moderate in degree. Therapy was discontinued in approximately 6% of patients because of adverse effects. These in decreasing order of frequency are nausea 51%, headache 18%, dizziness 16%, fatigue 8%, abdominal cramps 7%, lightheadedness 6%, vomiting 5%, nasal congestion 5%, constipation 3% and diarrhea 3%. A slight hypotensive effect may accompany Parlodel® (bromocriptine mesylate) treatment. The occurrence of adverse reactions may be lessened by temporarily reducing dosage to one-half tablet two to three times daily.
Dosage and Administration: The therapeutic dosage is one 2.5-mg tablet, two or three times daily, with meals. Duration of treatment should not exceed six months. It is recommended that treatment commence with one tablet daily, increasing to a therapeutic dosage within the first week, to reduce the possibility of adverse reactions.
How Supplied: Tablets, 2.5 mg, in packages of 30.

Before prescribing or administering, see package insert for full product information.

SANDOZ PHARMACEUTICALS, EAST HANOVER, N.J. 07936

Feosol®. Because stomachs aren't made of iron.

Feosol Spansule Capsules provide ferrous sulfate—iron in its most efficient (bivalent) form. Without extraneous minerals and vitamins. The iron is divided among coated pellets that disperse in the upper GI tract. The result is minimal stomach distress, hence fewer skipped doses. And studies* show that iron from Spansule Capsules is absorbed as completely as iron from solution.

Feosol. The brand of iron therapy most often recommended by physicians for iron deficiency and iron-deficiency anemia. Ask your Smith Kline & French Representative for samples.

Controlled-release pellets are designed to disperse the iron in the upper GI tract to minimize stomach distress.

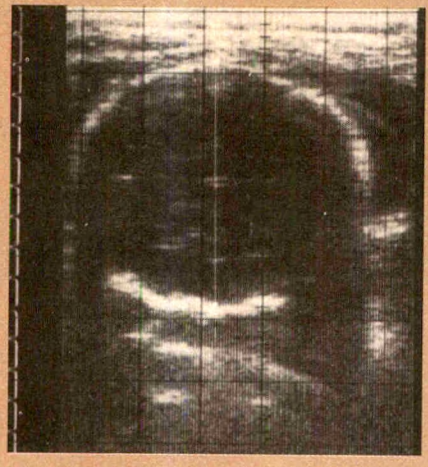
For delivering useful OB data, there's nothing quite like EkoLife®

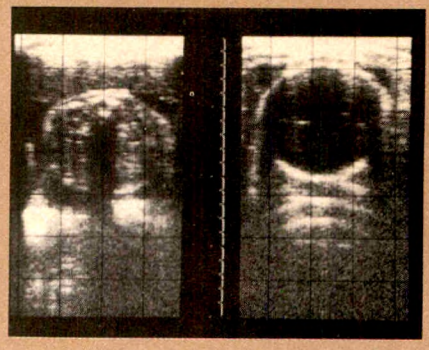
The Ekolife real-time scanner provides unique features to help make your OB data even more useful. For example:



An M-Mode Cursor, exclusive with Ekolife, can be positioned through any section of the scan to record M-Mode tracings of fetal breathing and limb activity. The tracings can then be recorded on an optional strip chart recorder.

Display in 2:1 shows the trunk with the M-Mode cursor running through the heart.

The Electronic Calipers with Digital Readout permit fast, accurate determinations of biparietal diameters or crown-rump measurements right on the display.



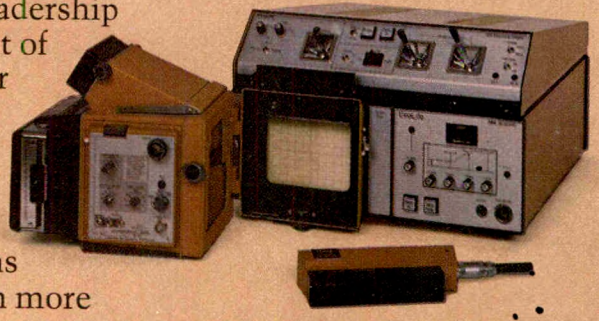
Biparietal diameter of fetal head using Electronic Calipers measurement is 8.0 cm which is approx. 33 weeks gestation.

A Digital Freeze Frame allows detailed, leisurely analysis of images prior to photography to help you get the exact image desired, faster and without wasting film.

A new Film Saver now lets you automatically photograph two different images on one sheet of film—a significant economy.

These features are further examples of SKI leadership in the development of new technology for OB scanning and of up-dating without obsolescence.

For all these reasons —and much, much more



Film Saver permits you to photograph two displays in one print. Display on left is cross-section on the trunk showing both kidneys. Display on the right is a BPD.

—Ekolife should be your first choice in OB scanning.

Send for complete information today.

Ten-year review of hysterectomies: Trends, indications, and risks

HASSAN AMIRIKIA, M.D., F.A.C.O.G., F.R.C.S.(C.), F.A.C.S.
T. N. EVANS, M.D., F.A.C.O.G., F.A.C.S.
Detroit, Michigan

This report concerns the indications, morbidity, and death associated with 6,435 consecutive abdominal and vaginal hysterectomies at Hutzel Hospital during a 10 year period. There was an extraordinary number of high-risk patients included in this group. Morbidity and postoperative bleeding were more common following vaginal rather than abdominal hysterectomy. These complications were also more common when the operation was performed during the proliferative phase of the menstrual cycle. There were 17 deaths. Thromboembolic complications were the major cause of death. Selective use of prophylactic antibiotics and low-dose heparin and reduction in the number of blood transfusions by preoperative endocrine and hematinic therapy may reduce the postoperative morbidity and mortality rates. Probably few operations will ever contribute as much to improving the quality of life of women as do indicated hysterectomies. However, the added risks do not seem to justify utilizing this operation for the sole purpose of sterilization in preference to simpler and safer procedures. (AM. J. OBSTET. GYNECOL. 134:431, 1979.)

AS THE FREQUENCY of hysterectomy has increased, the indications, risks and costs of the operation have become increasingly controversial. This analysis of over 6,000 hysterectomies was undertaken in an effort to clarify the various controversial points most frequently raised.

Study groups and methods of analysis

From 1965 to 1974, 6,435 hysterectomies were performed at Hutzel Hospital, which is the principal hospital affiliated with the Department of Gynecology and Obstetrics at Wayne State University. Of these, 90% were in private patients and one third of these had vaginal hysterectomies (Table I).

Age, parity, race, duration of hospitalization, indications, pathologic findings, morbidity, and deaths were recorded. Fewer than 1% were under 20 years of age (Table II). More than 70% were between 30 and 50 years of age. Fourteen percent were nulliparous, 74% had one to five children, and the remainder more than 5, with a maximum parity of 13 (Table III). Forty-seven percent were black and 53% were white. Duration of hospitalization ranged from 4 to 32 days, with an average of 10.5 for abdominal and 11.5 for vaginal hysterectomies.

There were 4,228 abdominal hysterectomies (67%) and 2,111 were performed vaginally. There was no significant racial difference in the number of abdominal operations. However, 1,304 (62%) vaginal hysterectomies were performed in white women, a possible reflection of the lesser incidence of uterine prolapse in black women with a greater incidence of leiomyomas.

Indications for hysterectomy

Indications for both abdominal and vaginal hysterectomies are recorded in Table IV. Uterine fibroids, adenomyosis, and endometriosis alone or in various combinations served as the indications for surgery in 4,977 (77%). Malignant disease was the indication in 626 (9%).

There has been a gradual increase in the number of hysterectomies done for leiomyoma in women of all races. This coincides with the period of increasing use of oral contraceptives but a cause-and-effect relationship has not been established. No relationship could be identified between the major blood groups and the incidence of hysterectomy for uterine fibroids.

There has been a progressive increase in the number

From the Department of Gynecology/Obstetrics, Wayne State University School of Medicine.

Presented at the Forty-sixth Annual Meeting of the Central Association of Obstetricians and Gynecologists, Kansas City, Missouri, October 13-15, 1978.

Total	866	4,734	717
Percent	14	74	12

of diagnoses of carcinoma of the cervix in situ throughout the 10 year period of study. Of the 431 hysterectomies for Stage 0 carcinoma of the cervix, 273 (63%) had residual carcinoma in the hysterectomy specimen. However, these data may be spurious since they also included a group of patients who had frozen section diagnoses followed immediately by hysterectomy.

There were 39 with radical hysterectomies. Of these, 33 had invasive cancer of the cervix, five had cancer of the endometrium and regional metastases, and one had cancer of the vagina.

There were 54 who had cesarean section hysterectomies. Only two of the 24 who received prophylactic antibiotics developed evidence of infection. However, 26 (48%) received 1 to 13 units of blood transfusions.

Major complications of hysterectomy are recorded in Table V. Morbidity based on the criterion of a temperature elevation of 100.4° F on two or more occasions 6 hours apart after the first 24 hours occurred in 19%. Twelve percent received blood transfusions during or following surgery and 1.4% had significant postoperative bleeding. Fewer than 1% had any injury to the bladder, ureters, or bowel and fewer than 1% in each category developed intestinal obstruction, thrombophlebitis, and pulmonary embolism. Among those who had radical hysterectomies, 32 received 2 to 16 units of blood. Fourteen developed urinary tract infections, four had pelvic abcess, two had bladder dysfunction and wound infection, and one had a vesicovaginal fistula.

Deaths

There were 17 postoperative deaths (Table VI). Five of these patients died of pulmonary embolism, two of subarachnoid hemorrhage, and one of ruptured cerebral aneurism. There were six who died of infection, including peritonitis (three), overwhelming septicemia (two), and pneumonitis (one). Two died of widespread metastases from ovarian and sigmoid carcinomas. Only one patient died of hemorrhage. There were five who died following vaginal hysterectomy performed because of pelvic relaxation. A comparison of morbidity and death rates in this study with those in other reported series is recorded in Table VII. Ten of the 17 deaths reported here were clearly not preventable. There may have been preventable factors in the remainder, but this is debatable because of the high-risk factors involved.

Comment

During the past three decades indications for hysterectomy have been extended, with an increase in the frequency of the operation for relief of symptoms,[27] sterilization,[2] in addition to organic disease and pelvic relaxation. Despite improvements in surgical technique, anesthesia, and supportive therapy, the mortality rate associated with the operation is still significant. The added risks indicate that hysterectomy as an alternative to tubal sterilization operations is unacceptable.

Thromboembolism is still an enigma that caused almost one third of the deaths reported here. Belding[3] reported an incidence of thromboembolic disease of 1.6% in postoperative patients compared with 0.6% in this report. Low-dose prophylactic heparin offers some hope of reducing the number of deaths from this cause. Kakkar, Corrigan, and Fossard[13] administered low-dose heparin (5,000 U) just prior to and at 8 to 12 hour intervals following the operation, with a substantial reduction in the incidence of thromboembolic disease.

Table IV. Indications for hysterectomy

Indications	Abdominal		Vaginal		Black	White	Total
	No.	%	No.	%			
1. Uterine leiomyoma	2,941	76	948	24	2,683	1,206	3,889
2. Adenomyosis	559	72	216	28	346	429	775

20	843	35.8	0	0.1
Present study	6,435	26	16	0.3

Utilization of prophylactic antibiotics, especially with vaginal hysterectomy, has become less controversial.[1, 4, 8, 12, 15, 17] Short-term utilization of antibiotics from 1 to 5 days after surgery has yielded favorable results.[1, 12, 15, 17] Such courses of therapy generally are initiated just prior to surgery. Elimination of all evidence of infection preoperatively obviously would reduce the risk of morbidity.

Attempts have been made to correlate febrile morbidity following surgery to the phase of the menstrual cycle. Neary and associates[16] found a greater proportion of positive vaginal cultures during the proliferative as compared with the secretory phase of the cycle. Galask, Larsen, and Ohm,[7] on the basis of animal experiments, suggested that estrogen promotes and progesterone decreases colonization of the genital tract. Goosenberg, Emich, and Schwarz[9] found a 25% morbidity rate after hysterectomy in postmenopausal women as compared with a 58% rate in the follicular phase and 53% in the luteal phase of the menstrual cycle of premenopausal women. Of the 6,435 hysterectomy patients in this report, 1,235 (19%) had febrile morbidity with 531 (43%) operated on during the proliferative phase and 419 (34%) during the secretory phase.

Blood transfusion remains an even greater risk factor than anesthesia.[6, 10, 14, 18, 19, 22–24] Preoperative suppression of bleeding with progestogens along with administration of iron to patients with anemia secondary to uterine bleeding has considerably diminished the need for transfusion.[21] One of the authors during the period of this study performed 64 vaginal and 134 abdominal hysterectomies without a single transfusion. The reason for the higher transfusion incidence with abdominal hysterectomy in this report was attributed to the number with uterine fibroids and secondary anemia. Postoperative bleeding was higher in vaginal hysterectomy (2.6%) than in abdominal procedures (0.9%).

Injuries to the intestinal and urinary tracts seemed to be related to the extent of surgery, indications, and anatomic distortion due to the extent of disease. When one can palpate the ureters, it is easy to avoid them. However, in the presence of extensive disease, especially endometriosis, identification of the ureter may be difficult. Preoperative intravenous pyelography is important, especially in those cases where a difficult surgical dissection is anticipated.[25]

Probably there are few operations today that contribute more to improving the quality of life of women than an indicated hysterectomy. However, the associated morbidity and mortality rates warrant critical consideration of the indications and contraindications to surgery.

Discussion

DR. FREDERICK J. HOFMEISTER, Wauwatosa, Wisconsin. My discussion will be given as a comparative review of my experiences. I am interested in a similar project, "a study of hysterectomies performed at Lutheran Hospital of Milwaukee during a 12 year period extending from January 1, 1966, through 1977". This is being done to determine if, in fact, the unnecessary hysterectomy does dominate the surgical scene. In making this comparison, one must keep in mind that there are differences of preferred techniques, patient population, and the fact that surgery may be done by the resident or the certified gynecologist.

During the period being studied 124,517 patients were discharged. Of these, 64,354 (51.6%) were surgical patients. Do hysterectomies dominate the scene? A total of 3,484 vaginal and abdominal hysterectomies were performed; only 5.4% of surgical procedures were, therefore, hysterectomies. This is 2.79% of all patients treated during this 12 year period of time. Abdominal hysterectomies accounted for 37.5% and vaginal hysterectomies 62.5%. Pathology, indications, personal interests, and expertise may account for this figure varying from the incidence of vaginal hysterectomies (33%) and abdominal hysterectomies (66%) reported by Drs. Amirikia and Evans. All patients at our institution were of the private category. The cesarean hysterectomy incidence in abdominal hysterectomies is very comparable at both institutions—Lutheran Hospital 1.98% and Hutzel–Wayne State 1.3%.

Ages are comparable: 0.3% of patients were under 20 years of age and 68% between 31 and 50 at Lutheran Hospital; 1% were under 20 and 69.7% between 31 and 50 at Hutzel.

Hospitalization at Lutheran Hospital averaged 8 days for vaginal hysterectomies, 9.4 days for abdominal hysterectomies, and increased to 11 days when reconstructive procedures were associated with the hysterectomy.

Of the 3,484 hysterectomies performed, 2,328 (66.8%) had uterine pathology categorized as either leiomyoma or adenomyoma. This is approximately 10% less than the 77% reported by Drs. Amirikia and Evans; of the 2,176 with tumors, 62% were performed vaginally.

Carcinoma of the uterus, endometrial, or in situ carcinoma of the cervix accounted for 225 (6.45%) of cases in our series.

Another 265 hysterectomies were listed as having no uterine pathology; these included salpingitis, ovarian carcinoma, endometriosis, pelvic abscesses, tuboovarian abscesses, and peritonitis with massive pelvic adhesions. These total 7.6% of all hysterectomies or 20.2% of abdominal hysterectomies.

It must be noted that the preceding cases tabulated as having no uterine pathology along with another 360 (10.3%) of hysterectomies which were performed for uterine prolapse, extensive pelvic relaxation, cesarean hysterectomy, and placenta accreta were also tabulated as having no uterine pathology. Would surgery under these conditions be regarded as unnecessary and unjustified by a person reviewing the chart, who is inexperienced and lacks clinical judgment?

Certainly when the final diagnosis is listed as chronic cervicitis, endocervical polyp, nabothian cyst, enlarged uterus, or "no reason", as in 425 (12.1%), I could agree that no uterine pathology was present. However, we must look deeper. There are no hysterectomies in our series listed as done for sterilization. Were physicians fabricating pathology to justify hysterectomy? Could this be the reason? I, personally, would advise my patient requesting a tubal interruption who had a history of menometrorrhagia or when palpable uterine fibroids are detected to have a hysterectomy. This is my concept of good therapy, but I would make this very clear on the records.

Complications causing postoperative morbidity existed in 65 vaginal hysterectomies and 38 abdominal hysterectomies, a total of 103 cases (2.9%). Included in these are excessive blood loss. In 26 (0.74%) of hysterectomies, hematoma formation or excessive blood loss was mentioned. Only six of these required transfusion (0.17%). These data date back to the time before the intelligent use of prophylactic antibiotic coverage was started. Presently I use antibiotics when either one or both tubes and ovaries are retained in both vaginal and abdominal cases. I also use antibiotics when the patient has had or has pelvic inflammatory disease, but not routinely in all hysterectomies.

How many deaths were associated with our series? There were three (0.086%): (1) fifth day postoperative—ventricular fibrillation and pulmonary edema, (2) fifth day postoperative—coronary occlusion, and (3) cardiac arrest in the recovery room.

I believe the authors have indicated the justification of a procedure which is not a rip off of the public and that they, as we, believe hysterectomy to be a valuable and necessary health-restoring surgical procedure.

DR. BRUCE C. RICHARDS, Lakewood, Colorado. Dr. Amirikia stated that as the frequency of hysterectomy has increased, the operation has become increasingly controversial, and I agree. Did you know that a woman's lifetime chance of having a hysterectomy in 1965 was 62%? Did you know that there were 751,000 hysterectomies done in 1976?[1]

Taking the PAS figures in 1972, the mortality rate for hysterectomy is 16.4 per 10,000. These figures, as you know, are taken from a broad range across the country. This is one half the mortality rate of appendectomy and one eighth that of cholecystectomy.[2] The mortality rate at Wayne State University–Hutzel Hospital for hysterectomies with 90% private patients is 26.4 per 10,000.

In the time available, I checked a sample of 1,065

consecutive hysterectomies done at a small hospital in Wheatridge, Colorado. There were no deaths. Without being able to prove it, I think there have been only two deaths in over 10,000 cases at this hospital.

The vast majority of these patients were white. The average hospital stay was 7.3 days abdominally and 6.3 vaginally vs. 10.5 and 11.5.

There were 60% of these hysterectomies performed vaginally compared with 33% in Detroit. Of those vaginal hysterectomies, 42% had a uterus weighing over 150 grams.

On a smaller sample (701) based on the same febrile morbidity definition, there were 26% with abdominal and 3% with vaginal hysterectomies vs. 16% and 26%. There *were* other complications that did not show as febrile. Notice, please, the great disparity in the vaginal figures and notice that morbidity and length of stay for vaginal hysterectomies are now less than abdominal.

I only wish to make one point. It certainly is not that the staff of that small hospital is any better than that of Hutzel Hospital in Detroit. In the first place, with prophylactic antibiotics, these recent statistics should be better than those from 10 years earlier. There were no radical hysterectomies. We do not have a residency staff. Our patients, I would have to think, would have over-all better health and probably less technically complicated surgery.

Although the authors promised to "clarify the various controversial points" regarding hysterectomy, they failed to do so. I also maintain that their figures, while impressive and coming from a large number of hysterectomies and a great Department of Gynecology, do not reflect the over-all statistics of the ordinary hospitals, where the vast majority of gynecologic work is done and done excellently. I would, therefore, suggest that their figures should not be accepted as standard.

DR. EVANS (Closing). I quite agree that there is probably no operative procedure carried out today that contributes more to improving the quality of life for women than does a hysterectomy, but it is important that we look very critically at the indications and the morbidity and mortality rates.

I think Dr. Richards should re-read the first paragraph. There was no promise to resolve the controversy; this study was undertaken in an attempt to try to resolve some of these issues. I now think that many of them can only be resolved in terms of prospective studies.

As we look into the future, I believe there will be a lot of differences in the categories of patients subjected to hysterectomy. For example, the large number who were operated on for bleeding without demonstrated pathologic change in the specimen is really no longer acceptable. Very, very few patients should ever have a hysterectomy just because of bleeding. That is an endocrine disease largely, and in most instances it can be treated medically and not surgically.

With regard to sterilization as an indication for hysterectomy, I agree with Dr. Hofmeister. I think, when there is a composite picture, where sterilization is a major consideration, but there are other concurrent indications, that perhaps there is a combined indication for hysterectomy. I support completely what Dr. Amirikia has said. There is no excuse for substituting a more major and riskier procedure for a simple, one-day in-and-out procedure to accomplish sterilization unless there are other indications as well.

Also, I think it would be pretty easy for many of the excellent gynecologic surgeons in this room to report a series of a thousand consecutive hysterectomies without appreciable morbidity or mortality rates, but there have to be institutions where this is not true. We have many, many high risk patients in our hospitals, and they are both in the private category as well as in the staff category. However, it is interesting to note that for 4 consecutive years the obstetric and perinatal mortality rates for the high-risk staff patients have been lower than for the private patients in the same institution. There have to be places for referral of high-risk patients. I am pretty sure if I were in private practice that a number of the patients in the mortality group would have ended up being referred to such a center as the Hutzel Hospital.

I am impressed about the low mortality rate in the patients with endometrial cancer. One died of bowel obstruction, another of sepsis. When you think of the tremendous number of high-risk patients subjected to operation for endometrial cancer, some weighing 300 and 400 pounds, I think such a low mortality rate is impressive.

I believe the final vote is not with respect to prophylactic antibiotics. I use prophylactic antibiotics as Dr. Hofmeister does, on a very selective basis in patients at high risk. I think the patient population that is being analyzed in terms of morbidity and death from hysterectomy is of critical importance. We all should look just as critically at posthysterectomy mortality cases as we do at maternal mortality cases to identify preventable factors to guide us in the future. Certainly we need to do an analysis of deaths in these patients.

Also, we should see fewer deaths in the future with the progressive decrease in the number of transfusions which are required. One can frequently avoid transfusions in patients even if they are severely anemic by giving them prophylactic progestogens and iron preoperatively. This can greatly reduce the risk of anemia, which can be greater than the risk of anesthesia.

I agree with Dr. Richards regarding the duration of hospitalization. I think it should be progressively shorter and shorter. This will be reflected by the nature

of the patient population, and whether they are at risk medically and or have been in the hospital for some days on the medical service before being subjected to operation. Over the 10 year period of Dr. Amirikia's investigation, there has been a progressive decline in the duration of hospitalization. Of course, there are variables, as exemplified by the patient who has a vaginal hysterectomy, as to whether there is a concurrent anterior and posterior repair done. The combined operation may be the reason for prolongation of hospitalization and not the vaginal hysterectomy alone.

One can do anything with statistical evaluations. I believe we should look very critically at each individual death. I hope, with the proper use of selective prophylactic antibiotics and low-dose anticoagulants, we can greatly reduce the mortality rate in the future.

Unsuspected subclinical pregnancies in patients with luteal phase defects

DONALD L. CLINE, M.D.
Indianapolis, Indiana

Patients with different types of luteal phase defects were studied with the use of the radioimmunoassay for the beta subunit of human chorionic gonadotropin (hCG) to determine if unsuspected subclinical pregnancies were more common in a particular type of defect. A type I luteal phase defect is always characterized by a chronologic lag in endometrial development when repeatedly studied with timed endometrial biopsies. A type II luteal phase defect is always characterized by an in phase endometrium when repeatedly studied by timed endometrial biopsies but always has less than a 14 day luteal span. All blood samples were drawn at least 7 days after ovulation/conception. In 22 cycles in which patients had a type I luteal phase defect, no subclinical pregnancies were detected. In 18 cycles in which a type II luteal phase defect was present, 12 instances of unsuspected subclinical pregnancy were detected and all ended in spontaneous abortion. This study shows that unsuspected subclinical pregnancies ending in abortion do occur and are quite commonly associated with the type II luteal phase defect. (AM. J. OBSTET. GYNECOL. 134:438, 1979.)

A CLASSIFICATION of luteal phase defects and possible etiologies was recently presented.[1] To review briefly, a type I luteal phase defect is characterized by a lag in the chronologic development of the endometrium with or without a short luteal span. The etiology of this defect is probably central. A type II luteal phase defect is characterized by in phase endometrial development but has a short luteal span. The etiology of this defect may be peripheral but is probably central, specifically a probable decrease in the length of time that luteinizing hormone (LH) is secreted from the pituitary.

Following this model one would expect to see few unsuspected subclinical pregnancies with a type I luteal phase defect because the endometrium is not adequately developed for proper implantation and placentation. Conversly, patients with a type II luteal phase defect would be expected to have frequent unsuspected subclinical pregnancies since the endometrium is developed in phase and will allow implantation and early placentation but the luteal phase duration is too short to allow the rescue phenomenon to occur.

Presented at the Forty-sixth Annual Meeting of the Central Association of Obstetricians and Gynecologists, Kansas City, Missouri, October 13-15, 1978.

Reprint requests: Dr. Donald L. Cline, 200 W. 86th St., Indianapolis, Indiana 46260.

Braunstein and associates[2] stated that the factors that predispose to early subclinical abortions are unknown. This study was conducted to determine if the detection of unsuspected subclinical pregnancies using radioimmunoassay of the beta subunit of human chorionic gonadotropin (hCG) would conform to the model presented and thereby elucidate at least one predisposing factor.[3]

Material and methods

Radioimmunoassay. The hCG beta subunit radioimmunoassay was used to measure hCG in serum samples.[3] There is no cross-reaction with human pituitary LH in physiologic concentrations.

Samples. Blood was obtained by venipuncture and the serum was rapidly separated from the clot and stored between −4° and −20° C until assayed. All samples were drawn at least 7 days after ovulation/conception. Any specimen with over 20 IU/ml was considered compatible with pregnancy.

Patients. Patients with various types of ovulatory defects and luteal phase defects were studied under a variety of treatment programs, utilizing the hCG beta subunit as an indicator of unsuspected subclinical pregnancy. These patients were all seen in my private infertility practice. All other causes of infertility had previously been investigated and either treated or ruled out.

Results

Seventeen patients were studied in the luteal phase utilizing the hCG beta subunit radioimmunoassay to detect subclinical pregnancies. Many patients were studied in more than one treatment cycle under various treatment regimens and therefore had different treatment cycles. For example, many patients with a type I luteal phase defect will experience conversion to a type II luteal phase defect under certain treatment regimens.[1] Table I shows 22 cycles in which the patient had a type I luteal phase defect and no subclinical pregnancies were detected. In 18 cycles in which a type II luteal phase defect was present, 12 instances of unsuspected subclinical pregnancy were found and in all 12 cases an early subclinical spontaneous abortion occurred. Tables II, III, and IV further clarify this study.

Comment

This study has shown and confirmed that subclinical abortions do occur. The cause of these subclinical abortions may at times be developmental abnormalities incompatible with life or a poor nidation site such as an intrauterine septum or myoma. This study, however, has shown that the type II luteal phase defect is quite commonly associated with subclinical spontaneous abortions.

Since no pregnancies were detected in 22 cycles in which a type I luteal phase defect existed, it can be assumed that an endometrium out of phase is usually not compatible with even early implantation and placentation. When patients with a type II luteal phase defect were studied, two of three showed unsuspected subclinical pregnancies which ended in subclinical

Table II. Menstrual cycles and treatment

Cycle	Total	No. without treatment	No. with treatment
Anovulatory	4	0	4
Type I defect	20	9	11
Type II defect	19	14	5
Viable pregnancy	16	1	15
Conversion to "in phase" endometrium	10	0	10
Total	69	24	45

Table III. β-hCG valves

Cycle	Total	No. without treatment		No. with treatment	
Anovulatory	4	0	(0*)	4	(0)

Viable pregnancy	16	1		15	
Conversion to "in phase" endometrium	10	0	(0)	10	(4)

*No. with β-hCG >3.2 IU/ml.

spontaneous abortions. Since the type II luteal phase defect by definition is characterized by an in phase endometrium but a short luteal span, one would anticipate these findings. Likewise, if one could lengthen the luteal span of patients with a type II luteal phase defect to allow the rescue phenomenon to occur, one would expect a considerable increase in salvageable subclinical pregnancies.

Table IV. Cycles terminating in subclinical abortion in eight patients with type II defects and β-hCG values <3.2 IU/ml

β-hCG (IU/ml)	Outcome: Serum sample drawn (days after ovulation)	Outcome: Bleeding began (days after ovulation)
Subclinical abortion:		
21.2	9	11
22.0	12	12
24.5	11	13
28.0	11	12
40.6	13	16
Clinically evident abortion:		
69.4	14	18
64.0	18	20
94.5	25	26

I would like to thank Dr. William Wahle of the Department of Pathology, St. Vincent Hospital and Health Care Center, Indianapolis, Indiana, for his assistance in performing the radioimmunoassay for the beta subunit of hCG and for his help in compiling the data used in this study. The assistance of the Department of Medical Affairs, St. Vincent Hospital and Health Care Center, is also greatly appreciated.

Discussion

Dr. Carolyn B. Coulam, Rochester, Minnesota. Dr. Cline's observation of the occurrence of subclinical pregnancies diagnosed by elevated β-subunit hCG in infertile patients has furnished a contribution to knowledge in this field. I am sure that he will not object to a slightly different interpretation of his data, especially since the conclusion is relatively similar.

Dr. Cline's Table I presents data on 17 patients in whom a total of 69 menstrual cycles are noted. Of the 69 cycles, four were described as anovulatory, 20 as type I luteal phase defects, 19 as type II luteal phase defects, 16 as viable pregnancy cycles, and 10 as cycles during which the endometrium converted to an "in phase" endometrial biopsy pattern. Of the 69 cycles described, there were 45 in which the patient was undergoing treatment and 24 in which no treatment was given, as summarized in Table II.

When those cycles in which a viable pregnancy was the outcome are eliminated, there were 13 instances in which a β-subunit hCG value was reported to be greater than 3.2 IU/ml, as shown in Table III.

At this point I would disagree with Dr. Cline's interpretation that a type I luteal phase defect is associated with no subclinical pregnancies because the endometrium is not adequately developed for proper implantation. The interpretation of Strott and colleagues[1] that the deficit is in the failure of adequate follicular maturation and ovulation rather than in luteinizing or "luteotrophic" hormone is a more likely explanation. Therefore, I would classify this group with the anovulatory cycles. Assuming that the remainder of the groups, including those with type II luteal phase defects as described, represent ovulatory cycles, a comparison of the pregnancy and abortion rates can be made between those receiving some form of treat-

ment and those receiving no treatment. I have placed the type II luteal phase defects in the ovulatory group because none of the cycles was described as having a luteal phase of less than 10 days.

Directing attention to only the ovulatory cycles in Table III, there are 15 cycles in which no treatment was received and 30 cycles during which various forms of treatment were undertaken. During the 30 treatment cycles, there were 20 pregnancies, for a pregnancy rate of 67%, and five abortions, for an abortion rate of 17%. These figures do not differ from expected pregnancy rates after induction of ovulation[2] or from previously reported spontaneous abortion rates.[3, 4] During the 15 nontreatment cycles, nine pregnancies occurred, for a pregnancy rate of 60%, which differs little from the pregnancy rate during the treatment cycles. However, eight of these nine pregnancies terminated in abortion, for an abortion rate of 53%—clearly higher than the expected rates previously reported. If we look closer at the eight cycles that terminated in abortion (Table IV), we can see that five of the eight could be classified as subclinical, because they occurred within the first 2 weeks of gestation. In the remaining three abortions, termination of pregnancy occurred after the second week of gestation and therefore would be clinically evident. These three clinically evident abortions represented a clinical abortion rate of 20%, which differs little from the spontaneous abortion rates previously reported, as above. This leaves a subclinical abortion rate of 33%, which is elevated over previously reported spontaneous abortion rates. However, I know of no data describing subclinical abortion rates as evidenced by elevated β-unit hCG in a normal fertile population. I am interested in knowing whether Dr. Cline has any such data to serve as a control.

Assuming that this subclinical abortion rate is elevated, an explanation for such an event can be gleaned by reviewing recent knowledge of receptor physiology. Follicular maturation and luteinization are associated with the appearance of receptors for follicle-stimulating hormone (FSH), estrogen, testosterone, LH, prolactin, and prostaglandins.[5] Once induced, normal corpus luteum function requires the continuous presence of small amounts of LH, and the decline of this function is associated with a decrease in the response of the luteal cells to gonadotropin. The inability of human corpus luteum cells to respond to LH in the late luteal phase may be associated with the loss of LH receptors. If corpus luteum dysfunction occurs because of a deficiency in LH receptors, and LH receptors are induced by FSH and augmented by estrogen, it is no difficult to envision a cause of this defect occurring before ovulation. It is not surprising, therefore, that this defect can be treated with ovulation-inducing drugs that enhance follicular maturation, as Dr. Cline's data suggest.

There is no evidence that other lutectropic hormones, such as prolactin, or luteolytic substances, such as prostaglandins, play a role in the human menstrual cycle. The one known luteotropin in man, hCG, which was present in the sera of Dr. Cline's patients in significant quantities, apparently was not sufficient to prevent subclinical pregnancy loss. This fact lends further support to a deficit in receptor activity as a cause of type II luteal phase defects, since LH and hCG receptors are probably the same.[6]

DR. ASGHAR AFSARI, Bloomfield, Michigan. The luteal phase defect is defined as an inadequacy of corpus luteum in the production of progesterone in either amount or duration or both.[1] The deficiency of function of the corpus luteum is now generally accepted as a definite but uncommon cause of infertility in women. Clinically it is regarded as causing an undesirable environment for a successful gestation by interfering with implantation or as causing an early occult abortion.[2] The incidence of this defective function is approximately 3.5% in a population of infertile patients. Similarly, among patients with habitual abortions, this problem is identified with a much higher frequency, in about 35% of cases. The higher incidence of an inadequate luteal phase among this particular group of patients is another indication of an endocrine problem rather than an anatomic anomaly.[5] The deficiency is not due to a single etiologic factor. Several factors have been implicated,[1] namely, defects of the hypothalamic-pituitary axis, ovarian defects, metabolic defects, and specific defects in luteal cell steroidogenesis. The relative deficiency of FSH during the follicular phase, an inappropriate FSH/LH ratio, and an inadequate tonic residual LH in the secretory phase are accepted to be the major causes of this entity. Moreover, a high level of prolactin, which may inhibit the cyclic pattern of FSH and LH secretion and thereby produce a luteal phase defect, has been suggested recently.[4]

The best result of treatment has been gained with the use of progesterone suppositories, with a success rate of 48% to 50% reported by Jones[1] and Soules.

In reviewing the manuscript, the tables were somewhat confusing and difficult to interpret. According to the tables, only one of 17 patients was not found to be pregnant, but the remaining patients were all respon-

sive to the therapy. This result is even more impressive after learning about the modalities of treatment. I wonder if Dr. Cline would elaborate on the results and the treatment, and also on any particular experience with the progesterone suppository.

Regarding the use of radioimmunoassay of the beta subunit of hCG, the incubation period of the test is described as being 24 to 72 hours, and I wonder if any consideration has been given to the use of radioreceptor assay (RRA) of hCG.[5] It has been proved that the quantitative RRA of hCG requires not more than a 15 minute incubation period and is highly sensitive, detecting as low as 6 mIU/ml or 0.5 ng/ml with the earliest detection time of hCG 6 to 8 days after ovulation. This might also help in further appropriate management and follow-up of these very anxious patients.

DR. R. RALPH MARGULIS, West Bloomfield, Michigan. The problem of luteal phase defect has been researched and widely discussed. This entity was initially brought to our attention by the presentation of Jones of the Johns Hopkins group although its validity has been doubted by many gynecologists.

I was interested in Dr. Cline's classification, based on length of luteal phase and type of endometrium. At William Beaumont Hospital in Royal Oak, we use a classification based on etiologic factors. For management purposes, this subdivides logically into two groups—those having normal prolactin levels and those with elevated prolactin levels.

Therefore, I would like to propose for clarification the following classification of deficient corpus luteum function, depending upon where the deficiency originates: (1) hypothalamic defect, (2) pituitary site, (3) ovary, and (4) partially unresponsive endometrium (theoretical, but not very likely). Those patients with this defect who demonstrate a normal serum prolactin level can usually be managed by the administration of clomiphene and/or hCG. A diminution in FSH production will in turn reduce the LH receptors of the follicular apparatus and, therefore, become a contributory factor in the eventual diminished production of progesterone. Clomiphene acts to increase FSH, thereby increasing follicular growth and, thus, producing increased estrogen and LH receptors. hCG acts as LH and leads to increased progesterone production. Management with progesterone alone will affect only the endometrium, since its influence on LH is unpredictable.

Many patients exhibiting this problem will have elevated levels of prolactin. Hyperprolactinemia will affect the hypothalamic release of gonadotropin-releasing hormone (GnRH), thus diminishing the secretion and release of FSH and LH from the pituitary. Through the mechanism discussed a moment ago, this indirectly leads to a reduction in progesterone. Cases with hyperprolactinemia may be successfully managed with bromocriptine (Parlodel) which will be effective at the hypothalamic, pituitary, and ovarian levels. Bromocriptine will: (1) increase dopamine receptors, thus increasing GnRH release, resulting in secretion and release of FSH, (2) decrease prolactin secretion by increasing the hypothalamic prolactin inhibiting factor, and (3) work directly on the ovarian follicular apparatus by blocking prolactin receptors and allowing LH receptors to function in stimulating production of progesterone. It has been proved that in the presence of increased prolactin, tissue cultures of granulosa cells do not produce progesterone. European investigators have been using bromocriptine successfully in correcting corpus luteum deficiencies.

PROFESSOR RONALD W. TAYLOR, London, England. We in our unit would agree with Dr. Cline in his conclusions. We have not used the same sort of classifications he has, but we have experience with 215 patients referred to us by other gynecologists in whom no obvious cause existed for their infertility. Prolactin levels within the upper limits of normal or above the limits of normal were found in more than 30% of these patients.

We have treated such patients both with clomiphene and with bromocriptine with 34 pregnancies resulting from clomiphene and 19 pregnancies from bromocriptine. An additional two patients became pregnant after treatment with hCG.

I very much endorse what has been said about the management of the patient with elevated prolactin values. This is important because it concerns the steroidogenesis in the corpus luteum. However, there is one additional factor which we have found in our investigations. We have been using Peridoxin (vitamin B_6) in a dose of 40 mg twice a day, providing patients do not have microadenoma of the pituitary which is responsible for the raised prolactin levels. There is something over a 60% chance that these patients will respond with a lowering of the elevated prolactin level. Unfortunately bromocriptine has many side effects. While we agree that it is very valuable, we recommend that a primary treatment in such patients be with Peridoxin because it is so innocuous and in our experience is very well worthwhile.

DR. JOHN S. GILLAM, Brekenridge, Minnesota. I

presented an almost identical paper 25 years ago, but I did not have the smart young men working with me that we have today. It has been very gratifying to hear of the clinical and laboratory correlations which have been revealed in this paper. I think that, like the work of Hertig, Rock, and Noyes, this research has contributed significantly to an improved understanding of this entity.

DR. JOE L. SIMPSON, Chicago, Illinois. While Dr. Cline is perhaps correct in assuming that there can be some subclinical pregnancies due to a type II luteal phase defect, I think it might be appropriate at this point to recall the weight of the evidence that suggests, in humans as well as in practically all animal studies, anomalies and chromosome abnormalities incompatible with life are certainly responsible for the loss of the vast majority of subclinical pregnancies.

For example, if we recall the work of Hertig and Rock who recovered preimplantation and early implanted embryos from a series of fertile patients, four of eight preimplanted embryos, which were less than 6 days of age, were so morphologically abnormal that continuation of the pregnancy could not have been expected. Likewise, among the early implanted embryos, the figures were something like eight of 26 which were incompatible with survival.

In very early preimplanted embryos from rodent species, it can be shown that a vast majority of chromosomal abnormalities present are not compatible with continued embryonic development. For example, YO mice can be recovered at the four-cell stage and monosomies and trisomies demonstrated. I think that the findings that Dr. Cline has shown us are quite relevant, but it should be remembered that his thesis is applicable to only a specific subset of the population. Overall, I think it is wise to remember that the vast majority of early losses are likely to be of genetic rather than endocrine etiology.

DR. CLINE (Closing). Regarding the comments of Dr. Coulam, I think she and I agree. My feeling is that the endometrium in the type I luteal phase defect is not in phase because of an inadequate, immature follicle.

Since I wrote this original small paper, we have studied various treatment modalities, and I have found that the preovulatory urinary estrogen level is always less than 50 μg/24 hours prior to the LH surge in the type I luteal phase defect. Once this defect is either converted or corrected, it goes hand in hand that the urinary estrogen excretion always rises to over 70 μg/24 hours in the treatment study. I think this goes along with the concept of the inadequately mature follicle.

I personally do not have any hCG data in a normal population.

Regarding Dr. Afsari's comments about luteal phase defects being uncommon, I will take considerable issue with that because I find these defects to be extremely common, and I, too, have many referrals from doctors who have done everything they can in treatment of patients. Most of these patients have been on a regimen of clomiphene for months and months and months.

What I am trying to say is that when a patient has had long-term clomiphene administration, rebiopsy should be performed. Just because these patients "look good on paper," they ovulate, and they have a 14 day luteal phase does not mean that they cannot have an endometrium completely out of phase and a preovulatory urinary estrogen excretion of less than 50 μg/24 hours. We have adopted, in my office, a philosophy of treat and biopsy, treat and biopsy, etc., until the defect is either converted or corrected.

Some of these patients will experience correction with Clomid or Clomid, Premarin, and hCG, and then Pergonal therapy will result in correction.

I did not use the radioreceptor assay because at the time I considered it probably not sensitive enough and still consider this to be true.

Regarding the question of receptors, this is certainly interesting and almost certainly correct and probably goes along with the estrogen studies that we have available now, but the preovulatory estrogen studies we have now have not been presented or published.

Regarding Dr. Taylor's comment, I personally have not studied ovulatory patients, regarding the prolactin levels, but certainly appreciate his comments and probably will do so in the future.

Finally, concerning the genetic aspect of all of this, I, too, have found translocation carriers in patients with early subclinical abortions but have not been able successfully to treat them and did not try.

Ovarian hyperandrogenism with normal and abnormal histologic findings of the ovaries

MOON H. KIM, M.D.
ROBERT L. ROSENFIELD, M.D.
ABDOL H. HOSSEINIAN, M.D.*
HARVEY G. SCHNEIR, M.D.
Columbus, Ohio, and Chicago, Illinois

Thirty-one patients with clinical features of polycystic ovary syndrome (PCO) were studied to determine the correlation between biochemical and histologic findings. The biochemical features investigated were the effects of adrenocortical and ovarian suppression by dexamethasone and oral contraceptives (Ovulen) on plasma free androgens. Four patients showed a histologic picture consistent with PCO (Group A), and five had histologically normal ovaries (Group B). The remaining 22 patients had no tissue available for histologic examination (Group C). The baseline values of plasma free testosterone (FTeI) were higher and those of testosterone-binding globulin (TeBG) were lower ($p < 0.05$) in Group A than in Group B, although plasma total testosterone (T) and the free 17β-hydroxysteroid androgen index (FHSI) were similar in the two groups. During dexamethasone administration in all study groups, T and FTeI fell slightly (17.7% to 33.8%), and FHSI levels decreased moderately (36% to 46.6%); in no case did both indices of free androgen levels fall to the normal range for dexamethasone-suppressed women. However, no change was noted in TeBG in all three groups. On the other hand, Ovulen treatment suppressed T and free androgens to normal in all groups, and raised TeBG more than 350% from the baseline. These data suggest a decrease in androgen production. The effects of dexamethasone and Ovulen on all three groups were similar in *percent* changes. As Group B patients resemble those of Group A biochemically and clinically, except for possibly being less hyperandrogenic, the concept of ovarian hyperandrogenism should be expanded to include patients with no anatomic ovarian abnormality, particularly in milder cases. (AM. J. OBSTET. GYNECOL. 134:445, 1979.)

POLYCYSTIC OVARY SYNDROME (PCO) commonly refers to patients with the clinical features of menstrual irregularity and variable degrees of obesity and hirsutism. This syndrome is characterized biochemically by excessive ovarian secretion of androgens as evidenced by increased levels of androstenedione (A) and testosterone (T) in the ovarian vein plasma and by increased free plasma androgens.[1, 2, 3] Also the testosterone-binding globulin (TeBG) capacity is significantly lower in women with PCO than in normal women.[3, 4] The gross characteristics of the ovaries in this syndrome are typically moderately enlarged, pearly white, sclerotic, and polycystic. There appear to be no unique histologic features of PCO.[5] Although capsular thickening, theca cell luteinization, stromal hyperplasia, and microfollicular "cysts" representing follicles arrested at various stages of development are thought to be histologically characteristic of polycystic ovaries, little information is available to correlate biochemical and histologic parameters.

In the present study we measured the plasma levels of total and free (unbound) androgens and TeBG capacity in patients with the clinical diagnosis of PCO and correlated biochemical parameters with histologic findings. Also the effects of estrogen-progestin on total and free androgens and TeBG were studied.

Material and methods

Study subjects. Thirty-one patients with the clinical features of PCO were studied. All patients had biochemical evidence of hyperandrogenism as indicated by elevated plasma levels of T, free testosterone index (FTeI), or free 17β-hydroxysteroid androgen index (FHSI), often with low TeBG capacity.[6] No subject had evidence of any other endocrinopathy, and none had received any hormonal medication for at least one month prior to the study. Baseline blood samples were obtained. The patients were then given dexamethasone, 0.5 mg every 6 hours orally for 3 days. At this time of adrenocortical suppression blood samples were again collected. The patients were then placed on a regimen of mestranol, 0.1 mg, and ethynodiol diacetate, 1 mg (Ovulen*) daily, and they had blood samples drawn between 14 and 21 days of medication. Blood samples were also taken from seven normal women with regular menstruations before and 18 to 21 days after the daily administration of Ovulen. All blood samples were collected between 8:00 and 10:00 A.M. Plasma was separated and kept at −18° C until the time of analysis.

Hormone assays and histologic examination. Plasma T, FTeI, FHSI, and TeBG capacity were determined by competitive protein-binding methods.[6, 7] 17β-Hydroxysteroid androgens are the total ether-extractable substances in plasma which have a high

*Ovulen, G. D. Searle & Co., Chicago, Illinois.

affinity for TeBG; two thirds of these substances in normal women are composed of dihydrotestosterone (DHT), androstenediol, and androstanediol, as well as testosterone.[8] These assay methods possess interassay coefficients of variation of 11%, 11.4%, 6%, and 13% for T, FTeI, FHSI, and TeBG, respectively.

In nine patients, ovarian tissue was available for histologic evaluation (hematoxylin and eosin stain). The tissue samples were obtained by multiple biopsies via laparoscopy in six patients and by wedge resection of the ovaries in two patients. The specimen from one patient was obtained following oophorectomy. The presence of any of the following findings was considered consistent with PCO: thick capsule, thecal luteinization, stromal hyperplasia, and multiple microfollicular cysts.[5] Four patients showed PCO pictures (Group A), and five had histologically normal ovaries (Group B). The remaining 22 patients did not have any tissue available for examination (Group C).

Results

Clinical data. The clinical features and ovarian histology of Group A and Group B are shown in Table I. Except for the histologic findings, there were no clear differences clinically between the groups. Group B patients tended to have less severe hirsutism.

Androgens in normal women. In seven normal women who served as controls, the baseline plasma levels (mean ± SEM) of T, FTeI, FHSI, and TeBG were 46 ± 5.3 ng/100 ml and 9.2 ± 0.5, 62.2 ± 3.9, and 41.9 ± 5.4 μg/L, respectively. Ovulen suppression reduced the mean levels of T, FTeI, and FHSI to 31.2 ± 3.7 ng/100 ml and 1.9 ± 0.5 and 22.8 ± 6.5 μg/L (mean changes of 32.2%, 80%, and 63.3%), respectively. On the other hand, the mean level of TeBG was increased to 82.8 ± 3.6 μg/L. The effects of dexamethasone suppression on these androgen parameters in normal women have been previously reported.[9]

Plasma T (Fig. 1). Although the mean control level of T in Group A was higher than in Groups B and C (Table II), the difference was not significant. With dexamethasone suppression the plasma levels of T fell in Groups A, B, and C (17.7%, 22.9%, and 33.8%, respectively). These changes were not significant. However, with Ovulen suppression, T levels normalized in all groups, decreasing by 50% or more (Table II). These values are significantly different from the control levels. While T levels as a group fell significantly, it is noteworthy that individually some did not show a significant reduction.

Plasma FTeI. In contrast to the levels of plasma T, a significant difference ($p < 0.05$) was noted in the mean control levels of plasma FTeI between Group A and

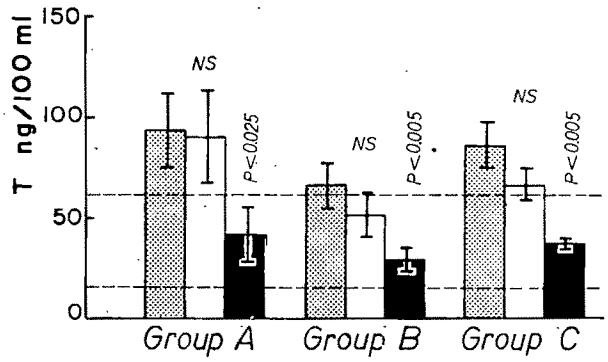

Fig. 1. Plasma levels (mean ± SEM) of total testosterone in three study groups of clinical PCO: Group A (positive histology for PCO), Group B (normal histology), and Group C (histology not studied). The shaded, white, and black bars respectively represent control values and values following dexamethasone and Ovulen suppression. The significance of the change from control was obtained by Student's t test (paired) with one tail. The dotted lines represent normal control ranges. NS: Not significant.

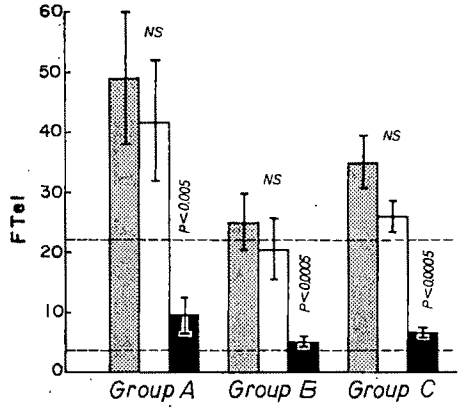

Fig. 2. Plasma levels (mean ± SEM) of FTeI. For explanations see Fig. 1 legend.

Group B (Table II). This is probably related to the lower TeBG levels of Group A. Dexamethasone suppression resulted in decreases of FTeI levels in all groups, although these changes were not significant (Fig. 2). On the other hand, the differences between the control levels and the levels with Ovulen treatment were highly significant in all three groups. The degree of decrease was comparable in all groups, ranging from 75.5% to 82.7%, and Ovulen treatment consistently normalized the levels of FTeI in all individual patients.

Plasma FHSI. The mean control level of Group A was higher, but not significantly, than that for Group B (Table II). As noted in Fig. 3, both suppressive treatments significantly reduced the levels of FHSI in all three groups. The FHSI decreased more than the FTeI and T with dexamethasone suppression (36%, 45%, and 46.6% in Groups A, B and C, respectively). With

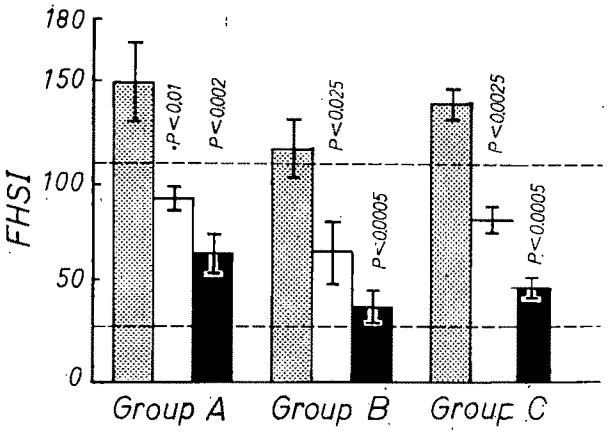

Fig. 3. Plasma levels (mean ± SEM) of FHSI. For explanations see Fig. 1 legend.

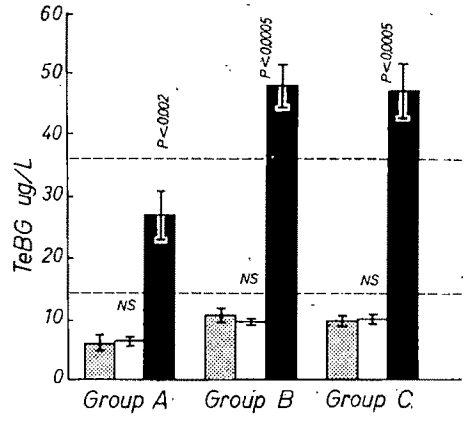

Fig. 4. Plasma levels (mean ± SEM) of TeBG capacity. For explanations see Fig. 1 legend.

Ovulen suppression, the FHSI, just as the FTeI, was again reduced to the normal range. The degree of suppression was the same in all groups (58% to 78%).

TeBG capacity. Plasma TeBG levels in all three groups were below the normal range. The difference between Group A and Group B was significant ($p < 0.025$). With dexamethasone suppression essentially no changes in TeBG levels were noted. However, Ovulen treatment resulted in a marked increase (over 350%) in TeBG levels in all groups (Fig. 4). This significant increase is believed to be due to the estrogenic component of Ovulen.

Comment

Patients with the clinical features of PCO typically have elevated plasma free androgen levels which are not normally suppressed by dexamethasone.[3-9] Assuming that dexamethasone in the dosage used in the study did not affect ovarian function,[9, 16, 17] lack of a significant reduction in FTeI and FHSI with dexamethasone suppression probably indicates the main source of androgens in the study patients to be the ovary.

Polycystic ovaries are typically enlarged, pearly white, sclerotic, and multicystic. However, the gross appearance is variable, as is the symptomatology.[10, 11] Despite numerous studies, there appear to be no unique diagnostic histologic features of PCO.[5, 10] In our nine patients with ovarian hyperandrogenism, defined by the above clinical and endocrinologic criteria, in whom ovarian tissue was available for histologic examination, four showed the histologic features of PCO. The ovaries of five patients were histologically normal. Although multiple biopsies might not have been representative of the entire ovaries, the findings suggest that ovarian hyperandrogenism can be associated with histologically normal ovaries.

The baseline free testosterone level in Group A patients (with PCO histology) was slightly higher ($p < 0.05$) than in Group B patients (with normal histology), although the difference in the FHSI was not significant. Therefore, it is possible that the amount of ovarian androgen production may parallel the degree of histologic change. Since it has been shown that the stromal compartment is the major source of androgen production in the ovary,[12] obvious stromal change might be expected to correlate with androgen levels.

All study groups showed low TeBG. This finding is in agreement with previously reported findings.[3, 14] Since obesity is commonly associated with low TeBG capacity, it may be partly related to the difference in TeBG levels between Group A and Group B.[3, 13] TeBG is a major determinant of androgen binding in plasma, the percentage of free testosterone being inversely related to the TeBG levels and representing the biologically active moiety.[6] High levels of FTeI and FHSI are the results of increased production of androgens and low TeBG capacity.

The pharmacologic effects and clinical significance of dexamethasone suppression in hyperandrogenic conditions should be interpreted with caution because of various controversial reports.[15, 16, 18] Several studies have shown that pituitary-ovarian suppression was more effective than pituitary-adrenal suppression in the treatment of hirsutism.[18-20] Our data provide an explanation for this by indicating that plasma free androgens are more markedly depressed by this treatment than are total plasma androgens.

The significant reduction of plasma T and FTeI (50% and 75.5%, respectively) levels in our patients during Ovulen treatment is obviously greater than the changes during dexamethasone suppression. Suppression of plasma T of a similar magnitude has been reported in women with PCO using other sex steroids.[21-23] The fact that plasma T levels decreased in

the presence of elevated TeBG indicates a reduction in T production since TeBG is a major determinant of T metabolism,[8] and this agrees with other investigations.[9, 20] The marked reduction of FTeI and FHSI then is probably due to decreased ovarian production of androgens and increased levels of TeBG capacity. The magnitude of suppression of plasma T, FTeI, and FHSI levels during Ovulen treatment was similar between Group A and Group B. This finding suggests that histologically normal ovaries can be the major source of ovarian hyperandrogenism. It is noteworthy that with Ovulen suppression the magnitudes of percent changes of T, FTeI, and FHSI levels in the study patients were comparable to those in normal control women; however, the levels of free androgens remained considerably higher than those in normal women. One should interpret the response of plasma androgen levels to estrogen-progestin treatment with caution as there is a question of some suppressive effects of estrogen-progestin on the pituitary-adrenal axis.[24, 25]

In all patients in the study, Ovulen treatment induced a marked increase in the levels of TeBG capacity (over 350% increase). It reflects the effect of estrogen component. Givens and associates[20] reported a similar finding using other estrogen-progestin combination. The effectiveness of raising the plasma TeBG levels appears to be variable, depending on the amount of estrogen and the type of progestin given.[20, 26]

The data presented suggest that the ovary is the source of hyperandrogenism in hirsute, oligomenorrheic patients in whom dexamethasone suppressibility is poor. Furthermore, Group B patients are identified as having an entity which clinically, biochemically, and functionally resembles Group A (PCO) but has normal ovarian histology. Therefore, the concept of ovarian hyperandrogenism should be expanded to include patients with no anatomic ovarian abnormality. Group A (PCO) and Group B (variant of ovarian hyperandrogenism with normal histology) may differ only in the degree of hyperandrogenism and ovarian histology. In view of the good correlation between the levels of luteinizing hormone (LH), androstenedione, and T during ovarian suppression and recovery from such suppression,[20] this difference may depend on the degree and chronicity of inappropriate LH secretion.[27] The results of the study show that estrogen-progestin preparations are more effective in correcting ovarian hyperandrogenism than expected from the measurement of plasma total T levels.

Discussion

Dr. Richard F. Mattingly, Milwaukee, Wisconsin. This is a very interesting, detailed, and sophisticated study of androgen metabolism.

This study of 31 women with elevated plasma androgen levels adds further information to the increasing body of knowledge of androgen biosynthesis and distribution. The authors have utilized an advanced radio-

immunoassay technique in measuring plasma T, FTeI, and FHSI as well as the TeBG capacity in this group of hirsuit women. All of this is highly technical work, which gives credence to the authors' findings.

This study represents an attempt by knowledgeable investigators to correlate biochemical events in steroid metabolism with histologic changes in the ovary. Their message to us today, following an elaborate metabolic study of various free and bound plasma androgens, is that the ovary is the source of the excess androgen in this group of cases and that the concept of ovarian hyperandrogenism should be expanded to include a group of women with histologically normal ovaries.

While these conclusions may be correct, one must question whether or not there is sufficient evidence in this study to substantiate this theory. Indeed it is our proposal that this report may be somewhat premature and that further studies will be required to clarify these preliminary observations.

Basically, the study of ovarian tissue in only nine of 31 cases (29%) provides much too limited histologic information to draw any conclusions regarding the androgen function of normal ovaries in hirsuit women. More importantly, the authors attempted to further divide their study of these nine cases into two groups (A and B) and those that showed no histologic abnormality (five cases). We submit that this division of cases is somewhat artificial since laparoscopic biopsy of the ovarian cortex provides only limited histologic information and may completely exclude the important medullary components of the gonad.

It would be difficult to say that the normal ovaries do not contain areas of hyperthecosis. This condition was originally described by Frankel (1943) and without a medullary biopsy this diagnosis can be made only by wedge resection.

The differential diagnosis between the so-called PCO and hyperthecosis is important in that there is much more virilization and a significant degree of androgen excess in the hyperthecosis ovary, and these ovaries do not respond well to clomiphene stimulation of ovulation. Such cases are always associated with hirsutism and with mild virilization.[1]

In contrast, only 50% of the cases with PCO will show hirsutism.

We are also concerned about the interpretation drawn from this brief, 3 day course of adrenal suppression with low-dose dexamethasone. Most investigators in the field have extended the adrenal suppression period for a minimum of 5 days and, more frequently, for a period of 7 days. We have not used the 2 week dexamethasone suppression test as advocated by Abraham and Busher,[2] but we are mindful of the fact that normal plasma levels of cortisol (F) do not provide conclusive evidence of complete suppression of the zona reticularis of the adrenal cortex. More conclusive information of adrenal suppression is available by measuring dehydroepiandrosterone sulfate, a "prehormone" which is excreted almost exclusively by the adrenal cortex. The fact that there was no statistically significant suppression of plasma androgens in this study, using a 3 day, low-dose dexamethasone technique, indicates that longer suppression studies are necessary before the adrenal source of androgen excess can be excluded. This, of course, is very important since the clinical management of patients with an adrenal source of androgen excess is much more difficult than that of patients with an ovarian source. We are also reluctant to rely on the levels of free 17β-hydroxysteroids as a sensitive monitor of androgen excess since this assay contains what we call a "mixed bag" of plasma androgens and may indeed mask the subtle rise in dihydrotestosterone (DHT) and their clinical effect on hirsutism. DHT levels would need to be elevated as much as four times according to Abraham and Busher[2] in order to increase this 17β-hydroxysteroid level to any significant clinical degree. We would be interested to know why the authors chose this specific assay in preference to measuring DHT.

This is an interesting study of a very complex problem of androgen dynamics. Distinct advances have been made in the past decade which more clearly define the specific hormones or "prehormones" that are involved in androgen metabolism and hirsutism. These advances have been made by the availability of sensitive radioassay studies. In the clinical interpretation of these highly sophisticated steroid studies, one must be cautious to avoid drawing conclusions from limited studies. In this regard, the hypothesis that androgen excess may be produced in normal ovarian tissues is an attractive, but as yet unproved theory since only one of the five cases with normal ovarian biopsies had adequate tissue for histologic interpretation.

To accept this theory would require histochemical evidence of a defect in the conversion of androgens to estrogens in a histologically normal-appearing ovary, as is seen occasionally in the conversion of testosterone to estradiol. There is a specific syndrome, 17β-reductase deficiency, in which this occurs, but we question if all these cases had this particular problem.

It may be preferable to combine the groups of cases and data, as well as the observations noted in the ovarian biopsies. When further studies are available, which include wedge resection of the ovaries, to determine the presence or absence of hyperthecosis, a more definitive statement can be made regarding the correlation of ovarian histology and ovarian hyperandrogenism.

DR. GEORGE D. WILBANKS, Chicago, Illinois. Dr. Kim and his associates have presented some very interesting data from 31 patients with clinical features of PCO, 27 of whom possibly did not have ovaries that were "polycystic." They classified these patients by biochemical "ovarian hyperandrogenism" rather than by histologic changes in the ovary. The authors have added some valuable information on this perplexing syndrome (or syndromes) but there still remain significant questions as to the contribution of adrenal androgens to the disease process.

The etiology of polycystic ovaries has been the subject of considerable discussion in the literature.[1] The role of the hypothalamus, the involvement of the ovaries, and the probable involvement of the adrenals are widely discussed problems. In most cases such patients may have, in addition to the polycystic ovaries, the typical clinical syndrome characterized by hirsutism, menstrual irregularities, and infertility. Such a clinical syndrome, however, is not necessarily associated with "polycystic ovaries" as this study shows. It seems more important to determine whether in such a syndrome there is hyperandrogenism rather than to start with the enlarged ovaries. This study, with good laboratory evaluation, proves that in all such patients one can document hyperandrogenism.

The next problem is to determine the source of the hyperandrogenism. There have been conflicting reports in the literature as to the relative role of the ovary and adrenal, which may reflect methodology and types of tests used rather than actual gland involvement.[2, 3] For example, certain studies by adrenal and ovarian vein catheterization suggest the ovary to be primarily involved; many others, utilizing adrenal suppression or stimulation tests, have suggested significant involvement of the adrenal, alone or in combination with the ovary.

The authors' study suggests that hirsutism is an ovarian problem. The method utilized depends on measuring (1) plasma T, (2) the FTeI, and (3) the free 17β-hydroxysteroid index. The 17β-hydroxysteroids are T, DHT, androstenediol, and androstanediol. Androgens like androstenedione, dehydroepiandrosterone (DHEA), and dehydroepiandrosterone sulfate (DHEA-S) are not measured by this method. The above methodology is based on the assumption that an index of the free androgen portion, i.e., the biologically active one, would be more meaningful. Rosenfield[4] has shown over the years that one can indeed document hyperandrogenism by much methods in patients with normal total T levels, who otherwise would have been considered normal. The reported results, however, may not conclusively indicate that the adrenal is not involved in that the 3 day dexamethasone suppression test is not long enough to adequately suppress adrenal androgen function, although it may suppress corticosteroid function. Had the suppression been longer, the observed drop may have been greater in these patients. Second, the observed lowering of androgens by Ovulen does not necessarily imply ovarian suppression because the increase in binding globulin leads to an increase in cortisol and a subsequent drop of adrenocorticotropic hormone which results in a drop of adrenal androgens.[5] The fact that patients with normal ovaries and those without biopsy showed a greater dexamethasone suppression may also support this point, i.e., that the patients with histologically "normal" ovaries and ovaries not examined had a significant adrenal component. Third, since DHEA-sulfate was not measured, a significant adrenal androgen component was not determined. Would Dr. Kim please comment on these points.

If indeed the measurement of these biochemical parameters indicates that there is no special diagnostic clinical features for patients with truly histologic polycystic ovaries and those with normal histology, this would eliminate the need for ovarian biopsies in establishing the diagnosis. If Ovulen treatment is effective in decreasing the hyperandrogenism in these patients, this would certainly simplify the treatment. Did the Ovulen treatment retard the hirsutism? Finally, if indeed these tests do indicate a primary ovarian involvement, are there specific clinical signs and symptoms, such as menstrual irregularity, anovulation, and infertility, that characterize this variant of the syndrome?

DR. JAMES A. MERRILL, Oklahoma City, Oklahoma. I think the authors have done an excellent job of illustrating that the critical issue is to identify patients with a syndrome of anovulation and hyperandrogenicity, determine from measurement of various biochemical parameters the probable origin of the biochemical defect, and then hopefully correct it. If one studies the morphology of the ovary, it will be found that those characteristics described as being typical of PCO may be found in a variety of related and unrelated disorders, including injuries to the central nervous system and spinal cord injuries, just to mention a few.

I think that the time when gross and microscopic

pathology of the ovary should be considered a cardinal feature in the diagnosis and/or treatment of this clinical syndrome has been gone for a long time. What Dr. Kim has said here today simply re-emphasizes that point and does so, in my opinion, in a very fine way.

DR. EDUARD EICHNER, Cleveland, Ohio. I have had a couple of patients with Stein-Leventhal ovaries who under stimulation of Clomid and gonadotropins apparently ovulated with the basal body temperature showing a normal ovulatory phase. When pregnancy failed to occur, wedge resection of the ovaries was carried out and under the microscope none of the specimens had a corpora albicans. This means that even though we had endometrium that suggested ovulation and basal body temperature that suggested ovulation, ovulation apparently had not occurred. Both of these patients became pregnant after wedge resection and were delivered at term.

DR. KIM (Closing). The last comment made by Dr. Merrill was indeed very important as one of the points in this study was to show that histologic evaluation or laparoscopic visualization of the ovaries really adds little in terms of making a diagnosis of ovarian hyperandrogenism and formulating a therapeutic approach. It is primarily a biochemical abnormality and is best dealt with biochemically.

Drs. Mattingly and Wilbanks had several important comments and questions. As to the question of biopsy not representing the entire ovaries, it is obviously an inevitable disadvantage of any form of biopsy. However, any possibility of misrepresenting the ovaries would have been smaller when multiple biopsies were taken. Certainly deep stromal tissue could have been missed. As far as the length of dexamethasone suppression is concerned, we are interested in the diagnostic application of such treatment. It is logical to find out if the population in study is different from the normal population. We have reported previously that in normal women dexamethasone suppression for 3 to 4 days would suppress not only the cortisol level but also most of the androgenic parameters studied. Therefore, we elected to use a 3 day suppression. As mentioned by Dr. Mattingly, it may take longer than 4 days to see any therapeutic effects of dexamethasone. For a diagnostic purpose the 3 to 4 day suppression would be adequate and informative as shown in this study.

Dr. Mattingly suggested the measurement of dehydroepiandrosterone sulfate (DHAS). Certainly it is the most abundant circulating androgen but the biologically least potent one. It is mainly from the adrenals, serving as a precursor, and has a very little significance in clinical androgenicity. Therefore, we limited hormone measurements to the biologically potent androgens. The reason for measuring the plasma FHSI was based on our previous studies that it represented the unbound 17β-hydroxysteroid androgens. A total of 75% of 17β-hydroxysteroid androgens in plasma, dihydrotestosterone, androstenediol, and the isomers of androstanediol, in addition to testosterone, would be measured in our assay. It represents an overall androgenic picture.

Dr. Wilbanks raised a practical question whether or not the estrogen-progestin treatment did improve hirsutism. Although I have no data to support it, my impression is that some of the patients did show clinical improvement. Documentation of clinical improvement of hirsutism parallel to biochemical improvement in a large series of cases should be done. As to the question of the primary ovarian involvement as a cause of ovarian hyperandrogenism, I do not think this is the case. The studies have shown that inappropriate LH/follicle-stimulating hormone secretion is operational as a cause of the syndrome. Our data simply indicate that ovarian hyperandrogenism, when encountered, is probably a gonadotropin-dependent condition rather than a primary ovarian disease. Regarding whether or not the adrenal components were ruled out, I cannot say that they were. Although there have been some studies suggesting a possible suppressive effect of oral contraceptive pills on adrenocorticotropic hormone–dependent adrenal function, it is probably not the case in ovarian hyperandrogenism. Because of an increase in the corticosteroid-binding globulin level during oral contraceptive treatment, one finds elevated cortisol levels which may affect adrenocorticotropic hormone–dependent adrenocortical function. But in our study the levels of T and TeBG behaved quite differently, suggesting that the adrenal component, if any, was negligible.

RICHARD E. SYMMONDS, M.D.
Rochester, Minnesota

A review of 106 patients with Stage I squamous cell cancer of the vulva treated at the Mayo Clinic from 1950 through 1975 is presented. Microinvasive lesions (5 mm penetration or less) were present in 96 patients (91%); invasive lesions (more than 5 mm penetration) were diagnosed in 10 (9%). Inguinal node involvement was present in nine patients (8.4%); one of these also had pelvic node involvement. Recurrence developed in 13 patients (12%). Four patients experienced inguinal node metastasis after initial surgical therapy. The incidence of positive nodes among patients with lesions invading the stroma for 3 mm or less was 3%. Thus, individualization for inguinal lymphadenectomy may be possible according to the age and condition of the patient when the depth of invasion is 3 mm or less. (AM. J. OBSTET. GYNECOL. 134:453, 1979.)

STAGE I SQUAMOUS CELL CANCER of the vulva[1] includes lesions, confined to the vulva, of 2 cm or less in largest diameter, in the absence of palpable, or with palpable but not clinically suspicious, lymph nodes in the groin (T1N0M0; T1N1M0). There is no general agreement regarding the extent of surgical therapy suitable for patients who have such lesions. Attention has been paid to the histologic features of the lesions[2, 3] as a basis of selecting patients for whom dissection of nodes can be avoided. However, several reports tend to indicate that early invasive carcinoma of the vulva may not behave like its counterpart in the cervix and that lymphadenectomy should be included in the initial therapy.

This study was designed to evaluate clinical and histologic factors that may affect prognosis and to outline a therapeutic approach for patients who have Stage I squamous cell cancer of the vulva.

Material and methods

The records of 693 patients with vulvar malignancy seen at the Mayo Clinic from January 1, 1950, through December 31, 1975, were reviewed. Vulvar lesions 2 cm or less in size were present in 151 patients. Excluded from this group were patients with vulvar malignancies other than epidermoid carcinoma (19), recurrent (seven) or metastatic (two) tumors, other concomitant pelvic malignancies (one), suspicious inguinal nodes (one), extension into the vagina, urethra, or perineum (seven), lesions with doubtful invasion (two), and cases with no available tissue slides (six). All patients were staged retrospectively according to the criteria of the International Federation of Gynecology and Obstetrics.[1] Stage I squamous cell cancer of the vulva was diagnosed in 106 patients, and these patients constitute the material for this study.

The records of these patients were reviewed for age, symptoms, and duration of symptoms, associated illnesses and vulvar diseases, previous medical vulvar therapy, treatment, recurrences, and outcome. Particular attention was paid to size, site, and number of lesions and to lymph node involvement. The slides from surgical specimens or preoperative biopsies (if excisional) were reviewed in all patients with reference to depth of invasion, tumor cell type, tumor differentiation, microscopic confluence, and vascular and lymphatic permeation.

Depth of invasion was measured from the surface of the squamous epithelium. If an ulcerated lesion was present, it was measured from the surface of the adjacent epithelium. Microinvasion was said to be present when there was 5 mm or less of stromal penetration and invasion, when penetration was more than 5 mm.

From the Mayo Clinic and Mayo Foundation.

Presented at the Forty-sixth Annual Meeting of the Central Association of Obstetricians and Gynecologists, Kansas City, Missouri, October 13-15, 1978.

Table I. Surgical procedures

Procedure	*No.*
Radical vulvectomy with bilateral groin node dissection	34
Radical vulvectomy with bilateral groin and pelvic node dissection	34
Radical vulvectomy with second-stage groin node dissection	3
Radical vulvectomy	10
Simple vulvectomy	17
Hemivulvectomy	2
Wide local excision	3
Local excision	3
Total	106

Confluence was defined as a group of tumor cells filling an area of 2 mm or more. A group of tumor cells surrounded by a definite endothelial lining was considered lymphatic permeation; the presence of blood elements was an essential requirement for the diagnosis of vascular permeation.

We have considered recurrence to be those lesions arising in a previously excised area—vulva, groin, or pelvis. Postoperative metastases are lesions arising in a previously untreated area, either groin or pelvis.

Results

Age and symptoms. The age of the patients ranged from 30 to 87 years (mean, 61 years). Thirty-three patients were nulliparous. Pruritus was the most common presenting symptom in 79 patients (75%). Other presenting symptomatology included ulceration in 58 patients (55%), tumoral induration or mass in 43 (41%), pain in 26 (25%), and bleeding in nine (8%).

Duration of symptoms was less than 1 year in 40 patients (38%) and 1 or more years in 66 (62%). Fourteen patients (13%) had symptoms for more than 10 years. Duration of symptoms did not correlate with size of the lesions, lymph node involvement, recurrences, or survival.

Associated illnesses. Associated illnesses included hypertension in 22 patients, diabetes in eight, thyroid disease in seven, skin diseases in six, and rheumatoid arthritis, multiple sclerosis, and chronic ulcerative colitis in one patient each.

Associated malignancies. Previous or subsequent malignancies occurred in 28 patients; they included seven cervical, six mammary, three uterine, two ovarian, two cutaneous, and two rectal lesions, and one case each involving the colon, anus, esophagus, tongue, larynx, and vagina (carcinoma in situ).

Associated vulvar diseases. Associated vulvar diseases were present in 85 patients (80%). They included vulvar dystrophy in 74 (70%) (atrophic in nine, hypertrophic in 41, and unspecified, when no previous biopsies were available, in 24), carcinoma in situ in 24 (23%), dysplasia in three (3%), and chronic vulvovaginitis in six (6%). None of the patients had venereal vulvar disease.

Of the 24 patients with coexisting in situ cancers, 16 had a single in situ lesion and eight had two or more lesions. In one of these patients an invasive recurrence developed. There were no in situ recurrences. None of these patients died of vulvar carcinoma.

Before the diagnosis of vulvar malignancy, 50 patients had medical treatment for vulvar symptomatology. Duration of the treatment ranged from less than 1 year in 58 patients to 20 years in three patients (mean, 5.1 years).

Treatment. Table I lists the surgical procedures. Radical vulvectomy was performed in 81 patients (76%), bilateral groin node dissection in 71 (67%), and bilateral inguinal and pelvic node dissection in 34 (32%).

Site of lesion. The right vulva was the most frequent site of the lesion, being involved in 49 patients (46%). The right labia minora and majora were involved in 31 and 28 patients, respectively. Other sites included left vulva in 28 patients (labia minora in 18, labia majora in 10), clitoris in 15, fourchette in 11, and perineum in two. Inguinal lymph node involvement correlated with the site of the lesion as follows: six of 28 patients with left vulvar lesions, one of 49 patients with right vulvar lesions, one of 15 patients with clitoral lesions, and one of 11 patients with fourchette lesions. Patients with right vulvar lesions had a significantly ($p < 0.05$) lower incidence of nodal involvement than did those with left vulvar lesions. There was no difference relative to survival rate. The only patient who had positive pelvic nodes had a lesion in the left labia majora.

Number of lesions. Multiple lesions existed in 10 patients, four patients having had two lesions, and six, four or more lesions. All of these tumors were microinvasive. None of these patients had positive nodes; one had a recurrence and another died as a result of vulvar cancer. There was no statistically significant difference ($p > 0.2$) relative to survival when these patients were compared with patients who had one lesion.

Size of lesion. Lesions smaller than 1 cm were present in 20 patients; lesions measuring 1 to 2 cm were present in 86 patients. All lesions smaller than 1 cm were microinvasive and were grade 1 or 2. Four had microscopic confluence and one showed lymphatic permeation. None of these patients had positive nodes or died of the malignancy. However, two had inguinal node metastases postoperatively and three experienced vulvar recurrence.

Among patients with lesions measuring 1 to 2 cm, nine (10.4%) had nodal metastases, 10 experienced vulvar recurrence, and four died of the disease. Microscopic confluence was noted in 36 lesions and lymphatic permeation in eight; tumor differentiation ranged from grade 1 to grade 4. The only patient with an anaplastic tumor (grade 4) had a 2 cm lesion. There was no statistically significant difference ($p > 0.4$) relative to survival between patients with lesions smaller than 1 cm and those with lesions 1 to 2 cm in size.

Nodal involvement. Inguinal node involvement existed in nine patients (8.4%). All except one underwent pelvic node dissection. One had positive pelvic (obturator and common iliac) nodes. This patient had a grade 2 lesion, 1.5 cm in size, with 5 mm of stromal invasion, microscopic confluence, and no lymphatic permeation. She died of vulvar cancer 6 months after surgery. Another patient with positive inguinal nodes died of intercurrent disease. The remainder are still alive and free of disease. The corrected 5 year survival rate for patients with positive nodes was 88.8% as compared with 97.9% for those with negative nodes. However, this difference was not statistically significant ($p > 0.1$). None of the patients with positive nodes experienced inguinal recurrence. Vulvar recurrence developed in one of nine patients who had positive nodes and in 12 of 97 with negative nodes.

Nodal metastases were ipsilateral in five patients and contralateral in four (two had lesions in the labia minora and two had lesions involving one side of the clitoris). The number of nodes involved ranged from one to five (mean, 2.1).

Depth of penetration. Histologic examination of the lesions revealed microinvasion (5 mm or less of penetration) in 96 patients (90%); nine of these patients had nodal involvement. Ten patients experienced vulvar recurrence, three had inguinal metastases (two with 2 mm of invasion and one with 5 mm of invasion), and three died of the disease (Table II).

Lesions that invaded the stroma for less than 2 mm showed no microscopic confluence and no lymphatic permeation. Among these patients, none had positive nodes and none died of the disease. One patient experienced a vulvar recurrence.

Invasion (more than 5 mm of penetration) was present in 10 patients (9.4%). None of them had positive nodes. Vulvar recurrence occurred in three patients, and one of these also had an inguinal recurrence. Inguinal node metastasis developed in one patient, who died of the disease.

Microscopic confluence. Microscopic confluence, as previously defined, was observed in 40 lesions (38%). Nodal metastases existed in six (15%) of these patients, whereas it occurred in three patients (5%) among those who did not have microscopic confluence. However, this difference was not statistically significant ($p > 0.2$). Among patients with lesions showing confluence, four died as a result of vulvar cancer. The difference was significant ($p < 0.01$) when compared with patients who had lesions without confluence.

Table II. Depth of penetration (millimeters) correlated with inguinal node involvement, survival, and development of inguinal node metastases postoperatively

Invasion (mm)	*No. of patients*	*No. of positive lymph nodes*	*No. of patients who died*	*No. with metastases*
1	19	0	0	0
2	26	1	0	2
3	23	1	1	0
4	16	4	0	0
5	12	3	2	1
>5	10	0	1	1
Total	106	9	4	4

Lymphatic permeation. Permeation of lymphatic channels was observed in nine patients. Two of these patients had positive nodes, whereas seven of the patients with no lymphatic permeation had positive nodes. One patient died of vulvar cancer and one experienced vulvar recurrence. There was no statistically significant difference relative to nodal involvement, recurrence, and survival between these groups of patients.

Vascular permeation. Permeation of vascular channels was not identified in any of the lesions studied in the present series of patients.

Tumor cell type. Large cell, keratinizing-type tumors were present in 89 patients (84%), large cell, nonkeratinizing in 12 (11%), and large cell, mixed keratinizing in five (5%). There was no correlation between lymph node involvement, survival, and recurrence and the type of epidermoid tumor.

Tumor differentiation. Tumor differentiation (Broders' classification) was distributed as follows: grade 1, 12 lesions (11%); grade 2, 79 lesions (75%); grade 3, 14 lesions (13%); and grade 4, 1 lesion (1%). Positive nodes were present in seven patients (9%) with grade 2 lesions and in two patients (14%) with grade 3 lesions. Among four patients who died, three had grade 2 lesions and one had a grade 4 lesion. In this particular patient, lymphatic permeation and confluence were present.

Follow-up. The clinical course subsequent to primary treatment was observed for 5 years or more in 76 patients, for 10 years or more in 47, and for 20 to 25 years in 10.

Recurrence. Invasive vulvar recurrence, as previously defined, occurred in 13 patients (12%). One additional patient experienced an in situ recurrence. The interval between surgery and recurrence ranged from 6 months to 11 years (mean, 6.4 years). None of the histologic and clinical parameters analyzed was found to correlate with vulvar recurrence.

Inguinal recurrence developed in one of 71 patients who underwent groin node dissection. This patient also had a vulvar recurrence. Inguinal nodes were negative at the time of original surgery.

Recurrence of vulvar dystrophy occurred in 33 patients (45%) among 74 with preoperative dystrophy. Two additional patients had vulvar dysplasia and another, carcinoma in situ.

Metastasis. Among 35 patients with no previous inguinal lymphadenectomy, four had biopsy-proved inguinal node metastasis—three within 3 years and one, 10 years after primary treatment. Three of these four patients also had vulvar recurrence. The original lesion was microinvasive in three of these patients (2 mm in two, 5 mm in one) and invasive in one. Two of these patients had lesions smaller than 1 cm, two showed microscopic confluence, and none demonstrated lymphatic permeation. All lesions were grade 2. One patient died as a result of vulvar cancer, two died of other causes but with tumor present, and the fourth, in whom the cause of death was unknown, had no tumor recurrence.

Treatment of recurrence and metastasis. Treatment of recurrence or inguinal metastatic disease included surgical resection in 11 patients and radiotherapy in three. Three of these patients died as a result of vulvar cancer from 3 months to 11 years (mean, 4.6 years) after secondary therapy. Two patients died of other causes but with cancer of the vulva present.

Survival. Cancer of the vulva was the cause of death in only four patients. Two died 6 and 9 months after the original treatment, one after 4 years, and another after 21 years. Twenty-four patients died of causes other than vulvar carcinoma; two had recurrence of tumor at the time of death. The cause of death was unknown in six patients; one of them had vulvar recurrence. Seventy-two patients are alive and free of disease. The corrected 5 year survival rate was 97.1%.

Comment

The epidemiologic factors among patients in the present series are similar to those for patients with all stages of vulvar carcinoma. Previously reported data relative to age,[4, 5] associated malignancies,[3, 4, 6] associated vulvar dystrophy,[5–9] and carcinoma in situ lesions[4, 7] compare favorably with those from our patients.

The distribution of the lesions was similar to that found by Figge and Gaudenz,[6] the right vulva being the site most commonly involved. These patients had a significantly lower incidence of nodal involvement, but their survival rate was similar to that in patients with lesions of the left vulva.

Multicentric lesions have been reported[7, 9] in an even higher percentage of patients than that found in this series. The number and size of the lesions were not significant prognostic factors in the present series of patients.

Inguinal node involvement was present in 8.4% of patients. Previously reported incidences of involvement for Stage I vulvar malignancies have ranged from 10.5% to 31%.[6, 10] Positive nodes were present only in patients who had lesions measuring 1 cm or more and in those with a depth of penetration of 2 mm or more. However, two patients with lesions smaller than 1 cm had inguinal node metastases postoperatively.

Microscopic confluence, lymphatic permeation, and tumor differentiation were not prognostic factors relative to nodal involvement. Microscopic confluence correlated significantly with patient survival, whereas lymphatic permeation and tumor differentiation did not. However, anaplastic lesions (grade 4), which are rare, seem to have an unfavorable prognosis. The only patient with an anaplastic tumor died as a result of vulvar cancer. Parker and associates[3] reported a similar case.

In the present series, the margins of excision appeared to be free of malignancy in all specimens, and therefore this is not a factor to take into account when examining recurrence in our patients. None of the clinical and histologic factors analyzed showed significant correlation with the development of vulvar recurrence. The prevention of vulvar recurrence still remains an unsolved problem for patients with complete excision of the lesions.

The high recurrence rate of vulvar dystrophy after vulvectomy, as demonstrated in this series and others,[6] indicates that dystrophic changes may develop in the site of a previously excised vulva.

Inguinal node metastases occurred in four patients after initial therapy. No correlation was found with the clinical and histologic characteristics of the lesions. One of these patients died as a result of vulvar cancer despite surgical therapy. Previously reported cases[11–14] tend to indicate that these patients have an unfavorable prognosis.

The incidence of inguinal node metastasis after initial surgical therapy, including inguinal lymphadenec-

tomy, was lower than that for patients who did not have initial dissection of nodes. Although the number of patients is small, this finding suggests that inguinal node dissection, as part of the initial therapy, would be helpful in preventing postoperative inguinal node metastases.

This study and previous reports[3, 10–15] tend to indicate that microinvasive cancer of the vulva behaves differently from its counterpart in the cervix and that nodal involvement or postoperative metastasis to nodes does occur in lesions with 2 mm or more of penetration. Therefore, it seems that if treatment or prevention of nodal metastasis is the goal in all patients, inguinal lymphadenectomy should be included in the initial therapy of Stage I squamous cell cancer of the vulva with stromal invasion of 2 mm or more. However, since the incidence of nodal involvement among patients with 3 mm or less of invasion is approximately 3%, individualization of treatment as far as inguinal lymphadenectomy is concerned can be considered according to the age and general status of each patient.

Discussion

DR. JAMES A. MERRILL, Oklahoma City, Oklahoma. The topic that has received and is receiving considerable attention currently is the treatment of *early* vulvar cancer. For many years the treatment of invasive vulvar cancer has been considered as a single entity and the method of treatment reasonably well standardized. In recent years, people have started to pay attention to the treatment of the early lesion with a view toward the possibility of individualizing treatment of patients with early lesions for the purpose of diminishing the morbidity associated with the disease and its treatment while not sacrificing curability. This review of 106 patients does little to clarify that topic for us, but it does indicate that attention is being given to the possibility of individualization.

Papers have been presented concerning the study of early lesions—Stage I with less than 5 mm of invasion beneath the surface—which have been associated with no lymph node metastases. The authors of those papers have suggested that, in selected instances of early disease, one might reasonably approach the treatment of the disease by radical vulvectomy alone without dissection of the nodes in the groin. Others have reviewed the same category of patients and have found positive groin lymph nodes in approximately 5% of patients. However, at least in one study it was shown that the bulk, if not all, of the cases in which positive lymph nodes were present were in patients whose tumors were anaplastic and in which there was microscopic evidence of vascular invasion. From this they concluded that certain groups of patients with early invasive vulvar cancer might satisfactorily be treated by radical vulvectomy alone, omitting the groin dissection except in those cases in which there was invasion deeper than 5 mm or the lesion was anaplastic or there was microscopic invasion of vascular channels.

I hope that we may learn some categories or definitions that will permit some degree of individualization. The most innovative approach to the management of early invasive cancer was that reported by DiSaia and associates.[1] Their proposal is to select patients carefully: young patients, patients with early lesions, patients whose depth of invasion is less than

5 mm. They have pointed out that the superficial inguinal lymph nodes can be considered as sentinel nodes for the metastasis of vulvar cancer. Thus, a sampling of these superficial inguinal nodes, above the cribriform fascia, is a reasonable method of assessing whether or not groin metastases are present. Their proposed procedure is to remove the superficial inguinal nodes (the sentinel nodes), to examine them by frozen section, and in those cases in which the nodes are negative to do nothing further to the groin and, moreover, to treat the minimally invasive vulvar lesion by a wide local excision. The results in 20 patients are quite good, albeit the follow-up has been relatively short. What is most impressive is the relative infrequency of sexual dysfunction in patients so treated.

I have several questions that I wish to ask the authors. I note that approximately 30% of the 106 patients had pelvic node dissection as part of the therapy. I would wonder what the indications were for pelvic node dissection in that 30% of cases.

I also note a 12% incidence of vulvar recurrence. That seems to me a moderately high figure, and I would ask if the authors have any explanation for that local recurrence rate. Did it have to do with the nature of the original operative procedure? Did it have to do with the known occurrence of multicentricity of this disease which can be not only spatial but also temporal? Were these recurrences multicentric sites in the temporal sense of the word.

I wonder if he could speak to a possible explanation of the apparent difference in node involvement on the two sides of the body.

DR. JOHN G. MASTERSON, Maywood, Illinois. This is a comprehensive analysis of the clinical and pathologic features associated with the management of 106 Stage I squamous cell carcinomas of the vulva during a 25 year period at the Mayo Clinic. The authors stated that an additional 45 patients with vulvar lesions 2 cm or less were excluded, including 19 with other histologic types of primary carcinoma of the vulva. Therefore, it would appear that their institution had a total of 125 Stage I carcinomas of the vulva during 1950 to 1975. During a comparable period, I managed 49 cases of Stage I carcinoma of the vulva including four malignant melanomas and adenocarcinomas. The mean age of 61 in the authors' series as well as the incidence of associated diseases such as hypertension, diabetes, and positive nodes are lower than that cited in previous reviews, but in the latter all of the four clinical stages of the disease were included. However, the high incidence of associated malignancies and vulvar disease as well as a long delay in the establishment of the diagnosis of vulvar cancer after the onset of the patient's symptoms and signs have again been borne out in this study as in earlier reports in the literature.

However, I was surprised by what I would construe to be a high incidence of local recurrence, namely, 12.27%, even though it did not appear to significantly affect 5 year survival data. Since only 64 percent of the patients in this series had a radical vulvectomy with either a bilateral groin dissection or a bilateral groin dissection and pelvic node dissection, I would be interested in knowing whether the incidence of local recurrence in the group so treated was the same as in 36% who had less extensive procedures. The authors have clearly shown that the incidence of inguinal recurrence is eight times higher in patients who do not have a groin dissection as part of their primary therapy.

The development of recurrent dystrophy in 44.5% of patients with previous dystrophy is similar to what has previously been observed in past surveys. Curiously enough, we have *only rarely* observed the development of a new or recurrent carcinoma in this postoperative dystrophy. I would be interested in knowing what the authors' experience has been.

The authors have not provided us with the actual number of the 106 cases that were involved in determining their excellent but corrected 5 year survival rate of 97.17% or their actual gross 5 year survival rate. Although we know that intercurrent disease is an important factor as a cause of death in patients with cancer of the vulva, I believe that we should report gross 5 year survival rates for each of the clinical stages of the disease, indicating, if you wish, the percent of deaths due to cancer and the percent due to intercurrent disease. Interestingly enough, we have shown via this statistical approach that the percent of deaths due to intercurrent disease in cancer of the vulva increases with the clinical stage of the disease. This observation suggests that there is possibly a significant relationship between the host resistance of a patient to malignancy and the intercurrent disease present in the given patient.

Finally, I heartily endorse the authors' recommendation that radical vulvectomy and bilateral groin dissection be the initial therapy for all Stage I squamous cell carcinomas of the vulva where the stromal invasion is 2 mm or more. And I would add a pelvic node dissection in patients with positive groin nodes or where the primary lesion involves the clitoris.

DR. ALFRED SHERMAN, Detroit, Michigan. I would like to ask the author, particularly in the patients with the 1 to 3 mm invasion in which there is a 3% nodal involvement, about the survival of those patients.

I am quite concerned with a situation where four patients develop inguinal node involvement and also 12% or 13% of patients develop local recurrences. I submit that there is no worse complication for this disease than recurrences in either the groin or in the vulva. So, despite the fact that patients may only have

lesions with 1 to 3 mm of invasion and despite the fact that they may only have a 3% nodal involvement, I think it behooves us to know whether or not nodal dissection in these patients would have increased their survival rate or would have prevented local recurrence even though they only have 3% positive nodes. I do not think that the addition of the inguinal node dissection adds any greater degree of morbidity to the over-all results in these patients and would certainly be justified if it decreased local recurrences or prolonged survival.

DR. PHILIP J. KRUPP, JR., Metairie, Louisiana. This work presents a serious effort to provide more much needed data so that one can individualize the treatment of these patients.

It should be pointed out that there is no definition for microinvasion of the vulva, and, indeed, one may not be able to isolate this entity statistically. I do applaud the authors' attempt to do so.

The sentinel node is a concept which has no basis in fact at this time. No one has yet showed me the location of such a node, and it will take a great deal of information to validate such a concept.

We still need to realize that the basis of therapy for vulvar cancer, as in other cancers, is wide removal of the lesion and its lymph drainage as completely as possible.

DR. MAGRINA (Closing). Dr. Merrill has commented on previous reports by Dr. Wharton and Dr. Parker. The selection of patients in both studies was chiefly based on the size of the lesions and did not take into consideration the clinical status of inguinal nodes, which we did in our series of patients. Although probably small, this could make a difference in the results.

We think that the proposal of DiSaia and colleagues, of sampling the superficial inguinal nodes and then deciding if further lymphadenectomy is indicated, is good for selected patients. However, it does not solve the problem of local recurrence that Dr. Merrill has mentioned. We compared the clinical and histologic factors, referred to previously, with vulvar recurrence and none of the factors showed a significant correlation. The possibility that some of these recurrences may constitute a second primary is raised by the fact that three patients developed a recurrence 10 years or more after the initial therapy.

In relation to our indications for pelvic node dissection, this study covers a 25 year period, and these were patients who were treated at the beginning of the study, when the indications for pelvic lymphadenectomy were still not clear.

We do not have a satisfactory explanation for the difference relative to node involvement between patients with left vulvar lesions and those with right vulvar lesions. The histologic characteristics of the lesions were similar in both groups of patients.

In reply to Dr. Masterson, the type of operative procedure showed no correlation with vulvar recurrence. Also, the margins of excision appeared to be adequate in all surgical specimens. Therefore, we do not know what factors are responsible for local recurrence of the tumor.

You have probably been surprised to see that the 5 year survival rate has been 97%, considering that four of 106 patients died as a result of vulvar cancer. Three of these patients died within 5 years; the fourth patient survived more than 5 years. This is why we have a corrected 5 year survival rate of 97%.

We feel that if treatment or prevention of node metastases is desired in all patients, inguinal lymphadenectomy should be performed with lesions invading the stroma 2 mm or more. However, when we further analyzed our data it was evident that lesions with 3 mm or less of invasion were associated with a low (3%) incidence of node involvement, as compared to almost 20% when the depth of invasion was 4 mm or more. This leaves a place for individualization for inguinal lymphadenectomy in the group of patients with 3 mm or less of invasion, based on the age and condition of the patient and the surgeon's personal approach. Inguinal lymphadenectomy should certainly be included in the initial therapy of patients with 4 mm or more of invasion.

In reply to the floor discussant, among 68 patients with 3 mm or less of invasion only one died as a result of vulvar cancer, as compared to three among 38 patients with 4 mm or more of invasion. However, the difference was not statistically significant.

The nonstress test for the antepartum assessment of fetal reserve

CHANG Y. LEE, M.D.
BRUCE DRUKKER, M.D.
Detroit, Michigan

Seven hundred and twenty-two nonstress tests (NSTs) that were performed on a total of 471 patients were reviewed. The results of the study suggest that the NST is a simple, reliable test as a primary screening procedure in antepartum fetal heart rate (FHR) monitoring. The active and reactive tests were indeed reliable indicators of fetal well-being while the nonreactive test required an additional discriminatory evaluation. A tentative classification is suggested for those cases with FHR decelerations associated with fetal activity and uterine contractions. (AM. J. OBSTET. GYNECOL. 134:460, 1979.)

ACCURATE EVALUATION of fetal well-being and maturity is essential in the management of high-risk pregnancies, which frequently require preterm delivery from an unfavorable or hostile intrauterine environment.

With the fetal heart rate (FHR) monitoring system, evaluation of FHR changes in response to the stress of uterine contractions produced by oxytocin infusion has been employed widely for the assessment of fetal respiratory reserve. The clinical value of the contraction stress test (CST) or the oxytocin challenge test (OCT) has been proved by Pose,[1] Kubli,[2] Ray,[3] and their associates, Freeman,[4] and others[5, 6] in the management of high-risk pregnancies.

More recently, FHR acceleration associated with fetal activity (FA) has received growing attention as a sign of fetal well-being and has been evaluated as a simple test for antepartum assessment of fetal reserve.[7–11] In a previous study,[7] fetal activity acceleration determination (FAD) or the nonstress test (NST) and the CST were performed simultaneously to evaluate the correlation between the two tests. When clear FHR accelerations with vigorous fetal activity were recorded, the subsequent CST was always negative. When inadequate or no FHR acceleration was recorded with infrequent and weak fetal movements (FMs), the subsequent CST was frequently "suspicious" or positive. There was also an excellent correlation between the results of the tests and outcome of the fetuses.

On the basis of this study[7] and with support from others,[8–10] the NST has been used at Henry Ford Hospital since January 1, 1976, as the primary technique for antepartum evaluation of fetal reserve in the management of high-risk pregnancies. The following is a report of our recent clinical evaluation of the NST as a primary screening test in antepartum FHR monitoring.

Material and methods

During a two-year period, from January 1, 1976, to December 31, 1977, the NST was performed 722 times on 471 patients in the fetal monitoring unit of Henry Ford Hospital, Detroit, Michigan, for the evaluation of fetal respiratory reserve. The FHR was recorded by ultrasonogram and abdominal fetal electrocardiogram (FECG) using Corometrics III and IIIA fetal heart rate monitors. Even though fetal activity could be recognized in most cases by abrupt changes on the uterine activity tracing recorded by external tokodynamometer, additional fetal activity markings were recorded by having the patient press the test button or marker on the Corometrics fetal heart rate monitors whenever fetal activity was felt. Table I reveals the reasons for the test.

When more than two FHR accelerations with fetal activity were clearly recorded, it was interpreted that the fetus demonstrated a sign of well-being and was classified as "active" (Fig. 1) FHR acceleration of more than 10 bpm was used as the criterion of the active test.

From the Department of Gynecology and Obstetrics, Henry Ford Hospital.

Presented at the Forty-sixth Annual Meeting of the Central Association of Obstetricians and Gynecologists, Kansas City, Missouri, October 13-15, 1978.

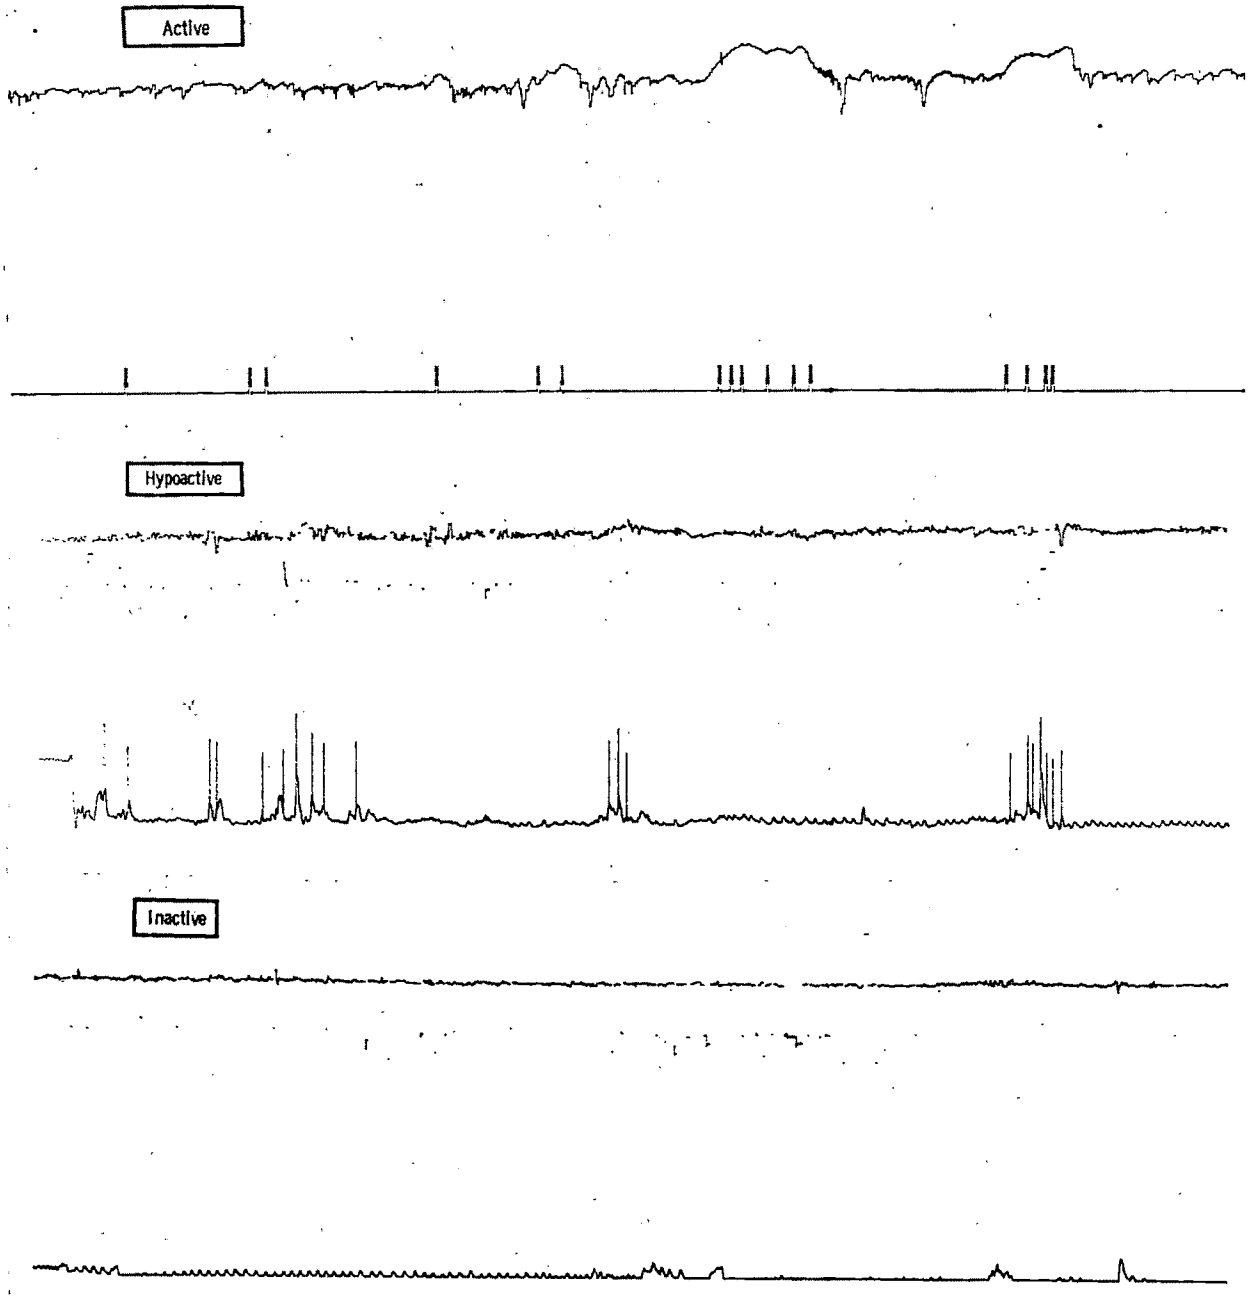

Fig. 1. Examples of active, hypoactive, and inactive NST.

In this group the test was repeated either biweekly or weekly. When the fetus recorded inadequate or questionable FHR accelerations with fetal activity (less than 10 bpm), the test was classified as "hypoactive." An inactive classification was used when the fetus demonstrated no FHR acceleration with infrequent or no fetal activity for the initial 20 minutes of FHR recording. In those cases with hypoactive and inactive tests, external manipulation was applied to stimulate fetal activity. When the fetus recorded FHR accelerations during the extended test with vigorous fetal activity responding to the external stimuli, the test was classified as "reactive." A classification of hypoactive-reactive and inactive-reactive tests was used for these patients and these cases were managed in the same way as were those with the active test. When the fetus did not respond to repeated external stimuli during an extended test, the test was classified as "nonreactive." Only in these nonreactive cases with initial hypoactive and inactive tests was the CST performed for further confirmation of the fetal

condition. The CST was performed in a routine manner as described by others.[5, 6]

In several cases, FHR decelerations were recorded continuously with fetal activity and in response to occasional Braxton-Hicks contractions. On the basis of previous observations[12] of the progressive changes in the configuration of variable deceleration and outcome of these cases, a tentative classification for these cases is suggested.

In some cases, 24 hour urinary estriol and human placental lactogen levels were also measured serially along with the tests, although the results of these biochemical analyses were not used for the evaluation of the tests. Management of the patients was based on the clinical impression of each case and the test results. Outcome of each fetus was compared with the results of the tests to evaluate their clinical value.

Results

The NST was performed 722 times on a total of 471 patients. Six hundred and twenty-one tests were active, and 75 tests were reactive (Table II). In these groups all infants were delivered either vaginally or abdominally in good condition (Apgar score 7 or above at 5 minutes) except for three cases. These three infants were moderately depressed (Apgar score 4 to 6 at 5 minutes) with a specific etiology of the low Apgar score. Only one fetus recorded persistent late decelerations during ac-

tive labor, and it was delivered in good condition by cesarean section (Apgar score 8 at 5 minutes).

Seven hypoactive fetuses were nonreactive to external stimuli. However, five of these recorded definite FHR accelerations with vigorous movements during a subsequent CST for further evaluation of the fetal condition. The CST results were negative in these five infants (Table III), who were delivered vaginally in good condition. In the two remaining hypoactive-nonreactive cases, the subsequent CST was negative in one case but continuously nonreactive. This fetus recorded persistent late decelerations with a mild degree of tachycardia during the induction of labor with intravenous oxytocin infusion on the day following the test. The fetus was delivered by cesarean section in good condition. A subsequent CST was positive in one other case, but the fetus was delivered in good condition by cesarean section on the day of the tests (Table III).

Five inactive FHR recordings were obtained from the five patients with hypertensive disease of pregnancy. Among these patients, two fetuses became reactive during the performance of the subsequent CST, which was negative (Table III). In the three inactive-nonreactive cases, the subsequent CST was positive, and all infants were delivered by cesarean section on the day of the tests. One infant was moderately depressed (Apgar score 6 at 5 minutes), and the other two were delivered in good condition. Signs of intrauterine growth retardation appeared in two infants (Table IV).

A mild degree of variable decelerations with fetal activity and/or uterine contractions was occasionally observed along with FHR accelerations in approximately 15% of the active and reactive tests. However, in four cases FHR decelerations were recorded continuously without a single FHR acceleration. In two fetuses a stressed pattern[12] of variable deceleration with fetal activity and/or uterine contractions was recorded continuously. The configuration of variable deceleration in these cases revealed precipitate deceleration and rapid recovery tracings (Fig. 2, *A*). In this case, when the NST

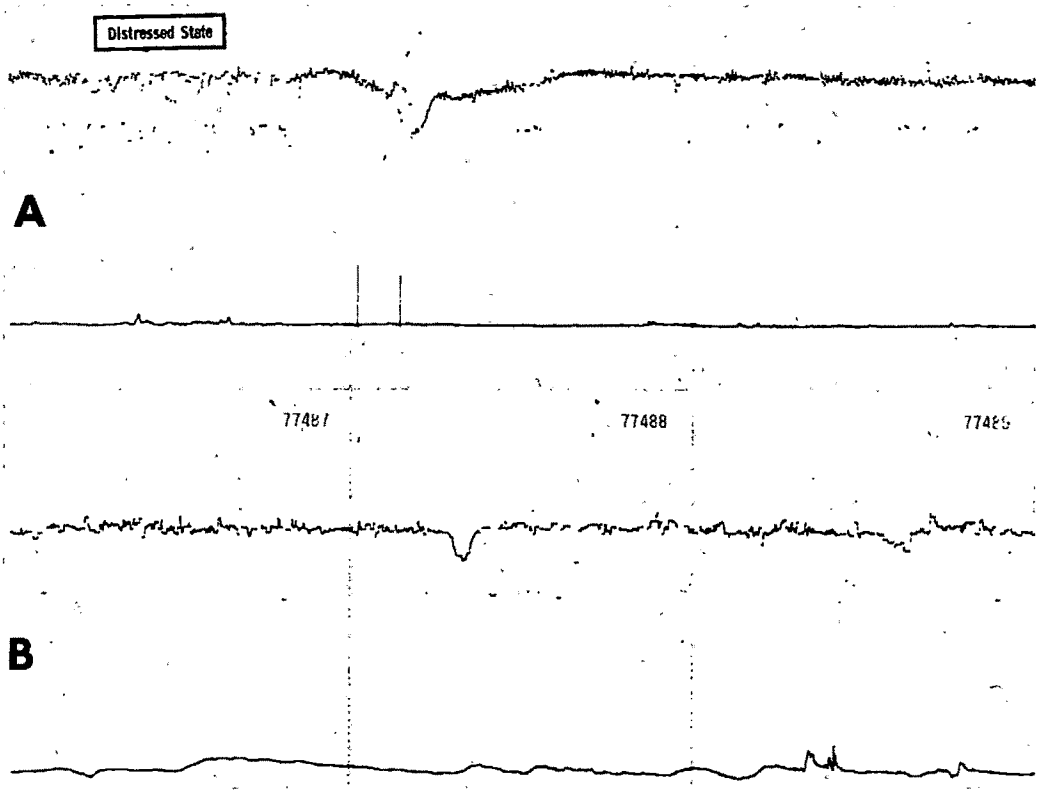

Fig. 3. Examples of a distressed state in a NST. *A:* A recording of what appeared to be a combination of a variable and late deceleration with fetal activity. *B:* Recording in a premature fetus of a distressed pattern of variable decelerations in a NST. Note the smoothly curved deceleration and recovery angles.

was repeated 3 days after the initial test, the fetus again demonstrated a stressed pattern of variable decelerations with fetal activity. Labor was induced with intravenous oxytocin infusion using internal FHR monitoring after the membranes had ruptured. However, after 4 hours of oxytocin infusion the fetus was delivered by cesarean section because of recurrent variable decelerations and poor progress of labor. A male infant, weighing 3,098 grams, was delivered in good condition (Table IV). The umbilical cord was wrapped around the neck, left shoulder, and left forearm. One other fetus who demonstrated a stressed pattern of variable decelerations with fetal activity in both the initial and repeated tests was delivered vaginally in good condition (Apgar score 9 at 5 minutes) (Table IV). Fetal activity continuously produced a mild degree of variable deceleration during the entire labor (Fig. 2, *B*).

A fetus of a postdate pregnancy demonstrated what appeared to be a combination of the distressed pattern of variable and late decelerations during the NST (Fig. 3, *A*). Although the patient was inadvertently released, she was admitted to the hospital in labor one week later with a history of no fetal movements for 2 days. The patient was delivered of a macerated female infant weighing 3,200 grams (Table IV). A fetus of 30 weeks of gestation recorded variable decelerations with somewhat blunted decelerations and recovery angles during a NST (Fig. 3, *B*). The mother was hospitalized with pregnancy-aggravated hypertension. On the evening of the test day, the patient started premature labor after the membranes had ruptured. The fetus demonstrated the distressed pattern of variable decelerations[12] during labor (Fig. 4) and was delivered by cesarean section in a severely depressed condition (Apgar score 3 at 5 minutes), and died of pneumonitis and septicemia on the third day of extrauterine life (Table IV).

In one case, what appeared to be a sinusoidal pattern[8, 16] was recorded for 12 minutes during the initial NST. The sinusoidal pattern disappeared spontaneously and the fetus recorded accelerations with FMs on the normal baseline FHR (Fig. 5). This FHR pattern was not observed when the test was repeated 3 days later, and the NST was active. The fetus did not dem-

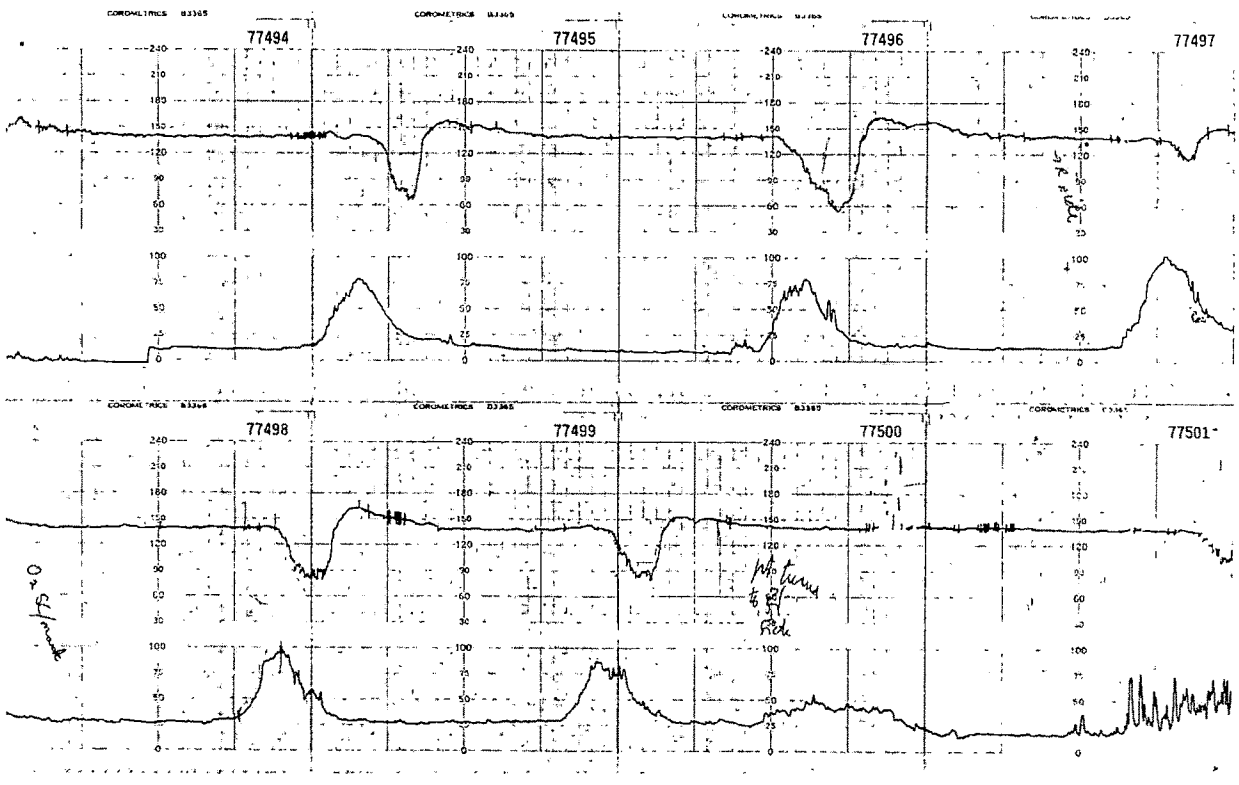

Fig. 4. A distressed pattern of variable decelerations in labor. Note the smoothly curved deceleration and recovery angles with overshoot acceleration.

onstrate a sinusoidal FHR pattern during labor and was delivered vaginally in good condition 8 days after the initial NST.

In seven instances the initial NST was unsatisfactory. However, in four cases the repeated NST was satisfactory and active. In two other cases, the patients went into labor spontaneously before the performance of a repeat test and were delivered of their infants in good condition. In one case, a repeated NST was again unsatisfactory because of extreme obesity and hydramnios. This patient was evaluated with biochemical tests.

Comment

The results of the study suggest that the NST is a simple, reliable test for primary screening in antepartum FHR monitoring. The active and reactive NSTs were indeed reliable indicators of fetal well-being. No fetal death occurred in these cases, and with three exceptions all fetuses in this group were delivered in good condition (Apgar score 7 and over at 5 minutes). These three cases all had a specific etiology of the fetal depression.

It was again apparent that the nonreactive NST with an initial hypoactive or inactive test requires additional discriminatory evaluation. For this purpose, the CST was used. Five cases with a hypoactive-nonreactive NST and two cases with an inactive-nonreactive NST became reactive to the stress of uterine contractions during the subsequent CST for further evaluation of the fetal condition (Table III). Phenobarbital administered to the patients with hypertensive disease of pregnancy might be the cause of the nonreactive test in some cases in this group.

Manning[13] suggested the need for further discriminatory evaluation of fetuses who had nonreactive-positive CSTs subsequent to nonreactive NSTs, with the observation of fetal breathing movements through real-time ultrasound. In his series, there was a much higher incidence of intrauterine growth retardation and low Apgar scores among the fetuses which revealed no breathing movements with the positive CST. The ideal test in antepartum fetal monitoring should not yield false positive signs of fetal compromise. At the same time, the test should give an early warning of fetal compromise and allow us to prevent fetal depression.

Recently, Braly and Freeman[14] evaluated the significance of baseline reactivity in their positive OCT cases. The fetal outcome was uniformly good in those cases with baseline FHR reactivity. Half of these pa-

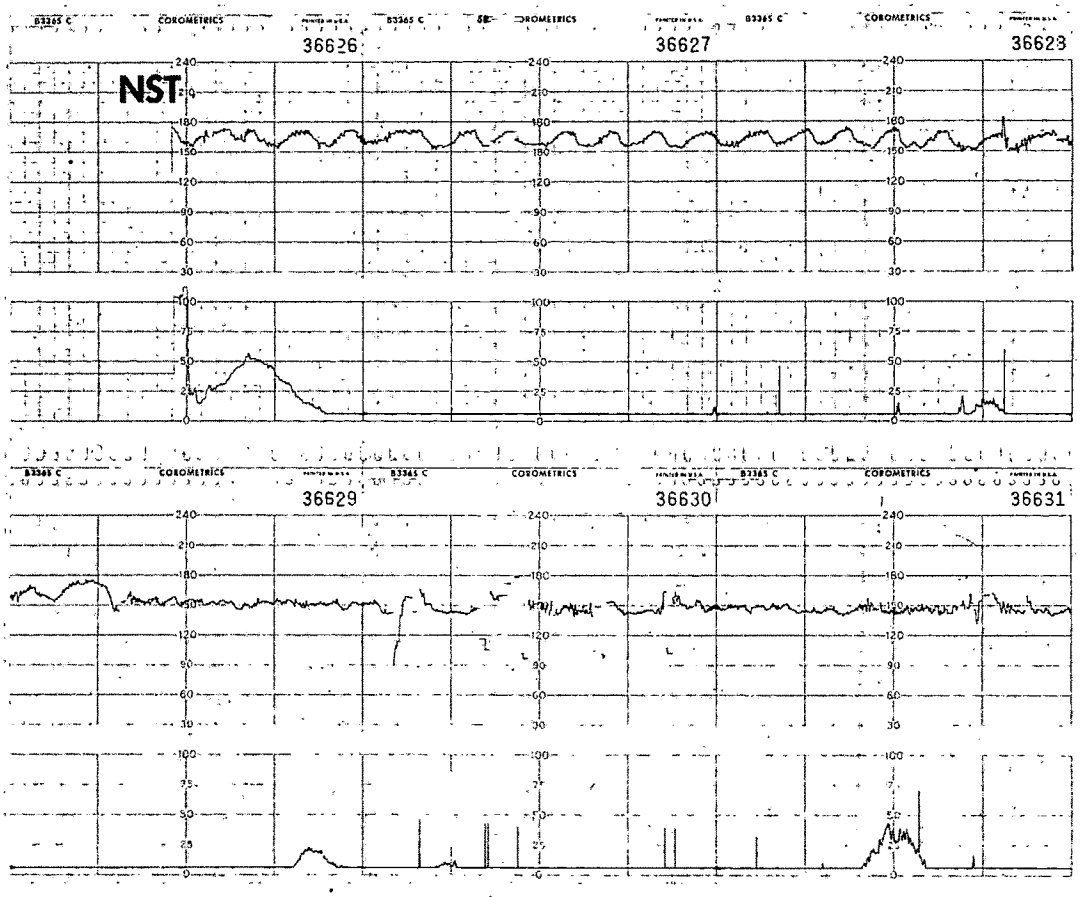

Fig. 5. Recording of what appeared to be a sinusoidal FHR pattern for 12 minutes. Note the spontaneous disappearance of the sinusoidal pattern.

tients tolerated labor well, without revealing signs of fetal distress, and were delivered vaginally of their infants. When the positive OCT was associated with a nonreactive FHR recording, a trial of labor uniformly resulted in signs of fetal distress. It is apparent, in this study, that FHR reactivity was present in all cases with a false positive OCT. This study also suggests that a nonreactive-positive CST is a reliable indicator of fetal compromise. However, a further discriminatory evaluation with fetal breathing movements may be helpful in extreme prematurity with a nonreactive-positive CST.

Rochard and associates[8] and others[9-11] classified the NST into two main groups—"reactive" and "nonreactive" tests. The NST was classified as "active," "hyporeactive," and "inactive" in this study, depending on the degree of FHR accelerations associated with fetal activity. When the external stimuli or stress of uterine contractions was applied to the fetus, then a reactive or nonreactive classification is appropriate, depending on the fetal response to the stimuli or stresses (Fig. 5).

Occasionally FHR decelerations were observed between the accelerations in approximately 15% of active and reactive NSTs. Visser and Huisjes[10] classified this group as "decelerative." In their series, 13 of the 20 patients with a decelerative NST showed signs of fetal distress in labor. In 12 of the 20 patients with a decelerative test, the infants were small for dates. In the present study, however, all the active and reactive tests that were recorded with occasional FHR decelerations resulted in delivery of infants in good condition. An increased incidence of intrauterine growth retardation was not observed in this group of patients.

Using a high paper speed in FHR monitoring, Timor-Tritsch and associates[15] observed that 66.7% of fetal activity produced a combination of FHR accelerations and after-coming decelerations. In four cases in our series, however, the fetus demonstrated FHR decelerations continuously with fetal activity and uterine contractions without a single recording of FHR acceleration. Even though the number is limited to four cases, it was apparent in this study that these cases were composed of two different groups of fetuses. Two fetuses that demonstrated a stressed pattern of variable

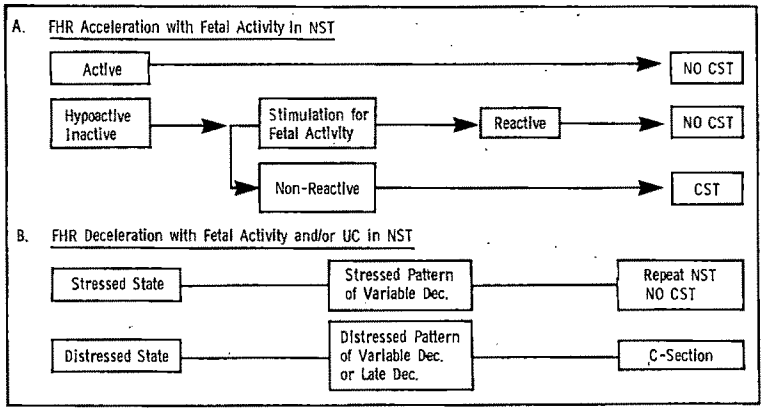

Fig. 6. Evaluation of fetal well-being using FHR monitor. *DEC:* Deceleration; *UC:* uterine contraction.

deceleration[12] during the performance of the NST were delivered in good condition, while the other two who demonstrated a distressed pattern of variable deceleration[12] and a combination of distressed variable and late decelerations resulted in prenatal deaths.

On the basis of the clinical experience with these cases, a tentative classification is suggested for the deceleration group in Fig. 6. Admittedly, more clinical studies are needed for better evaluation of fetal status in this deceleration group. An abdominal wall FECG enables us to evaluate FHR beat-to-beat variability and will be helpful in the differentiation of the stressed and distressed fetus in the deceleration group.

In the series reported by Kubli and associates,[16] a sinusoidal FHR pattern was found in nine of 12 fetuses prior to death. Rochard and co-workers[8] observed 10 perinatal deaths among the 20 fetuses demonstrating a sinusoidal FHR pattern. An additional 40% of fetuses with this type of FHR pattern in their series required prolonged hospitalization after birth. In one case observed in our series, the recording of a sinusoidal FHR pattern was temporary and was not found during the repeated NST or in labor.

In summary, the NST is a simple, reliable test as a primary screening procedure in antepartum fetal monitoring. The active and reactive tests were indeed reliable indicators of fetal well-being, while nonreactive tests were needed for further discriminatory evaluation. A tentative classification is suggested for those cases with FHR decelerations associated with fetal activity and uterine contractions. Since the NST requires only 20 to 30 minutes of FHR recording without oxytocin infusion, it is suitable as an office procedure.

Discussion

DR. RICHARD P. BENDEL, Minneapolis, Minnesota. This paper by Lee and Drukker adds to the growing list of reports indicating that the NST is a valuable tool in the antepartum assessment of fetal-placental reserve. At Hennepin County Medical Center, I have reviewed nearly 500 NSTs done during the past two years and have found nearly identical results, i.e., an active fetus with good FHR accelerations is virtually assured of a good outcome. Obviously, a normal NST does not preclude a poor fetal outcome if labor is mismanaged, cephalopelvic disproportion is not recognized, or a catastrophic event such as abruptio placentae supervenes.

When the fetus is hypoactive or inactive, the authors proceed to stimulate the fetus, and if it then becomes reactive, that also is reassuring and the fetus can be considered with those fetuses active to begin with. We likewise have resorted to stimulation of the fetus by external manipulation or having the mother get up and move around for a few minutes and then reapplying the monitor. Up until now I have been questioning whether that ploy was legitimate. I am glad to learn that these hypoactive-reactive fetuses are also healthy.

Using an acceleration of 10 bpm as the criterion for an active test is disturbing to me. Initially, we used an acceleration of 20 bpm as the end point, but we soon realized that an acceleration of 15 bpm was equally predictive of good fetal reserve. However, I have found some records where apparent accelerations of 10 bpm were associated with a positive contraction stress test (CST) and decreased uteroplacental reserve. This is especially a problem with ultrasound pickup of the FHR, where the apparent baseline variability can often be 10 bpm. I would like Dr. Lee to comment on this point.

Last, I find very confusing the discussion of the four cases where the fetus showed no accelerations and continuous variable deceleration with fetal activity and/or uterine contractions. The authors classified these into two categories called "stressed" and "distressed" patterns. The criteria for these patterns are apparently discussed in an unpublished work. Without presenting further explanatory material in the text of this paper, it is almost impossible to understand their classification as set out in Fig. 6.

DR. R. W. TAYLOR, London, England. Dr. Lee's previous paper in 1976 led me to use the NST in the study of high-risk patients in my own department.

I find the philosophy behind the NST satisfying. It is an attempt to determine the well-being of the fetus, where all placental function tests so far described tell of one aspect of function of that organ and can at times be seriously misleading.

The OCT meets the requirements of a test of fetal well-being but probably because of early poor results before the days of second electronic fetal monitoring this has not found wide acceptance in Britain. Perhaps the very term "stress test" had something to do with that rejection.

We have only 2 years' completed experience but it does seem to confirm the conclusions presented. The main problem with this paper is in the definition of a "high-risk" case. This is so wide that the number of "sick" fetuses is very small. In this the authors are doing what they set out to do, namely, evaluate the NST as a primary test, but it would stand better if there were more positive results to analyze.

In our unit we have used the NST mainly where there is other evidence of fetal malaise—poor growth rate, maternal hypertension, poor liquor volume, or poor urinary excretion of estriol and pregnanediol.

In 73 patients monitored for a mean period of 11.7 days between 33 and 37 weeks, 17 patients showed good signs of fetal activity and good fetal heart acceleration. All were subsequently delivered of babies of good weight, in good condition, and we concluded that our initial diagnosis was incorrect and our fears groundless.

In 56 babies where we had a poor response on at least two occasions labor was induced. In the past 18 months our usual method of delivery has included the insertion overnight of prostaglandin paste, with subsequent artificial rupture of membranes and oxytocin infusion if necessary. There were 14 vaginal deliveries and 22 babies were delivered by cesarean section—18 because of fetal distress, usually confirmed by a fetal scalp sample. In 20 cases where placental function tests were poor but the NST was initially satisfactory, there was a mean gain of 17 days in utero before the NST became poor and we felt obliged to deliver the baby. In our view this fact alone justifies the faith that the authors would have us put in this test. At present the NST is often difficult to interpret and only for a moderately sophisticated unit. However, with the availability of computer-assisted monitoring this should change.

DR. PETER E. FEHR, Minneapolis, Minnesota. Many people have shown that there is a sleep cycle in the fetus and mothers have said, "I think the baby has been

sleeping for a bit." I think it is important for us to realize that a normal fetal sleep cycle can run probably 20 minutes, so we might be inclined to call a 30 minute test "positive" unless we do some stimulation.

Sureau and colleagues[1] of Paris, France, would certainly disagree with your statement on the sinusoidal test, and though I have heard Sureau and I have heard you, I am going to be doing contraction stress testing on all sinusoidal patterns because I am concerned when I see a pattern that is internationally considered dangerous.

My own feeling is you are overreacting to a positive CST by doing a cesarean section on the day of the test. I believe that the statistics will show that almost 50% of these babies can be delivered vaginally, and because of the false positive CST rate, I believe that an attempted induction of labor with good electronic monitoring and scalp sampling is an appropriate approach. I would challenge anyone in our hospital who would perform a cesarean section on the basis of a positive CST without an attempted induction of labor.

Finally, I believe that the NST carefully applied at weekly intervals to patients who have a potentially diminished fetal-placental reserve is a very valid test and certainly should reduce significantly the stillbirth rate of unknown etiology in that high-risk group.

I would certainly agree with the idea of using the CST in cases where the NST is doubtful, and as far as the second category or the two new categories, Dr. Bendel and I concur that we have some real question about their validity.

In our own series, when a patient is having spontaneous contractions and there are late decelerations in the fetus, we assume this is a positive stress test, and we regard these to be the same as any other late decelerations in labor. If the patient has a closed cervix and three contractions in 10 minutes, all of them accompanied by late decelerations, the patient should probably be delivered by cesarean section.

DR. JACQUES F. ROUX, Lansing, Michigan. Dr. Lee was one of the first investigators to outline in the literature the importance of fetal motions as they relate to the FHR. This was a very valuable contribution to our field.

However, we should remain critical of the NST because no data were obtained in patients who were not stress-tested.

It would have been an excellent contribution to our understanding of the NST if the author had chosen at random patients who would be stress-tested but who would be managed without consideration of the results of the NST. It would be a study very similar to that of Dr. Haverkamp. His group has questioned with reason the clinical value of FHR monitoring in well-supervised patients.

In our experience, an abnormal NST was associated two thirds of the time with a problem during labor, but it could be a minor problem, for instance, a loose cord around the neck, an abnormal presentation such as a posterior presentation, or a near-term breech presentation.

In most of the cases cesarean section was not performed. On the other hand, a normal stress test was associated with complications during labor 25% of the time. I believe that the NST is a useful test if it is evaluated in the general clinical context of the case. The NST should replace the OCT because it can be repeated more frequently, it is less emotionally "loaded," and it is almost as good a predictor of fetal outcome as the OCT.

DR. ROGER HERTZ, Cleveland, Ohio. I would like to bring up one point regarding fetal behavioral cycling based on work done in Dr. Rosen's laboratories at Cleveland Metropolitan General Hospital by Timor-Tritsch and associates.[1]

In a research setting, we have noted that "quiet" periods or what we think may be a fetal "quiet sleep state" does indeed occur and that these periods may be considerably longer than previously appreciated.

In a study of 16 normal term pregnant patients in our laboratories fetal "quiet sleep" or periods of inactivity with minimal variation in FHR have been observed for up to 50 minutes. The finding that normal fetuses can have prolonged inactive periods should be borne in mind in analyzing antepartum monitoring data. Interrupting these periods of inactivity by stimulation (evoked response) as suggested by others may be a reasonable approach requiring further study.

DR. ROBERT A. MUNSICK, Indianapolis, Indiana. I would like to ask Dr. Lee if he can review his data and tell us the possible difference in results if one looked only at the presence of fetal motion on the tokograph without checking the heart rate. Does he have data as to the results of only palpation of motion? Would this have the same results as a history taken from the mother regarding activity in the previous 24 hours?

DR. LEE (Closing). I am encouraged by the comments made by Professor Taylor since their experience in England is similar to ours. In the previous studies,[1, 2] the term "fetal activity acceleration determination" was used on the basis of the following concept: If a fetus

can perform a vigorous activity which requires FHR acceleration, the fetus can be considered to have a good functional reserve. A chronically decreased fetal reserve may make the fetus unable to perform a vigorous activity which requires FHR acceleration.

I am also encouraged by the discussion from Dr. Roux since he has recognized our previous study[1] as a first paper that appeared in a journal.

Dr. Roux and Professor Taylor questioned the justification of the cesarean section in the case of a nonreactive-positive CST following a nonreactive NST. Recently Braly and Freeman[3] evaluated the significance of baseline FHR reactivity in their positive OCT cases. When the positive OCT was associated with a nonreactive baseline FHR recording, a trial of labor uniformly resulted in signs of fetal distress. Our previous experience was similar to the results of this study, and because of this reason we have included baseline FHR reactivity in the interpretation of the CST.

In the classification of an active test, we used a clear recording of more than two FHR accelerations associated with activity. I think that the presence of recognizable FHR accelerations is more important than the number of beats of acceleration per minute. Usually, FHR acceleration of more than 10 bpm can be recognized as a clear FHR acceleration. By using more than two FHR accelerations over 10 bpm as the minimum criterion of an active test we could eliminate many hypoactive and nonreactive NSTs.

There was a question regarding the necessity for and method of fetal stimulation to produce fetal activity. We all have observed that each fetus demonstrates its own cycle of quiet and active periods. The duration of each cycle is variable, especially in the fetus of a high-risk pregnancy. External stimulation has been effective in the differentiation of the healthy fetus in a quiet state from the one who has a low functional reserve. Administration of phenobarbital has been used in the management of patients with hypertensive disease of pregnancy. External stimulation is especially necessary in these cases. We have used external shaking of the fetus as a method of stimulation since it has been used effectively and safely. In certain cases, uterine contractions were necessary to awaken the fetus from the quiet sleep state.

Using a high-speed recording, Timor-Tritsch and associates[4] demonstrated that 99.7% of fetal movement lasting more than 3 seconds was actually associated with FHR accelerations. A question raised was whether the fetal activity recording alone is sufficient as a test. We would like to evaluate both FHR accelerations and fetal activity as a test, since in certain cases fetal activity produced FHR decelerations.

European investigators, including Kubli and Rochard and their associates, have observed more frequently the sinusoidal FHR in a compromised fetus. We observed only one case of what appeared to be a sinusoidal FHR for only 12 minutes and this FHR pattern was not observed in the repeated test or in labor. Because of a limited, rather confusing experience with the sinusoidal FHR, we could not include this FHR in our classification of NST at the present time.

A further explanation was requested on the classification of the NST shown in Fig. 6. When the NST is active or reactive, it is not necessary to proceed to the CST. However, a nonreactive NST with an initial hypoactive or inactive test does require the performance of a CST for further confirmation of the fetal condition. Five fetuses with a hypoactive-nonreactive test and two fetuses with an inactive-nonreactive test became reactive during the performance of the CST and all CSTs were negative. Two fetuses demonstrated a stressed pattern of variable deceleration[5] without revealing a single FHR acceleration during the NST. The configuration of variable deceleration in these cases revealed an acute deceleration and recovery angle with precipitate deceleration and rapid recovery tracings.

A blunting or rounding of deceleration and recovery angles and a smoothing of the rectangular waveform with loss of jaggedness are progressive changes observed in the distressed pattern of variable deceleration.[5] These changes may represent a sluggish reaction of the autonomic nervous system in the hypoxic or acidotic fetus to hemodynamic changes occurring during umbilical cord compression.

Two fetuses who displayed a stressed pattern of variable deceleration were delivered in good condition. If the fetus is premature, the NST can be repeated. However, the CST is not recommended since uterine contractions may place more stress on the fetus. Perinatal death occurred in one fetus who demonstrated a distressed pattern of variable deceleration and in one who displayed what appeared to be a combination of a distressed pattern of variable deceleration and uniform deceleration. Admittedly, more study is needed in this deceleration group. Nevertheless, a tentative classification was suggested since these cases were composed of two different groups of fetuses.

THE PRELUDE TO THE GOOD YEARS AHEAD...

PREMARIN®
(CONJUGATED ESTROGENS TABLETS, U.S.P.)

given properly,
confers significant benefits
until she feels fine on her own.

Menopausal women can benefit from PREMARIN® as much as ever...

Moderate to severe vasomotor symptoms—flushes and sweats—that exceed the patient's ability to cope, rapidly respond to adequate estrogen replacement therapy with PREMARIN. A marked reduction in frequency and severity is seen in the great majority of patients.

...so it's as important as ever to provide counseling about proper use.

As with any medication, counseling on proper use is a prerequisite to obtaining the maximum benefits. In this regard, although the evidence must be considered preliminary, it is encouraging to note that two studies*† suggest that cyclic administration is more advantageous than continuous administration.

- IDENTIFY THE PATIENT WHO CAN BE HELPED
  the patient with moderate to severe vasomotor symptoms with no contraindications to estrogen therapy.
- GIVE NO MORE THAN SHE NEEDS
  as with any medication, the lowest dose needed to relieve symptoms should be employed.
- ESTABLISH THE CYCLE OF TREATMENT
  be sure the patient understands the need for an interrupted regimen: a "rest period" each month when *no* estrogen is taken.
- FOLLOW HER PROGRESS REGULARLY
  semiannual reassessment of the continuing need for therapy—and to rule out any potential problems—will provide the maximum benefit during treatment.

PREMARIN®
(CONJUGATED ESTROGENS TABLETS, U.S.P.)
0.3 mg/0.625 mg/1.25 mg/2.5 mg

THE PRELUDE TO THE GOOD YEARS AHEAD

BRIEF SUMMARY
(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULAR)
PREMARIN® Brand of Conjugated Estrogens Tablets, U.S.P.

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.

Three independent case control studies have reported an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for more than one year.[1-3] This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade.[4] The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment[1] and on estrogen dose.[3] In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration;[3] it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.

The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a non-steroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare.[5,6] This risk has been estimated as not greater than 4 per 1000 exposures.[7] Furthermore, a high percentage of such exposed women (from 30 to 90 percent) have been found to have vaginal adenosis,[8-12] epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb reduction defects.[13-16] One case control study[16] estimated a 4.7-fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 per 1000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well controlled studies that progestogens are effective for these uses. If PREMARIN is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the advisability of pregnancy continuation.

DESCRIPTION: PREMARIN (Conjugated Estrogens Tablets, U.S.P.) for oral administration contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters.

INDICATIONS: Based on a review of PREMARIN Tablets by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications for use as follows:

Effective:

1. Moderate to severe *vasomotor* symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression without associated vasomotor symptoms, and they should not be used to treat such conditions.)
2. Atrophic vaginitis.
3. Kraurosis vulvae.
4. Female hypogonadism.
5. Female castration.
6. Primary ovarian failure.
7. Breast cancer (for palliation only) in appropriately selected women and men with metastatic disease.
8. Prostatic carcinoma—palliative therapy of advanced disease.
9. Postpartum breast engorgement—Although estrogens have been widely used for the prevention of postpartum breast engorgement, controlled studies have demonstrated that the incidence of significant painful engorgement in patients not receiving such hormonal therapy is low and usually responsive to appropriate analgesic or other supportive therapy. Consequently, the benefit to be derived from estrogen therapy for this indication must be carefully weighed against the potential increased risk of puerperal thromboembolism associated with the use of large doses of estrogens.[19]

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

"Probably" effective: For estrogen deficiency-induced osteoporosis, and only when used in conjunction with other important therapeutic measures such as diet, calcium, physiotherapy, and good general health-promoting measures. Final classification of this indication requires further investigation.

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 2. Known or suspected estrogen-dependent neoplasia. 3. Known or suspected pregnancy. (See Boxed Warning). 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. A past history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

WARNINGS: At the present time there is no satisfactory evidence that estrogens given to postmenopausal women increase the risk of cancer of the breast,[17] although a recent study has raised this possibility.[18] There is a need for caution in prescribing estrogens for women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease, or abnormal mammograms. A recent study has reported a 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease in women receiving postmenopausal estrogens.[17]

Adverse effects of oral contraceptives may be expected at the larger doses of estrogen used to treat prostatic or breast cancer or postpartum breast engorgement; it has been shown that there is an increased risk of thrombosis in men receiving estrogens for prostatic cancer and women for postpartum breast engorgement.[19-22] Users of oral contraceptives have an increased risk of diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction.[23-30] Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users.[31,32] An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives.[33,34] If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization. Estrogens should not be used in persons with active thrombophlebitis, thromboembolic disorders, or in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease. Large doses (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown[35] to increase the risk of nonfatal myocardial infarction, pulmonary embolism and thrombophlebitis. When doses of this size are used, any of the thromboembolic and thrombotic adverse effects should be considered a clear risk.

Benign hepatic adenomas should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Hepatocellular carcinoma has been reported in women taking estrogen-containing oral contraceptives.[36] Increased blood pressure may occur with use of estrogens in the menopause[37] and blood pressure should be monitored with estrogen use. A worsening of glucose tolerance has been observed in patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolau smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc. Oral contraceptives appear to be associated with an increased incidence of mental depression.[23a] Patients with a history of depression should be carefully observed. Preexisting uterine leiomyomata may increase in size during estrogen use. The pathologist should be advised of estrogen therapy when relevant specimens are submitted. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, metabolic bone diseases associated with hypercalcemia, or in young patients in whom bone growth is not complete.

The following changes may be expected with larger doses of estrogen:

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered.

d. Impaired glucose tolerance.

e. Decreased pregnanediol excretion.

f. Reduced response to metyrapone test.

g. Reduced serum folate concentration.

h. Increased serum triglyceride and phospholipid concentration.

As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy, including oral contraceptives: breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea; premenstrual-like syndrome, amenorrhea during and after treatment; increase in size of uterine fibromyomata; vaginal candidiasis, change in cervical erosion and in degree of cervical secretion; cystitis-like syndrome; tenderness, enlargement, secretion (of breasts); nausea, vomiting; abdominal cramps, bloating; cholestatic jaundice; chloasma or melasma which may persist when drug is discontinued; erythema multiforme; erythema nodosum; hemorrhagic eruption; loss of scalp hair, hirsutism; steepening of corneal curvature; intolerance to contact lenses; headache, migraine, dizziness, mental depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance, aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea, and withdrawal bleeding may occur in females.

DOSAGE AND ADMINISTRATION: 1. *Given cyclically for short term use only:* For treatment of moderate to severe *vasomotor* symptoms, atrophic vaginitis, or kraurosis vulvae associated with the menopause (0.3 to 1.25 mg or more daily).

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Administration should be cyclic (e.g., three weeks on and one week off).

Attempts to discontinue or taper medication should be made at three to six month intervals.

2. *Given cyclically:* Female hypogonadism. Female castration. Primary ovarian failure. Osteoporosis.

Female hypogonadism—2.5 to 7.5 mg daily, in divided doses for 20 days, followed by a rest period of 10 days' duration. If bleeding does not occur by the end of this period, the same dosage schedule is repeated. The number of courses of estrogen therapy necessary to produce bleeding may vary depending on the responsiveness of the endometrium.

If bleeding occurs before the end of the 10 day period, begin a 20 day estrogen-progestin cyclic regimen with PREMARIN (Conjugated Estrogens Tablets, U.S.P.), 2.5 to 7.5 mg daily in divided doses, for 20 days. During the last five days of estrogen therapy, give an oral progestin. If bleeding occurs before this regimen is concluded, therapy is discontinued and may be resumed on the fifth day of bleeding.

Female castration and primary ovarian failure—1.25 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Osteoporosis (to retard progression)—1.25 mg daily, cyclically.

3. *Given for a few days:* Prevention of postpartum breast engorgement—3.75 mg every four hours for five doses, or 1.25 mg every four hours for five days.

4. *Given chronically:* Inoperable progressing prostatic cancer—1.25 to 2.5 mg three times daily.

Inoperable progressing breast cancer in appropriately selected men and postmenopausal women—10 mg three times daily for a period of at least three months.

Patients with an intact uterus should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

HOW SUPPLIED: PREMARIN (Conjugated Estrogens Tablets, U.S.P.) No. 865—Each *purple* tablet contains 2.5 mg in bottles of 100 and 1,000. No. 866—Each *yellow* tablet contains 1.25 mg in bottles of 100 and 1,000. Also in unit dose package of 100. No. 867—Each *red* tablet contains 0.625 mg in bottles of 100 and 1,000. Also in unit dose package of 100. No. 868—Each *green* tablet contains 0.3 mg in bottles of 100 and 1,000.

New Books in Medical Sciences from Johns Hopkins

Genetic Disorders among the Jewish People

Richard M. Goodman, M.D.

This book by a leading authority on Jewish medical genetics is the first comprehensive reference work to organize and classify the known medical conditions that affect the Jewish people. The descriptions of over one hundred conditions include information on diagnosis, prognosis, prevention, and early detection. The author also discusses genetic disorders mentioned in the Bible and Talmud, the historical development of Jewish communities, and the genetic heterogeneity of the Jewish people. $32.50

The First Year of Life

Janet B. Hardy, M.D., C.M.; Joseph S. Drage, M.D.; and Esther C. Jackson

As part of a long-term study of the causes of neurological and sensory disorders in children, *The First Year of Life* describes the conditions, events, and abnormalities reported during the nursery stay and the remainder of the first year of life for over 38,000 infants. The book provides data on fetal and neonatal death, low birth weight, congenital malformations, visual and auditory impairments, and other abnormalities. $25.00

PERSONALIZED LIBRARY CASES

Keep your personal copies of AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY in these specially designed library file cases. Designed to keep your journal copies near at hand in your office, library, or home.

Your case is heavy bookbinder's board in rich red Kivar cover. Files are scuff-resistant and washable.

Lettering is stamped in gold leaf and the cases make a fit companion for the most costly binding.

Files are reasonably priced—only $4.95 each, postpaid (3 for $14., 6 for $24.). Add $1.00 postage per case for orders outside U. S. Satisfaction unconditionally guaranteed or your money back! Use the coupon for prompt shipment.

FACULTY POSITIONS

There are currently openings for full-time faculty in Obstetrics and Gynecology who have Board certification or eligibility. Teaching, research and patient care interests important. Special training and expertise in maternal and fetal medicine, reproductive endocrinology, gynecologic oncology or ambulatory care is desired. Academic rank and salary are dependent on qualifications. If interested, please send curriculum vitae and bibliography to:

William N. Spellacy, M.D.
Professor and Head
Department of Obstetrics & Gynecology

TODAY'S PREGNANT WOMAN

SHE'S GOT A LOT OF LIVING TO DO

MATERNA™ 1•60

Prenatal Tablets

WE EVEN NAMED IT AFTER HER

Each tablet contains:	MATERNA™ 1•60 Prenatal Tablets (Film Coated)	For Pregnant or Lactating Women—% of U.S. RDA
Vitamin A Acetate	8,000 I.U.	(100%)
Vitamin D	400 I.U.	(100%)
Vitamin E (as dl-Alpha Tocopheryl Acetate)	30 I.U.	(100%)
Vitamin C (Ascorbic Acid)	120 mg.	(200%)
Folic Acid (Folacin)	1mg.	(125%)
Thiamine (as Thiamine Mononitrate Vitamin B_1)	3 mg.	(176%)
Riboflavin (Vitamin B_2)	3.4 mg.	(170%)
Vitamin B_6 (as Pyridoxine Hydrochloride)	4 mg.	(160%)
Niacinamide	20 mg.	(100%)
Vitamin B_{12} (Cyanocobalamin)	12 mcgm.	(150%)
Calcium (as Calcium Carbonate)	350 mg.	(26%)
Iodine (as Potassium Iodide)	0.3 mg.	(200%)
Elemental Iron (as Ferrous Fumarate)	60 mg.	(333%)
Magnesium (as Magnesium Oxide)	100 mg.	(22%)
Copper (as Cupric Oxide)	2 mg.	(100%)
Zinc (as Zinc Oxide)	15 mg.	(100%)
Dioctyl Sodium Sulfosuccinate USP	50 mg.	

A phosphorus-free vitamin and mineral dietary supplement with surfactant, for use during pregnancy and lactation. Recommended intake: 1 daily or as prescribed by physician.

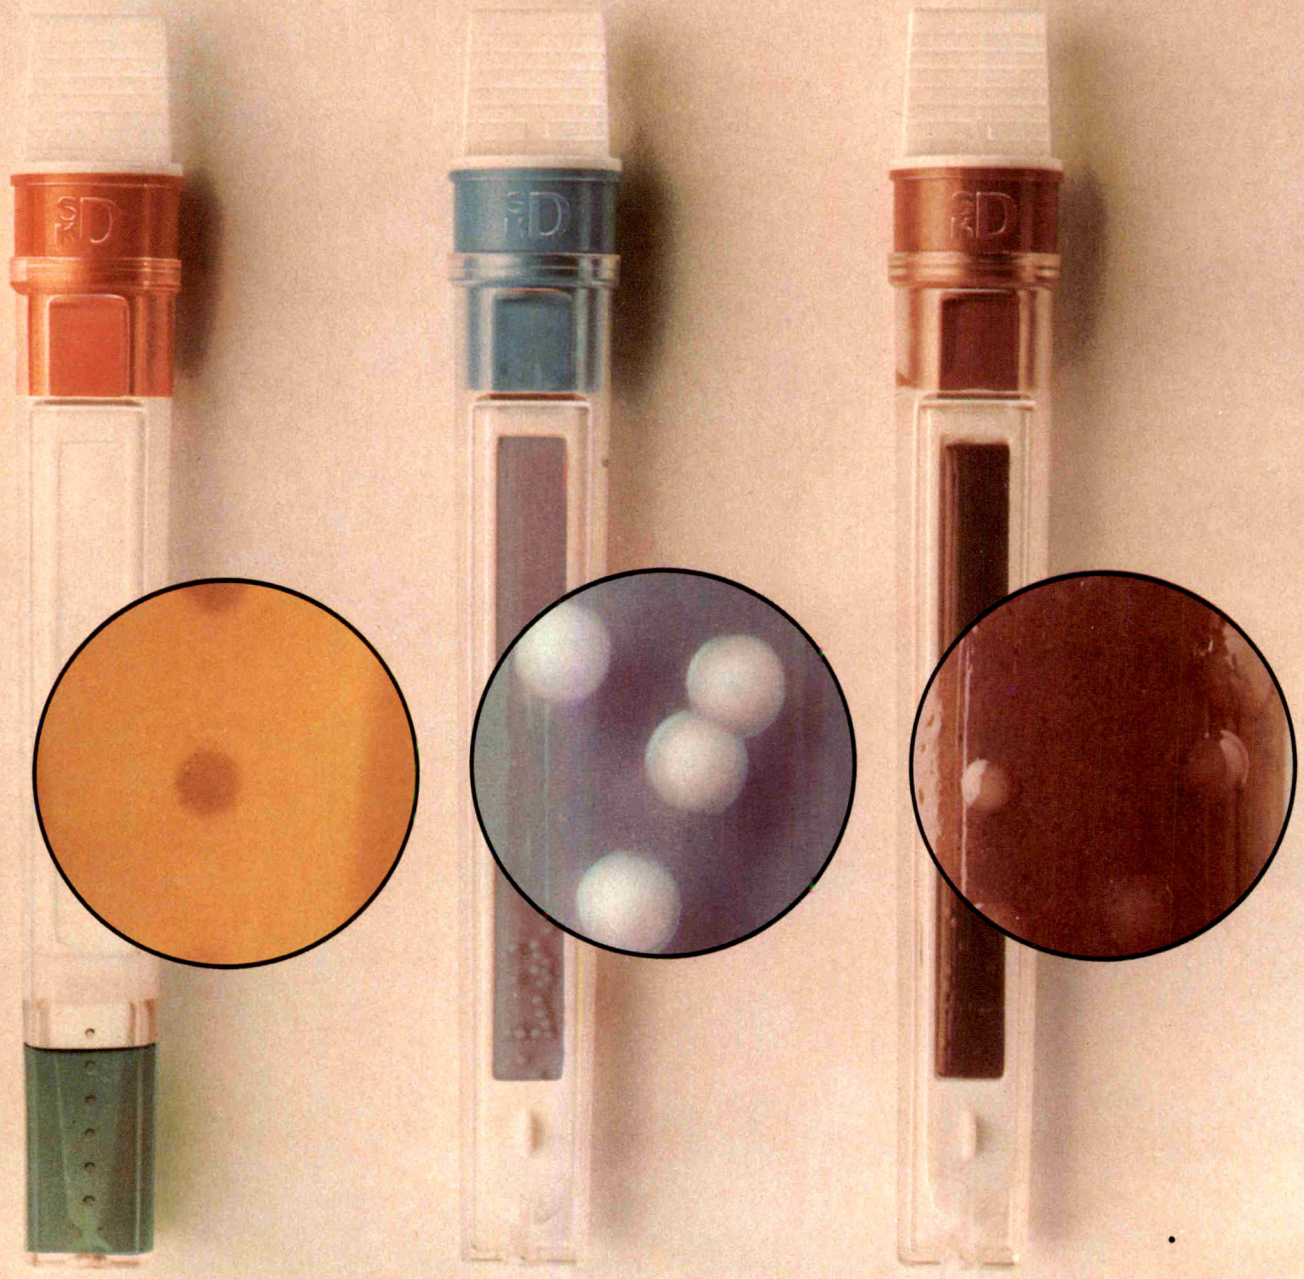
PRECAUTION: Folic acid may obscure pernicious anemia in that the peripheral blood picture may revert to normal while neurological manifestations remain progressive. Allergic sensitization has been reported following both oral and parenteral administration of Folic Acid. Supplied: Bottles of 100.

Lederle LEDERLE LABORATORIES, A Division of American Cyanamid Co., Pearl River, N.Y. 10965 405-8

Isocult®

The inexpensive, in-office culture tests for *Trichomonas vaginalis,* Candida (Monilia), *N. gonorrhoeae*

It's as simple as swabbing a specimen on the culture media, inserting the color-coded tube into a slot of an office incubator and reading results against an identification chart 24 to 48 hours later.



All three tests contain highly selective media that give you the right results, right in your office. And there are also two combination tests that let you check for *N. gonorrhoeae* and Candida or *T. vaginalis* and Candida simultaneously.

You save time. You save space—the incubator is no bigger than your *PDR.* And you save money. You can cover the low cost of the 'Isocult' system and your professional time and still charge your patient less than the cost of a standard laboratory culture.

There's an 'Isocult' culture test for Bacteriuria too. It's reliable, rapid, inexpensive and easy to interpret (results are available within 18 to 24 hours).

'Isocult' is available through local distributors, nationwide. To order or for more information call toll free: (800) 538-1581. (In California call the number below, collect.)

A radioreceptor assay for human chorionic gonadotropin in normal and abnormal pregnancies: A clinical evaluation

ROBERT P. LORENZ, M.D.
BRUCE A. WORK, M.D.
K. M. J. MENON, PH.D.
Ann Arbor, Michigan

The human chorionic gonadotropin–radioreceptor assay (hCG-RRA) offers a rapid and accurate method of diagnosing early and abnormal pregnancies. Such a method is described along with clinical correlations in 139 assays done on 122 patients with amenorrhea, normal pregnancies, infertility, trophoblastic disease, ectopic pregnancies, and missed or incomplete abortions. The accuracy of the test is correlated with weeks of amenorrhea, weeks after ovulation, and clinical diagnoses. The overall accuracy of the assay was 95%. Those performed more than 28 days after the last menstrual period had an accuracy of 96.4%. There were no errors in the diagnosis of eight ectopic pregnancies among 33 suspected cases. Three patients are described who had serial changes from negative to positive early in pregnancy, providing data on precise timing of a positive result. Cases of missed abortion sometimes demonstrate a positive hCG-RRA after documented fetal loss. Recommendations for the most appropriate use of the hCG-RRA are presented based on the clinical experience at one referral center during the period January, 1977, to June, 1978.
(AM. J. OBSTET. GYNECOL. 134:471, 1979.)

THE INCREASED RELIABILITY of the human chorionic gonadotropin–radioreceptor assay (hCG-RRA) pregnancy test over the widely used urinary hemagglutination-inhibition tests has been previously documented.[1–3] Studies vary as to the assay technique employed, the resulting accuracy, and the clinical indications for the test. Based on laboratory data, Lee and Ryan[4] questioned the accuracy of the assay in very early pregnancy.

Landesman and Saxena[3] achieved good results using an assay technique which required repetition of a standard curve for hCG with each set of specimens. Fourteen serial hCG dilutions were used. Roy and associates[1] also had reliable results with an assay using a single reference serum of 100 mIU/ml hCG. An alternative method not requiring the routine use of such standard(s) is presented and evaluated.

From the Department of Obstetrics and Gynecology, University of Michigan.

Presented at the Forty-sixth Annual Meeting of the Central Association of Obstetricians and Gynecologists, Kansas City, Missouri, October 13-15, 1978.

The reported clinical accuracy of the hCG-RRA varies between 85% and 100%. The accuracy of our alternative assay is evaluated and compared to previous studies.

Suggested clinical indications cited in the literature include use with menstrual extraction, trophoblastic disease,[5] threatened abortion, infertility and ovulation induction, spontaneous abortion, ectopic pregnancy, and incomplete abortion.[1–3]

The following study is based on the clinical experience with the hCG-RRA used by the University of Michigan Gynecology-Endocrinology Laboratory from January, 1977, to June, 1978.

Material and methods

Partially purified plasma membranes were prepared from bovine corpus luteum by a method adapted from that reported by our laboratory.[6] A brief description follows: Approximately 20 gm of tissue was homogenized in 7 volumes of sucrose (0.25M) in a Dounce homogenizer. The homogenate was filtered through two layers of cheesecloth and the centrifuged at 400 g for 4 minutes. The supernatant was saved. The sediment was resuspended in 8 volumes of sucrose buffer,

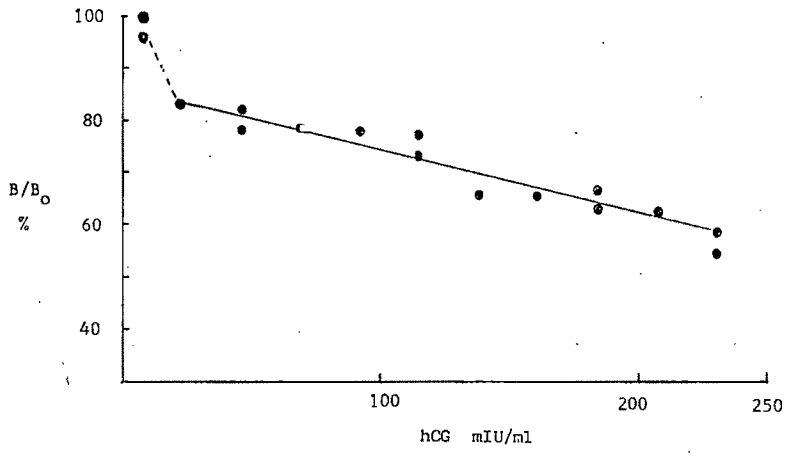

Fig. 1. Standard curve of hCG-RRA.

homogenized in a Dounce homogenizer, and centrifuged at 400 g for 4 minutes. The resultant supernatant was combined with the first supernatant and spun at 700 g for 10 minutes. The supernatant from the above was again centrifuged at 9,000 g for 15 minutes. The resulting sediment was homogenized in 50 ml of sucrose buffer. This fraction contained partially purified plasma membrane.

hCG (11,500 IU/mg) was iodinated by the procedure of Tsuruhara and associates.[7] The specific activity of the ^{125}I-hCG ranged from 40 to 60 cpm/pg.

The binding assay was performed by incubating 50,000 cpm of ^{125}I-hCG in 100 ml of buffer (10 mM Tris hydrochloride, pH 7.5, 1 mM calcium chloride, 0.1% bovine serum albumin) with 100 μl of the patient's serum sample and 40 μl of the membrane preparation. The volume of the incubation mixture was adjusted to 300 μl by the addition of the buffer. Incubation was performed at 37° C for 30 minutes and was terminated by the addition of 1 ml of buffer. The contents were then chilled in ice and centrifuged at 5,000 rpm for 20 minutes in a Sorval refrigerated centrifuge (4° C) using an SS34 rotor. The supernatant was then carefully decanted and the residue was counted in an automatic gamma counter. A control experiment was performed by incubating 100 μl of serum previously pooled from young, healthy women at midcycle. The pregnancy test was considered positive if the ratio of the radioactivity of the patient's serum to the control (B/B_0), expressed in percent, was less than 75%.

The sensitivity of the assay was redetermined at the end of the study period by a control experiment. Measured amounts of hCG (11,500 IU/mg) were added o normal male serum and then underwent the above assay. The results, B/B_0, are plotted against the concentration of hCG (milli-International Units per milliliter) in Fig. 1.

Clinical data were obtained from available medical records supplemented by patient interviews when necessary.

During the study period, January 1, 1977, to June 30, 1978, 503 patients underwent 535 hCG-RRA tests at the University of Michigan Medical Center Gynecology-Endocrinology Laboratory. Clinical data were available and analyzed for the study group of 122 patients undergoing 139 tests. The patient population was characterized by an average age of 27.5 years, average gravidity of 1.3, and average parity of 0.9. Thirty-nine percent of the patients were gravida 0, and 53% were para 0. The indications for the test according to the medical records (some patients had multiple diagnoses) were: rule out normal pregnancy, 61%; possible ectopic pregnancy, 30%; preoperative or preradiation, 7%; missed or threatened abortion, 5%; ovulation induction, 4%; and trophoblastic disease, 3%.

The following definitions were employed by Roy and associates[1] and will form the basis for a comparison with that study: (1) false negative rate: the percent of pregnant patients misclassified by the test; (2) false positive rate: the percent of patients not pregnant misclassified by the test; (3) clinical sensitivity: the percent of positive results when pregnant; (4) clinical specificity: the percent of negative results when not pregnant; (5) predictive value of a positive test: the percent of positive results that are true positive results; (6) predictive value of a negative test: the percent of negative results that are true negative results; (7) accuracy or efficiency: the percent of correct results both positive and negative of all tests performed.

Results

Clinical outcomes. As with most groups of patients undergoing pregnancy tests, the majority (58%) were not pregnant. Pregnancy continued beyond 20 weeks

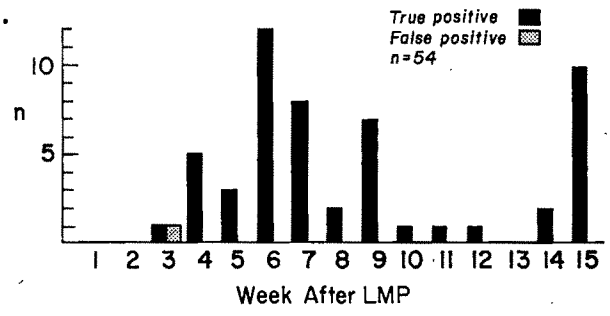

Fig. 2. HCG-RRA: Positive results versus menstrual age.

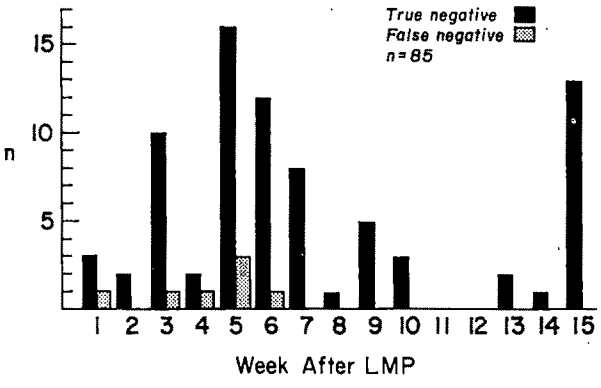

Fig. 3. HCG-RRA: Negative results versus menstrual age.

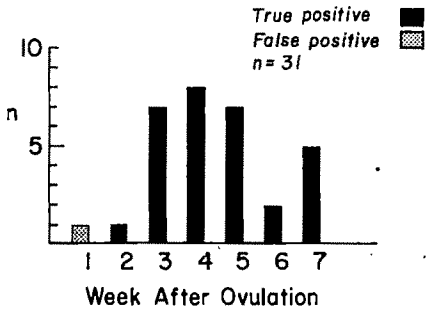

Fig. 4. HCG-RRA: Positive results versus ovulation date.

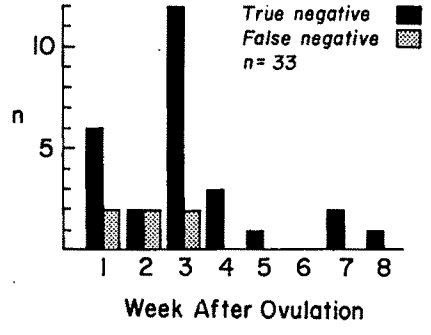

Fig. 5. HCG-RRA: Negative results versus ovulation date.

in 19%; spontaneous abortion occurred in 10%; elective abortion, in 7%; and 7% had verified ectopic pregnancies.

Accuracy. Because any pregnancy test depends on the stage of gestation, the patients were classified by menstrual history and, when available, history of date of presumed ovulation. The latter was determined by calculating the date 14 days prior to the expected menses in patients with very regular menses or by basal body temperature records when available.

Ninety-five percent of all hCG-RRAs done on the study group were accurate. Tests done after the twenty-eighth day following the last menstrual period, the usual time of the expected menses in most cases, were 96.4% accurate. During the third week after the last menstrual period, the accuracy was 85%—the commonly accepted accuracy of the standard urinary hemagglutination-inhibition pregnancy test at 6 weeks of amenorrhea. The accuracy of the hCG-RRA is shown according to menstrual and ovulatory history in Table I.

Patients with positive hCG-RRAs are classified by menstrual age in Fig. 2. Only one test was false positive, giving a false positive rate of 1.2%. This test occurred on menstrual day 15, possibly reflecting an unusually high midcycle luteinizing hormone (LH) peak which would confuse a receptor assay that reacts to elevation in either hCG or LH.

Patients with negative hCG-RRAs are classified by menstrual age in Fig. 3. Seven tests were false negative, resulting in an overall false negative rate of 11.7%. False negative results did not occur after 6 weeks of amenorrhea, the time when the standard urinary tests are just becoming reliable.

When those patients who gave a reliable history for the date of presumed ovulation were reclassified, the results were comparable. These results are shown in Figs. 4 and 5.

For the total study group, the sensitivity of the assay was 88%; the specificity was 99%; the predictive value of a positive test was 98%, and the predictive value of a negative test was 92%. The validity is assessed in Table II.

Ectopic pregnancies. Thirty-three patients underwent 36 tests for a diagnosis of possible ectopic pregnancy. There were no errors in this group: 23 were not pregnant, eight had clinically confirmed ectopic pregnancies, and two had intrauterine pregnancies documented at later elective abortion. Approximately 50% of this group had the study done within 28 days of the last menstrual period.

Early pregnancy. It is not unusual for the hCG-RRA to reflect accurately the presence of an early pregnancy before evidence appears on physical examination. This situation occurred in three cases in the study group, including one patient who underwent an ovarian cystectomy for a bleeding adenexa with a "normal-appearing" uterus at the time of laparotomy. A few

Table I. Accuracy of hCG-RRA

Predictive value (%):				
Positive	86	100	100	100
Negative	85	85	92	100

days later she passed pathologically confirmed gestational tissue.

Incomplete abortion. Minimal amounts of residual functioning trophoblastic tissue may be sufficient to maintain a positive hCG-RRA, even after viability of the pregnancy is lost. One patient presented with a clinical picture of complete abortion at 8 weeks of gestation and was managed conservatively with uterotonic drugs. She did well clinically and reported only minimal spotting for 4 days, during which time the hCG-RRA was positive on three determinations. On the fifth day she reported passing a small amount of tissue, and the hCG-RRA was negative on the following day.

Serial changes from negative to positive. It would be useful to know the exact timing of the conversion of the hCG-RRA from negative to positive during an early pregnancy. Three patients who were subsequently documented to be pregnant had closely spaced hCG-RRAs that converted from negative to positive. T. K. had a negative result on day 22 after presumed ovulation and positive results on days 23 and 30. D. A. had a negative result on day 14 after ovulation and positive results on days 16 and 21. L. H. had a negative result on postovulatory day 12, then a positive test on day 19.

Comment

The clinical specificity, the predictive values of positive and negative results, and the overall accuracy (efficiency) of this assay are comparable to the results of Roy and associates.[1] The false negative rate in early pregnancy, however, is higher. This could result from: (1) decreased sensitivity of this technique in early pregnancy or (2) more errors in reporting or recording the true last menstrual period. The former explanation is unlikely because the control experiment described documented the in vitro sensitivity.

In the cases of suspected ectopic pregnancy, the 100% accuracy of this study is an improvement over the false negative rate of 10% reported by Roy and associates.[1]

Any attempt to correlate the results of pregnancy tests done early in gestation with the stage of gestation is limited by the vagaries of menses, ovulation, and patient histories. For this reason data regarding date of presumed ovulation were studied as was menstrual history alone. The reliability of the test was approximately the same in both the ovulatory group and the menstrual group. If one accepts the ovulatory data, the conclusion might be that the test is somewhat less sensitive than the menstrual data indicate. However, the discrepancy may reflect only the increased difficulty in accurately determining the ovulation date.

Review of our clinical experience has led to some general guidelines for appropriate indications. All pregnancy tests suffer from a higher frequency of false negative than false positive results, so the two results should not be weighted equally. In any case no single laboratory test should be the basis for clinical management without appropriate consideration of the complete clinical picture. However, this study has reviewed numerous clinical situations where disregard for a positive hCG-RRA could be the basis for mismanagement. Early unruptured ectopic pregnancies, a corpus luteal cyst associated with an undiagnosed intrauterine pregnancy, and retained products of conception demonstrated positive hCG-RRAs. On the other hand, the sensitivity of the assay has prevented the use of this qualitative test to confirm the diagnosis of an inevitable abortion. The test has been positive after fetal death in our experience. The correct distinction between complete and incomplete abortion may be possible, but only if a few days have elapsed since the initial passage of tissue. In the management of trophoblastic disease, the hCG-RRA may be useful in initial diagnosis, but the qualitative assay for hCG-RRA often becomes negative while circulating hCG is still present as measured by the hCG β-subunit radioimmunoassay. Thus, in documented trophoblastic disease when speed is not critical, the more sensitive and no more costly hCG β-subunit assay is employed. We have noted an encouraging and marked increase in the use of the hCG-RRA by other medical services in our institution in patients scheduled for elective surgical, radiologic, or nuclear medicine procedures.

Discussion

DR. FREDERICK K. CHAPLER, Iowa City, Iowa. Radioreceptor assays are based on displacement of labeled hormone from a receptor site by unlabeled hormone in the patient's serum or urine. It represents measurement of a biospecific hormone-receptor interaction and does not measure antigenic determinants on a hormone, as radioimmunoassay does. Consequently, it has great appeal to me because it measures an actual step in hormone action.

The authors have reported their experience with a qualitative radioreceptor assay for hCG. They described a new method, evaluated its accuracy, and gave some recommendations for its use. Their alternate assay method did not make use of routine standard preparations. Instead they used a sample of pooled LH peak serum as the control. This theoretically prevents false negative tests from arising due to an unexpected or midcycle LH surge (the radioreceptor assay does not distinguish between hCG and LH). The first question I have is concerned with the dose-response curve. The initial curve seemed displayed in an unorthodox fashion, but the revised curve looks more like a logit-log transformation. If this is so, it should be labeled as such. The method of determining a positive answer is a little confusing to me. Originally, the answer was based on a difference of 2,000 counts, between the control and unknown sample. This was changed to a percentage or ratio of B/B_0. Was this alteration due to a time-dependent loss of specific activity of the tracer or to some other problem concerning specific activity? Also why was an aliquot of the pooled LH peak serum not placed in each tube? What is the turnaround time, including counting time on the gamma counter? The literature usually states that this is under 2 hours and I would just like to know what the authors' time is.

The accuracy of this "yes/no" assay has been evaluated from several different and somewhat confusing aspects, but, in general, the authors' accuracy compares favorably with that reported in the literature. There is one point regarding the false negative analysis that needs clarification. It was stated that "when patients were classified on the basis of presumed ovulation the results were comparable." I am not sure to what they are comparable. The figure showing false negative values based on menstrual history indicated these to be seven of 85 while the figure of false negative values based on ovulation dating indicated six of 33. I think these can be compared, but they are quite different. Perhaps the purpose of that was just to show the vagaries of attempting to estimate a point in time based on a last menstrual period and/or a presumed ovulation.

The recommended indications for use of this assay seem appropriate, although some may doubt the clinical significance of being able to document the serial change of hCG from negative to positive. Perhaps this has value in treating patients with presumed luteal deficiency problems with progesterone suppositories. Since the assay is not quantitative, I agree that it has limited, if any, use in the management of trophoblastic disease or in threatened abortions. Much has been written concerning the radioreceptor assay's role in many abortions. Its high degree of accuracy on the first or second day of a missed menstrual period, as the author's have shown, should prevent most unnecessary procedures. Its use as a quick, sensitive, preoperative or preradiation pregnancy test will also be very valuable to the clinician. The radioreceptor assay for hCG seems very useful in the management of an unruptured tubal pregnancy and may well save some patients from laparoscopy and others from a laparotomy under emergency conditions. Certainly, this assay has to be compared with the beta-subunit hCG radioimmunoassay which is more sensitive but takes considerably longer, up to 48 to 72 hours. The radioreceptor assay's short turnaround time of 2 hours is a distinct advantage.

I would like to thank the authors for stimulating my interest in the radioreceptor assay, and I recommend the excellent review article by Saxena and Landesman[1] in the May 1, 1978, issue of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY. One final question to Dr. Lorenz: Have you had any experience with the commercially available hCG radioreceptor assay kit? Although its sensitivity limit seems to be a little high, I would appreciate any comments he might have concerning its use.

REFERENCE

DR. LORENZ (Closing). As Dr. Chapler has indicated, this laboratory technique for the hCG-RRA is a qualitative and more simple approach not requiring the usual hCG standards of previous studies.

Dr. Chapler's questions related to the original dose-

response curve and the determination of a positive result are based on a previous draft of this paper. Fig. 1 is a dose-response curve for the low concentrations of hCG found in early pregnancy. As the units and scale of the axes demonstrate, it is not a logit-log transformation. The abscissa represents the amount of hCG added to male serum in milli–International Units per milliliter. The ordinate is the ratio, expressed in percent, of the radioactivity of the standard serum, B_0. The curve demonstrates that a positive result, i.e., B/B_0 less than 75%, occurs in the range of 125 mIU of hCG/ml. This is the concentration of hCG that occurs in pregnancy at about the time of the missed menses. Expressing the results as B/B_0 does allow for time-dependent loss of specific activity of ^{125}I-hCG. Adding the pooled female sera to each assay would have transformed the result to $(B + B_0)/2B_0$ but would not have improved the reliability.

The comparison between the accuracy of the assay based on menstrual history to that based on ovulation data is valid when adjusted for the stage of gestation. By 6 weeks of amenorrhea 66 of 74 tests were correct, for an accuracy of 89%. Of the 46 tests done within 4 weeks after ovulation, 39 were correct, for an accuracy of 86%.

The serial changes from negative to positive results in three patients were offered not as an example of an indication for use of the hCG-RRA but as a demonstration of the timing of the earliest positive results in those cases.

We have not had an opportunity to compare our hCG-RRA with the commercially available method.

Social problems of women patients in a private obstetrics and gynecology clinic

LORETTA J. BARTON, B.A., L.S.W.
CAROL D. H. HARVEY, PH.D.
DAVID M. BARTON, M.D., F.A.C.O.G.
Boise, Idaho, and Seattle, Washington

Patients present or exhibit problems other than physical ones to their physicians and need access to some type of assistance for them. Over a 1 year period, women patients were referred to and seen by the medical social worker employed by a private obstetrics and gynecology clinic. Their social problems were studied by content analysis of patients' records, patients' social services cards, and monthly social services summaries. Results showed that 163 women exhibited 288 social problems consisting of three major types, financial, marital, and emotional. Various relationships were shown between the type of social problem and the primary reason the patient visited the clinic. It was also shown that if a patient has a financial problem, she is more likely to have a greater number of social problems than are other patients. (AM. J. OBSTET. GYNECOL. 134:477, 1979.)

WOMEN WHO WERE REFERRED over a 1 year period to a social worker employed by a private obstetrics and gynecology clinic were studied via content analysis in order to: (1) describe social problems that patients presented or exhibited, (2) explain how patients' ages and reasons for coming into the clinic were related to social problems, (3) determine whether or not financial problems are associated with social ones, (4) test the relationship between stress of illness, pregnancy, or infertility and social problems, (5) demonstrate that patients present more than physical problems to health care providers and (6) make it known that a social worker ought to be a part of the health care team.

This study deals with medical social work, a field where social work is practiced in a medical setting. Its primary responsibility is to help patients and their families deal with psychosocial needs which affect their abilities to adjust to illness or make optimum use of medical care.[1]

Medical social work deals with conditions that are disturbing to humans, including dependency, pain, mutilation, and death.[2]

Presented at the Forty-sixth Annual Meeting of the Central Association of Obstetricians and Gynecologists, Kansas City, Missouri, October 13-15, 1978.

Reprint requests: Loretta J. Barton, 1305 Warm Springs Ave., Boise, Idaho 83702.

Methods

The data were obtained from each patient's social services card kept by the clinic social worker, from the patient's office record kept by the health care team, and from monthly summary sheets provided by the social worker. Information on the social services card was obtained both from personal interviews by the social worker and also from office records. The office record contained the patient's physical and personal history, laboratory reports, and notations made by the clinic staff after personal or telephone contact with the patient. (In this study the office record was used primarily to check reliability of the social services card.) The social worker's monthly summary sheets were a compilation of the frequency and types of social problems presented by the patients. (The original purpose of these sheets was to keep the physicians in contact with patients' psychosocial status; in this study the sheets were also used as reliability checks.)

The term "social problem" is used in this study to cover situations which caused discomfort or trouble to the patient. For instance, "divorce" is classified as a "social problem," although in actuality the situation of divorce may not be a problem to all subjects. Situations resulting in discomfort to some patients are also listed as "social problems," such as "infertility adaptation." In

Table I. Primary reason for patient visit to clinic at the time of referral to a social worker

Reason for visit	%*

general, the term "social problem" is used here to delineate a problem other than a physical one presented by the patient or observed by a member of the professional health care team.

This sample consisted of 163 women who were referred to the social worker because they had a social problem. The number represents approximately 6.5% of the clinic patient population. The type of social problem was determined during the social work interview, involving the medical social worker (L. J. B.) and the patient.

Results

Two sets of results are discussed, including (1) descriptive, univariate analysis and (2) explanatory, bivariate analysis.

Single-variable descriptive results.

Age. Patients' ages ranged from 3 to 70 years, with a mean of 28 and a median of 26.

Medical staff person who referred patient to social worker. The modal referral source is Dr. A with 37% of the referrals, Dr. B refers 26% of the patients, and Dr. C, the newest physician, present only the second half of 1976, refers 6%; nurse-practitioners refer 10% of the patients; and the business office staff, 8%. The remaining 12% come from other sources, including office nurses, medical students, friends, or self-referral. The greatest percentage (69) of referrals thus come from the combined physician group.

Patients with financial problems	10	52	63
Numbers on which percentages are based	84	44	35

*$\chi^2 = 42.7$; $P < 0.0001$; $\lambda a = 0.19$.

Primary reason for visit to clinic at time of referral. The primary reasons for clinic visits are shown in Table I. The highest frequency of "other" occurs in 25 patients who came in with a gynecologic complaint. Ten came in for a routine examination, seven had an emotional or "nerves" problem, four did not visit the office after being informed of a "suspicious" Papanicolaou test, two had family problems, and one reported sexual dysfunction.

Types of social problems. A frequency distribution of the social problems presented by the patients is in Table II. It shows that the three most frequently occurring problems are financial problems, marital problems, and sexual dysfunction. "Other" and family problems follow closely in rank.

If all emotional or adaptation problems are combined into one category, then emotional problems become the largest category, representing 35% of the patients. Financial problems represent the second most frequent problem (33%). If marital and divorce or separation problems are combined, then this category rep-

resents the third most frequent type of social problem presented (27%).

Only one patient came in with sexual dysfunction as the primary (stated) reason for her visit to the clinic; however, in the interview by the social worker and/or physician, 24 patients reported sexual dysfunction. While only seven patients came into the clinic specifically because of "nerves," a total of 64 presented emotional problems.

Number of social problems per patient. The mean number of problems per patient is 1.76. Fifty-two percent of 163 patients have one social problem each; two problems are exhibited by 27%; and three problems by 16%; four problems are presented by 4%; and five problems by 1%.

Explanatory results. It is helpful to explain how some of the preceding items correlate.

Age by primary reason for visit to clinic. Table III shows that infertility patients are likely to be older; in the pregnancy-related group the opposite is the case. The surgery-related group appears to be older; the "other" group shows no relationship of age and reason for visit. The patients with pregnancy-related problems have the greatest frequency of being referred to a medical social worker at a young age and the oldest age referrals are in the surgery-related group.

Age by number of social problems. Using the Pearsonian r, age is shown to be weakly and inversely related to the number of social problems ($r = -0.15$, $P < 0.03$).

Financial problems by number of social problems. In Table IV it can be seen that association between financial problems and number of social problems exists. Those individuals who did not have a financial problem are more likely to have fewer than two social problems, while the individuals who had financial problems are more likely to have more than two social problems in

addition to their financial one. The data also show that while 14% of the entire sample has three or more social problems including a financial one, 8% of the 163 who do not have financial problems have three or more social problems.

Primary reason for office visit and number of social problems. There is no association between the primary reason for office visit and the number of social problems. However, if a patient comes to the clinic for infertility, the chances are greater that she has only one social problem (80% chance as compared to 43% in the pregnancy-related group, 53% in the surgery-related group, and 49% in the "other" group).

Primary reason for office visit and type of social problem. Table V shows that the infertility-related group ranks high in adoption interviews. The surgery-related group ranks high in family problems and surgery-related emotional problems. The "other" group ranks high in marital problems, sexual dysfunction, and general emotional problems, as well as in pregnancy-related cases with absence of husband. The pregnancy-related group holds the highest percentages in the problems of finance, divorce, miscellaneous, grief, prenatal or postpartum emotions, and "other reason for clinic visit" in absence of husband. Also the pregnancy group ranks high along with the surgery-related group in discharge-planning problems.

If four classifications denoting emotional problems from Table V are combined, and marital and divorce, financial, and other problems are grouped, another type of picture is seen (Table VI). Emotional problems appear to be evenly experienced by three of the four reasons for initial visit, with the exception of the infertility group. Financial problems are experienced the most frequently in the pregnancy-related group, which could also have been the main reason for referral to the social worker. Within the marital problems group, it is interesting to note that the "other" reason for clinic visit appears to be marital problems (which is more frequent than in the other groups). From Table V, sexual dysfunction also occurs more frequently in the "other" group.

Comment

A total of 163 female patients presented or exhibited to their physicians 288 social problems in 1 year. Since couples tend to seek help for their marital problems first from the clergy and second from their physicians,[3] there appears to be great value in making the services of a social worker available to help patients alleviate the distress and discomfort caused by social problems.

The "other" group of patients presented some interesting phenomena, such as high percentages of marital problems and sexual dysfunction in relation to other patients. Evaluating this group in terms of actual physical illness or the possibility of psychosomatic complaints by reviewing their clinic records a year later would show if significant physical pathology was ever found. The statistics presented by this group indicate that women do indeed go to their physicians for reasons other than physical complaints; they may in fact go to the physician with a variety of situational and emotional complaints as well. However, the patient appears not to come in with a complaint of a social problem but complains instead of a gynecologic problem. Perhaps she even chose a time of trouble to come in for her routine examination.

An association was also found between age and infertility-related reasons for visit and subsequent referral to the social worker. A possible explanation is that the infertility patient may be more worried and upset as she becomes older and still remains infertile. The infertility patient must have some wealth, as infertility tests and procedures can be quite expensive. The data did show that only 5% of the infertility group had financial problems.

In regard to the pregnancy-related group, it was found that as the patient became older, she was less likely to exhibit social problems. This might be explained that as a woman gets older, she may adapt to the stress of pregnancy and have less need for social services; also, the chances for pregnancy itself decrease as age goes over 30.

The surgery-related patients were older. This would be expected as the numbers of operations performed also increase with age, according to information from the physicians in the clinic. The "other" group appeared to show no association between age and the likelihood of social problems appearing although there was some peaking in the middle years.

We referred to a social readjustment rating scale and found that the problems of the women examined in this study were included in the top half (or highest ranking) of the stress scale.[4] High-stress events are pregnancy, personal injury or illness, sexual difficulties, change in financial status, divorce, marital separation, death of close family member, and change in health of a family member. No real statistical evidence was shown as to whether these life-event stresses cause or are possibly caused by stress. The patients who had social problems also had stresses. It was estimated that about 6.5% of the patient load of the clinic during 1976 experienced problems in relation to stress; stress may have caused social problems for some.

While only one patient came into the clinic for the primary reason of sexual dysfunction, a total of 24 ex-

hibited this problem. Perhaps individuals today still are reluctant to seek help for sexual problems.

A further study would measure and evaluate social services provided. A control group could be used to determine if social services do alleviate the problems of patients and, hence, the problems of illness.

We would like to thank the Boise (Idaho) Valley Obstetrics and Gynecology Clinic for their cooperation in providing subjects for this study.

Discussion

DR. ROBERT M. KRETZSCHMAR, Iowa City, Iowa. It has been clearly demonstrated through this work that the social worker serves as a physician-extender in management of problems that significantly alter the health of the patient.

We have long recognized the presence of social workers in hospitals, particularly hospitals financed with state, county, or city support. This paper clearly describes how a social worker can function in the private health care arena in an outpatient situation.

I have reviewed the social service statistics for our Obstetrics Service during the year July 1, 1977, through June 30, 1978. During that period of time at the University Hospitals in Iowa City there were 3,083 deliveries. Single women made up 956 of this patient population. Forty percent of the deliveries were in teenage women. Of the total number of patients 675 had referrals to our Social Services Department. The majority of the referrals came from the patients or their families. Doctors accounted for only 75 of the referrals. Our Social Services Department, in reviewing charts, identified 494 additional patients who were in need of service and received service from our Social Services Department. This case finding was initiated by the social workers and done by reviewing in an ongoing fashion the patients' charts in our clinic and postpartum area. This indicates that roughly 40% of the services rendered by our Social Services Department was from cases not referred to the Social Services Department. I wonder if this same type of case finding could be employed in the private sector with the same type of results?

The total number of patients served on our Obstetrics Service was 38% of the total number of patients delivered. The types of problems encountered in the obstetric area were remarkably similar to those reported in this paper. The largest category was problems related to pregnancy of an unmarried woman, representing 693 cases, as a primary reason for Social Services contact. This was a secondary reason for service in 461 additional patients.

Problems in current functioning or relationships represented 110 primary reasons for Social Services contact and 398 secondary reasons for Social Services contact. Environmental stresses including financial need represented 162 primary reasons for Social Services contact and 126 secondary reasons for Social Services contact. Ambivalence or conflicts about parenting represented 30 primary reasons for Social Services contact and 71 secondary reasons for Social Services contact. There were additional problems that were managed by the Social Services unit with a total number of problems of primary and secondary categories totaling 2,705 problems.

Our social workers also reviewed charts for potential problems that fell into the same categories listed above but these problems were not managed by the Social Services Department. The total number was 1,477 potential problems. This indicates that we probably need more social work services in our Obstetrics Department. It also indicates that possibly in addition to those problems identified and treated by our social workers, there are a large number of problems which, through chart review, can be identified as potential problems, with potential patients in need of service. In the future could the authors try to review charts to identify social problems as reported in the record and thereby increase their effectiveness in the total comprehensive health care of the patients in their clinic?

DR. JAMES H. MAXWELL, Colorado Springs, Colorado. The authors have demonstrated the need for the services of social work expertise in dealing with the problems that appear in the clinical practice of obstetrics and gynecology. If anything, it is surprising to me that only 6.5% of their total clinic population had identifiable needs that resulted in referral to the social worker. One wonders if this low percentage would not increase as this particular team interacts with each team member and learns what role each fills. Adding further credence to this concept is the fact that financial problems (32%) and unwanted pregnancy (10.4%) are easily identifiable problems that are readily referred, whereas sexual dysfunction is apparently much more difficult to

detect and refer. (One patient was initially identified and referred, yet 24 patients eventually were identified as having sexual dysfunction upon referral and social worker interview.) What is true of sexual dysfunction is true of most of the other reasons for referral.

What the authors do not say in the paper is as important as what they do say, and what they do not say raises a multitude of questions in the mind of this reviewer.

There is no mention made of what criteria were used in establishing which clinic patients were referred to the social worker. One might suggest the use of a relatively simple inventory test such as that of Stewart at the University of Michigan.

The authors really do not establish the effectiveness of the social worker in the private context.

No mention is made of the model used by the social worker. Is the social worker more than a "unifier" for referrals? If so, what other function is served?

Also nothing is said of the goals of the social worker. Is initial evaluation, then referral, the only goal? I doubt it. Is correlation of services an additional function? No mention is made of the social worker's teaching function and counseling function and the dynamic interplay that exists between those two functions.

Finally, the authors do not discuss how long patients were seen by the social worker or how this therapy resulted.

As I said previously, "what the authors do not say in the paper is as important as what they do say." These "dark holes" in this paper (to borrow a term from astronomy) I am sure are proper subjects for future research and reporting. I, for one, eagerly look forward to seeing these "dark holes" filled in with light.

We are dealing, in our specialty, with women—many of whom are hurting, fearful, and troubled. Dostoevsky said, "Her's is a soul that has not yet found peace, and it must be treated gently because there may be a treasure in it."* The authors of this excellent paper have given us yet another tool with which to deal with the troubled soul we see daily in our clinics.

DR. JOHN COPPES, Albuquerque, New Mexico. Working with a Maternity and Infant Care Project, I am convinced of the need for a multidisciplinary team. Outcome statistics are often not good measurements of such efforts. Was there any study or anything shown in the pregnant women as to the improvement of prenatal care? Were there any more visits, and was the outcome of pregnancy changed in any way? In those pregnancies that were unwanted, was there any follow-up on child abuse or any problems of that nature in the unwanted child?

DR. LEE J. MONLEZUN, Lake Charles, Louisiana. I would like to share with the Association something that happened to me about 6 or 8 months ago. My brother is a psychiatric social worker, as well as a recent graduate of the Harvard School of Public Health; he returned to Louisiana to go into practice with me.

He entered my office, and he immediately began as a psychiatric social worker to see referred patients. He calls it a "psychosocial consultation." It is an ongoing consultation with my patients. Some 12 to 15 other obstetricians-gynecologists in town began to use him, and over the last 6 to 8 months he has acquired a tremendous practice.

I see patients at 6 month and 1 year intervals and have subsequently seen patients that I initially referred to him with much improved emotional and physical health.

It is like giving up a part of your practice, like stopping obstetrics and only practicing gynecology. A tremendous load has been taken off me. If one is looking for time off and for a person that can help, consider a psychiatric social worker.

DR. BROOKS RANNEY, Yankton, South Dakota. Since I practice in a region which is quite similar to that of the authors, it may be interesting to share with you a few general statistics concerning these problems which have been discussed.

First, most of our patients have real, physical problems which bring them to the obstetrician-gynecologist. Some may also have significant emotional problems. We do not have a social worker, but our obstetric-gynecologic "nurse-specialists," whom the patients may already know and trust, sometimes help us in the discovery and elucidation of these emotional problems. Most patients prefer that these be private, confidential discussions, only with their physicians.

Statistically, the problems we see fall into four major categories in the following order of frequencies:

1. Financial problems—severe debt caused by mismanagement or no management of the family budget, which results in severe family disharmony.
2. Alcoholism or drug abuse—primarily, in our area, alcoholism, usually by the spouse, but sometimes by the patient.
3. Sexual problems—various types of sexual incompatibilities between mates, or sexual infidelities, usually, but not always, committed by the man.
4. "Inconsiderateness" within the family—a lack of thoughtfulness concerning other members of the family which is often caused by a boorish, self-centered attitude by the husband, but sometimes is caused by a petulant, self-centered attitude by the wife.

These four categories of emotional problems are the ones most commonly seen in our region.

DR. GERALD B. HOLZMAN, East Lansing, Michigan. Several investigators in our area have demonstrated how cultural differences influence patient compliance.[1] Have the essayists in their analyses looked at the effect of cultural differences on the problems that they have enumerated?

REFERENCE

1. Snow, L. F., Johnson, S. M., and Mayhew, H. E.: The behavioral implications of some old wives' tales, Obstet. Gynecol. 51:727, 1978.

DR. ERNST R. FRIEDRICH, St. Louis, Missouri. What we are talking about is the realm of psychosomatic medicine. This is nothing new. When I was in medical school at the University of Heidelberg 25 years ago, we had a Chair of Psychosomatic Medicine. We have been trained (partially, at least) in psychosomatic medicine, but what we are all admitting now is that we do not train our medical students and our residents in this field. This is the reason why we are willing now to give up part—a very important part—of our practice to some paramedical personnel.

We are training more and more obstetricians and gynecologists, and some of us who are involved in their training are a little bit concerned whether we will have enough work for them in the years to come. Perhaps this is a field that we should get more involved in: Train our medical students and residents in psychosomatic medicine and do part of this important work ourselves rather than delegating it to others.

If other trained paramedical personnel are available, this is fine; they should be put to work. Maybe it is cheaper now, but we should also have in mind the long-term goals of our own specialty in the years to come.

DR. BARTON (Closing). I will attempt to answer several of the questions but will begin by saying that the last remark about our role in "psychosomatic care" and your training in this is a key issue. Many of us have not felt very comfortable in some of these things, either individually or in training. This is reflected in the attitudes of physicians in general, who express some skepticism about the value of paramedical personnel and specifically social workers in some of their roles in the health care team.

Dr. Kretzschmar had some very important statistics, from an institutionally related form of social work, particularly his methods of referral, physicians versus the surveillance system approach. Obviously, as was pointed out, only 6.5% of our total patient population were referred, and the majority were referred by physicians in private offices.

Others came from nurse-practitioners and office personnel. I am sure that if we had a surveillance system wherein charts were reviewed by the social worker more problems would be detected and, perhaps alleviated.

There would still be the question of physician acceptance of unsolicited review of charts as well as the question of financial reimbursement in offices that operate on a fee-for-service basis. We have found that some degree of explanation to the patient is necessary in our referral to a social worker as well as clarification and better communication with the social worker in resolution of the problems presented.

Statistics have been published dealing with what resources women consult for psychosocial problems and particularly marital problems. Members of the clergy are consulted first, physicians are second. Perhaps the definition of "physician" also would have to be considered.

Dr. Maxwell's question reflecting the 6.5% of our total population studied deals with the sensitivity of the physicians involved and their perceptions of problems of the patients; we all need to learn more about the sensitivity factor.

The things that we did not say certainly are important. Quantifying these data and making some effort to obtain more objective data in these fields are difficult. We are looking for suggestions as to how to do these effectively.

The perinatal team approach was commented upon, and it was questioned whether the prenatal care was improved and whether follow-up of unwanted children or unwanted pregnancy factors was done. In some instances referral to other community resources was utilized and in particular our maternal and infant care program supported by state and federal funds. Others were dealt with on an individual basis.

The discussion about the use of the psychiatric social worker reflects similar problems that can be approached in these workers' growing roles.

Dr. Ranney's comments about his ranking of the numbers of social problems as reflected in financial, alcohol and drugs, sexual, and family problems are also true in our cases. Alcohol and drugs per se might be objective factors underlying some of the emotional problems.

We did not deal with the compliance question and cultural differences, and again these would probably reflect our patient population versus that in other communities.

I think this study has served a specific purpose in attempting to quantify and assess the value of the social worker in a practice setting as well as to identify the frequency and the type of problem in that setting.

Once again, we are reminded of the fact that patients presenting physical complaints have a variety of underlying contributing factors of emotional and social adjustment. Personnel in a counseling capacity can serve as a valuable asset in dealing with some of these factors.

One-way maternal transport: An evolving concept

Inpatient services

FRANK H. BOEHM, M.D., F.A.C.O.G.
MARY F. HAIRE, R.N., B.S.N.
Nashville, Tennessee

Transporting the high-risk pregnant woman to a tertiary center prior to labor or delivery, in an attempt to offer more intensive care to the patient and her infant, has gained increasing support from medical communities over the past few years. Because of this concept, tertiary centers need to be actively involved in the organization of these transport systems and to be certain that all members of the perinatal team at the referring as well as the receiving center are kept informed of events. This paper describes how Vanderbilt University Hospital initiated an active one-way maternal transport system and how that system is maintained and reviews the first 176 patients treated under that system. Establishing direct lines of communication between the practicing physician and the tertiary center and emphasizing continuing education at all levels seem to be important aspects in the development and maintenance of such a referral system. (AM. J. OBSTET. GYNECOL. 134:484, 1979.)

IN 1974, the Tennessee State Legislature passed a bill to allow the development of a plan that would implement a program for the diagnosis and treatment of certain life-threatening conditions present in the newborn infant and to establish a Newborn Advisory Committee. This legislation was the first step taken by the state to develop the regionalization of perinatal health care, a process defined as the organization of a region in which there are defined levels of perinatal care, consisting of at least one tertiary-level hospital whose primary concerns are education, communication, consultation, and transportation. This step was taken because Tennessee, when compared to the other states, ranked fourth from the bottom in infant mortality rate and because it had been demonstrated in other states that this process of regionalization could contribute to a lowering of the neonatal mortality rate. Arizona, by regionalizing neonatal intensive care units, reduced its infant mortality rate from forty-third to eleventh in this country during the five years from 1967 to 1972.[1] The Tennessee Newborn Advisory Committee established newborn care guidelines and did much in other areas to attempt to reduce neonatal deaths. The neonatal mortality rate in this state dropped from 16.2/1,000 in 1970, to 11.6/1,000 in 1976.[2] In the same period the infant mortality rate fell from 21.3/1,000 to 16.1/1,000, equal to the national rate in 1976.[2] Through further legislation in 1977, this committee was expanded to encompass obstetric concerns and is now known as the Perinatal Advisory Committee. Although somewhat delayed in becoming actively involved in the regionalization process, the state's Obstetrical Society recently came out in favor of regionalizing perinatal health care.

While the pediatricians had a great deal of experience in setting up the various aspects of regionalization, there was no clear mechanism to guide the obstetric side. In 1975, therefore, a 2 year grant was given to Vanderbilt University Hospital to design and implement a plan to effect obstetric regionalization in middle Tennessee, a 37 county area with a population of 1,270,000 and approximately 22,000 deliveries per year. From the beginning it was clear that one of the methods for lowering the neonatal mortality rate was the establishment of a two-way newborn transport system. Nevertheless, after a review of the data from the neonates transported to Vanderbilt, it seemed that many of those brought by the transport van could have been more safely transported in utero had there been a mechanism by which the mother could be easily re-

From the Department of Obstetrics and Gynecology, Vanderbilt University Hospital.

ferred to the tertiary center prior to delivery. Therefore, while a great deal of emphasis was placed on establishing numerous nursing and physician continuing education programs on modern obstetric subjects, and while certain consultative services such as the establishment of a Xerox Telecopier Network[3] were made available to hospitals and physicans in the area, this report will discuss those plans which led to an active one-way maternal transport system in middle Tennessee and how that system was implemented and will present a summary of the maternal transport patients admitted to Vanderbilt from July 1, 1976, to July 1, 1977.

The plan

The fault of many programs originating from tertiary centers seemed to be poor communication between the institutions involved. Physicians in small community hospitals often expressed concern that members of the tertiary center's "ivory tower" could not understand their needs or situations and, consequently, would not willingly respond in a positive fashion to various programs proposed by the tertiary center. Therefore, it seemed imperative to visit each hospital in middle Tennessee offering obstetric care so as to identify specific needs and problems in the area and to open lines of communication. Accordingly, funds were obtained through the Regional Medical Project to hire a highly specialized obstetric nurse to visit the 46 hospitals in middle Tennessee that give obstetric care. After arranging the initial visit by telephone or letter the nurse went to each hospital to survey the obstetric facility, to gather as much information as possible, and to schedule an all-day meeting at a later date with the hospital administrator, the director of nursing, the head nurse of obstetrics, as many of the local physicians practicing obstetrics as possible, herself, and the senior author (F. H. B.). Such an arrangement allowed the reviewers to be better informed concerning the various local medical and political situations prior to discussing with these physicians the regionalization concept.

At these second meetings, regionalization of perinatal health care was explained and copies of the document entitled "Towards Improving the Outcome of Pregnancy,"[4] prepared by The American College of Obstetricians and Gynecologists, The American Medical Association, The American Academy of Pediatricians, and The Academy of Family Physicians, were given to each person attending the meeting. The physicians were told that if they had any obstetric problems on which they wanted consultation, they could call 24 hours a day and speak to a full-time faculty member. This point was important since it seemed that private physicians felt more comfortable consulting with (or possibly transferring patients to) another private physician. This system would help circumvent problems that arise when a referring physician speaks to medical personnel with perhaps less training than he or she has or with whom the physician is unacquainted and may not, in fact, trust. Physicians were told that Vanderbilt Hospital would not turn away any obstetric emergency and that every attempt would be made to keep patient expenses down. Furthermore, emphasis was placed on our desire to give rapid, detailed follow-up information to the referring physician and institution since many physicians felt the lack of follow-up was a major deficiency in tertiary center care. The task then facing the tertiary center was to be certain that when consultation occurred it would comply with the verbal commitments made at these visits.

High priority had been given at each visit to continuing education for nurses and physicians in the area. A position, therefore, was created for a second highly trained and specialized registered nurse who could effect and coordinate the consultative and educational commitments of regionalization. Such an individual was important not only for the educational aspects of a regionalization project but also to help implement a continuing liaison between the various hospitals and physicians and the tertiary center. In particular, two outstanding concepts of this job were: (1) outlying hospital visits and (2) in-hospital (tertiary center) duties. Outlying hospital visits included educational programs for nurses in which such subjects as fetal monitoring, high-risk obstetrics, and other related topics were openly discussed. Physicians at the potential Level I and Level II sites were occasionally visited to review problems, to give follow-up information for previous consultations or referrals, to give out information about services available at the tertiary center, and to communicate to the physicians that the tertiary center continued to be actively interested in events in their areas. Hospital personnel were also given follow-up information on patients they had transferred to the tertiary center. Finally, public relations in the local area was an important part of this job inasmuch as local consumer needs could best be met by active communication between the tertiary center and the area served.

In-hospital or tertiary center responsibilities revolved around three important aspects. The first of these was to coordinate the transfer of patients from Level I or Level II hospitals to the tertiary center, assuring that this transfer was without significant technical problems and helping members of the patient's family make the emotional transition from local hospi-

tal care to medical center care. These tertiary level duties also involved a series of mechanisms such as helping the patients be admitted to the hospital, following up all tests that were done, and, finally, seeing the patient each day to provide a sense of continuity of care. Second, the nurse-coordinator kept records on all in-patient consultations and communicated by phone with the referring physicians at each stage of the patient's progress. A final letter after delivery was written to the physicians giving details of the patient's course. Third, this coordinator gathered educational material to be distributed to the nurses and physicians delivering obstetric care in middle Tennessee to keep them abreast of the newer techniques and advances in obstetrics. At the present time there are two such regionalization nurses performing the duties outlined above, with one being responsible for in-house tertiary center duties and the other handling the outlying hospital educational visits. Certain overlapping in all these responsibilities obviously exists.

Results and comment

Beginning July 1, 1976, formal records were kept on all patients transported to Vanderbilt Hospital for intrapartum or postpartum care. From July 1, 1976, to July 1, 1977, a total of 176 patients, from 42 cities, were transported to Vanderbilt University Hospital for problems arising in the intrapartum and postpartum periods (Table I). Prior to this time approximately one to two patients were transferred to Vanderbilt Hospital each month. These patients came by car, ambulance, or helicopter from various sites throughout Tennessee and the southwestern section of Kentucky. Ten patients were sent from regions in Tennessee other than the middle perinatal region, 58 were from southwestern Kentucky, and the remaining 108 patients were sent from the middle Tennessee area in which Vanderbilt serves as the tertiary level hospital.

As can be seen in Table I the military base in our area transported the largest number of high-risk pregnant women with 26% of the total number of patients referred. This is not surprising since, for many years, military medicine throughout this country has triaged patients to tertiary centers even before regionalization or maternal transport concepts were widely discussed and developed. As the benefits of this type of program become known, more acceptance by nonmilitary medical personnel will occur and the number of civilian transports will continue to increase.

After reviewing the patient's problem with the referring physician by phone, the patient and her family were sent directly to the Fetal Intensive Care Unit, bypassing the more inconvenient emergency room admission route. The nurse regionalization coordinator met each family as soon after arrival as possible to assist them in becoming settled in their new environment. Work-up was done by the house officer on duty, and the senior author (F. H. B.) or his associate reviewed each case after admission, discussing the problem at length with the patient and her family not only to impart information but also to help reduce anxiety levels. After delivery, the referring physician was notified by phone by either the senior author or the nurse-coordinator, with emphasis being made on sharing educational information. This phone call is extremely important as it keeps the referring physician involved in the team effort as well as allows him to be fully informed if the patient's family calls him for further information.

Of the listed indications for referral (Table II), 90 were for premature labor or premature rupture of membranes. As referring physicians became acquainted with newer techniques in treating such disorders, such as the use of beta-mimetic drugs to stop contractions[5] and the use of steroids to accelerate lung maturity,[6] it was hoped that the philosophy of the referrals would change. Patients are also referred to the Level III center for tests and techniques that are not available in the smaller community hospital (Table III). As fetal monitoring gains more acceptance and becomes more readily available in Level I hospitals, the high-risk patients referred merely for this technique, either prior to or during labor, will decrease.

Table IV reveals that of the 169 patients transported for delivery, 56 (33%) underwent cesarean section. This percentage is not unexpected in such a high-risk population and compares to an overall 12% cesarean section rate in the hospital. Five-minute Apgar scores reveal that the majority of neonates are delivered in good condition with 139 (77%) having scores in the 7 to 10 range (Table V). Thirteen neonatal deaths occurred in this high-risk group (Table VI), for a neonatal mortality rate of 79.3/1,000 compared to an overall

13	Weight not available	Eclampsia/asphyxia

Summary: <1,000 grams, six deaths; 1,000 to 1,500 grams, one death; 1,501 to 2,000 grams, two deaths; 2,001 to 2,500 grams, two deaths; >2,500 grams, no deaths; weight not available, two deaths.

neonatal mortality rate of 11.6/1,000 in Tennessee in 1976.[2] Listed also are a wide range of neonatal complications, confirming that these high-risk neonates often require intensive care at a high-level facility (Table VII). A diagnosis of prematurity was made in 90 of the 163 live-born babies (55%).

As can be seen in Table VIII the average weight of the babies was 2,293 grams or 5 pounds, with 12 neonates weighing less than 1,000 grams and 64 weighing more than 2,500 grams. The majority of the neonates, therefore, ranged in weight from 1,000 to 2,500 grams (56%). Six weights were unavailable. Recent reports[7] indicate a 30% to 60% survival rate in the 600 to 1,000 gram range. Six of the twelve neonates in this series weighing less than 1,000 grams died, for a survival rate of 50% (Table VI), representing a signficant advance in neonatal survival in this weight category over the past ten years, and indicating a need for a change in attitude toward the premature fetus. Currently, we are treating

11	2,381	Premature rupture of membranes × 3 days with septicemia
12	2,410	Premature rupture of membranes (loss of fetal heart tones in labor—true knot in cord)
13	2,778	Pregnancy-induced hypertension
14	3,240	Multiple congenital anomalies
15	3,515	Automobile accident—abruptio placentae
16	3,799	Rh disease
17	Weight not available	Fetal death 37 days previously, unknown etiology

Summary: <1,000 grams, four deaths; 1 000-1,500 grams, two deaths; 1,501-2,000 grams, four deaths; 2,001-2,500 grams, two deaths; >2,500 grams, four deaths; weight not available, one death.

a 28 week gestation as aggressively as a term gestation.

Table IX reviews the 17 stillbirths. Fifteen of this number were dead upon arrival at our institution and represent a group of patients where delay in transport or consultation may have played an important role in the overall outcome. Multiple congenital anomalies occurred in three of the total group (17.6%), while five cases (29%) were associated with abruptio placentae. Therefore, approximately 47% of the stillbirths can be listed as nonpreventable; however, the majority (greater than 50%) may have been prevented if consultation and/or maternal transport had been undertaken prior to the fetal death. Educational aspects of regionalization continue, therefore, to represent a major aspect of our overall middle Tennessee program.

Because of the rising medical costs there is a continuous awareness of the economic burden placed on the patients who are transported from the surrounding communities. Consequently, it was reassuring to note that the average hospital stay of the patients delivered vaginally was only 4 days and that of those undergoing cesarean section was only 8 days (Table X). Every attempt was made to send the patient home early or back to the referring hospital for recovery in an attempt to hold down these costs. The average neonatal stay was 8 days (Table XI), with only 14 neonates requiring a

hospitalization of longer than 20 days. Many of the neonates were also referred back to their home hospitals for growth after the initial stabilization period was past. Follow-up on the hospitalization required at the referring institution is unavailable.

A formal letter outlining the care given (Tables III and IV) and the results (Tables V, VI, and VII) was sent the day following discharge. Patients were instructed to return to their own physicians for postpartum care unless specific reasons such as related specialty consultations or follow-up testing necessitated further visits to the tertiary center. Whenever possible, the majority of antepartum care was given at the referring site and the patient was transported to the tertiary center for delivery only.

Currently the Vanderbilt Fetal Intensive Care Unit is receiving approximately one in-patient referral per day from middle Tennessee and surrounding areas. An update of our data indicates that while only 176 maternal transports occurred in 1976, 253 patients were transported in 1977, and in the first quarter of 1978, 108 patients have been sent to the tertiary center for delivery. It has been obvious that as lines of communication have opened, physicians have responded positively and are consulting frequently on complicated obstetric cases. That such a maternal transport system can work was noted by Harris and associates[8] in Arizona who reported that the neonatal mortality rate was lower for the maternal-fetal transports than for newborn transports in comparable groups of mortality risk.

Discussion

DR. JOHN B. NETTLES, Tulsa, Oklahoma. In the development of regional systems for the improvement of health care the pediatricians are farther along than are the obstetricians. The authors have presented quite clearly a concept that will help most of us who are trying to develop a regional system of obstetric care. I emphasize "regional system" rather than "regional center," for what is needed is not merely a transfer of patients with complications to a sophisticated center, but rather a system that involves everyone concerned, with each person and each facility doing what it can best do. Although the Vanderbilt University Hospital makes a major contribution to the reduction of morbidity and mortality rates through their sophisticated personnel facilities, I suspect that an even greater contribution to their program, and to us, is in their humanistic approach and their efforts to improve

communication. Dr. W. P. Gideon, a member of our faculty, observed that this paper might be entitled "Toward an improved outcome of communication."

It is gratifying to see the key role the nurse has in the program in such critical areas as establishing rapport with the hospitals in the area, giving emotional support to the patients and their families, learning about and correcting problems throughout the area, developing appropriate continuing education programs, bridging the "town/gown" gap, assuring a continuum of care, and keeping the referring physician up to date on developments. I understand that Ms. Haire is accepted by the referring physician as well as is Dr. Boehm and probably much better than a member of the house staff who happens to be on duty at the time. This program is a fine example of the collegial relationship between our disciplines that is fostered by such groups as the Nurses Association of the American College of Obstetricians and Gynecologists.

In the Tulsa area we have increased our use of maternal transport and while at present our experience cannot be easily evaluated from the statistical standpoint certain facts are obvious. Perhaps the most noticeable changes are in the profile of the obstetric services in the referring hospitals and the economic impact. For instance, one major hospital in our referral area had several case presentations for each monthly perinatal morbidity and mortality conference prior to our increased use of maternal transport. Now the hospital has such conferences quarterly or less frequently because of the tremendous decrease in neonates with complications. Another shift has been in the number of days of high-cost, long-stay neonates. This would not be of as much importance if these costs were paid for by third parties, but when the proportion of inability to pay is unusually high in those patients transferred the tertiary hospital must find some way to recoup the added costs. We too have used maternal transfer in both directions, for example, one of the Indian Health Service hospitals may refer a patient to Saint Francis Hospital which houses the Eastern Oklahoma Perinatal Center for delivery. The patient and perhaps her infant may be returned to the Indian hospital as soon as practical, thus making a lesser dent in contract health funds and enabling the Indian Health Service to offer more services to other patients.

In summary, it is refreshing to see a joint paper by a physician and a nurse before this association and their teamwork in developing a program that should help all of us who are following in their footsteps. I would like to ask three questions: (1) What is the secret for obtaining legislature support? (2) How cost effective is the Xerox Telecopier Network? (3) What problems, if any, have occurred with the shifting of costs of those unable to pay—primarily to the tertiary hospital?

DR. LEE B. STEVENSON, Farmington Hills, Michigan. I have deliberately avoided bringing the Michigan experience into this discussion as well as neglected the Michigan adaptation of "Towards Improving the Outcome of Pregnancy."

The wooing and winning of physicians' patients in central Tennessee by the Vanderbilt system is mindful of a quote from "Anna and the King of Siam": "Et cetera, et cetera, et cetera" or education, transportation, communication; education, transportation, consultation; education, transportation, communication. Repetition of each of these is vital to the success of such a lifesaving venture.

Their plan and results are adequately described. The military's use of the program makes one wonder how many of the consultations or transports were on a Friday afternoon or prior to a holiday. This "dumping" has been a problem in other communities as a convenience for the too-busy practitioner.

Another question raised by the presentation is whether the primary physician has privileges at the tertiary center for any or all of the components of his patient's care. The text is hazy on this aspect but leads me to believe that no such provision exists.

Education seems to be the second key to reducing the number of referrals without adversely affecting the perinatal mortality and morbidity rates. Results of some studies show that the outcome for the referred parturient and her infant are often not as bad as anticipated.[1] In the Goodlin[1] study in California, only 18 of 200 transferred cases required neonatal intensive care facilities.

Two areas of concern were not specifically addressed: One is the product and the second is the cost. What is the quality of the infant in childhood and adolescence and as an adult? We are constantly harangued from all sides about the perinatal mortality rate, the problems of prolonged institutional care, and the cost of this care. But what is the end product, or "the bottom line," of our extra efforts in this perinatal jungle?

Is the expense justified? Is the concept truly cost effective? Costs at Level I or Level II community hospitals cannot be compared to the excessively high and often inadequately reimbursed expenses at a Level III center. Third-party payment programs require cost accounting and no satisfactory method recognizes program advantages of comprehensive perinatal care for mother and infant, even when the perinatal period is essentially uncomplicated. As Dr. Hermann Ziel has pointed out in some of his talks on regionalization in Michigan, "Third party payment programs have failed to recognize the cost of many important program elements in their reimbursement methodology." The problem is particularly acute in regional centers which serve as the focal point for planning, implementing, and evaluating comprehensive perinatal care. Unfortunately, there is little hope that regionalized perinatal care can be financially feasible for either the physician or hospital until this situation is corrected. Both the Vanderbilt program and the Arizona program had

special financial arrangements which allowed feasibility.

In the booklet "Towards Improving the Outcome of Pregnancy," financing of regionalization is addressed and the generation of new costs by improved care and technology is recognized. Costs will be increased by education and training of personnel. The providers of services, "both individual and institutional, must increase their effort and proficiency in identifying actual costs and in relating these to the benefits in terms of morbidity and mortality."[2]

Do the authors have any comments on the financing of perinatal care—which includes maternal and neonatal care? Are late follow-up studies on the "product" a part of the Vanderbilt study?

2. The National Foundation/March of Dimes: Towards Improving the Outcome of Pregnancy, Recommendations for the regional development of Maternal and Perinatal Health Services, New York, 1976, Committee on Perinatal Health.

DR. I. RAY KING, Knoxville, Tennessee. As of September 1, 1977, I assumed the directorship of the East Tennessee Regional Obstetrical Program. I went through the literature trying to find how to implement a regional obstetrical program and there were very few articles describing such a program. One of the first ventures was to go with my regional obstetrical nurse to Vanderbilt and spend a day with Miss Haire and Dr. Boehm. This has been very rewarding and I would like to relate a few things that have happened.

In the eastern Tennessee region we have some 16,000 deliveries. In the first 9 months of our consultation and referral service, we have had 59 maternal transports to the University Hospital in Knoxville and 53 outpatient consultations. I do not have figures on how many were referred prior to this time, but there were no more than one or two maternal transports per month.

I would like to emphasize a few things. The personal relationship that Dr. Boehm has described is of ultimate importance. We now know most of the people in East Tennessee who deliver obstetric care on a first-name basis. We have done this in 1 year's time and this is the keystone of our acceptance.

Also we at the tertiary center have to accept that we are going to have many uninteresting, even though challenging, problems, such as premature rupture of the membranes and premature labor. We have a few "interesting" patients but most deliveries are routine. Those of you who may enter into a regionalization project at the tertiary level will have to accept some humility, realizing that many of the patients referred are not referred because our delivery method is better than others but because of the neonatal center.

There are two problems I would like to address. One has to do with providing enough staff to accept the consultations and referrals. We did not have on our full-time staff an adequate number of obstetricians. We solved this problem by persuading eight physicians in our city to accept this responsibility and through our grant they are paid 50 dollars per day. This may seem like a large payment, but when a patient is referred, she is charged on a fee-for-service basis and unfortunately we have a very poor collection rate. The other problem I would like to address has been brought up by the other discussants and that is the financial aspect. I have just finished reviewing the first 6 months of this year's hospital business office records, giving 3 months' collection time, and the collection rate has been only 30%. I would like to ask Dr. Boehm if the patients are more affluent in middle Tennessee or have better health insurance coverage? What has been their method of coping with this problem? Part of the reason for doing my study on the hospital financial deficit, and I am sure Dr. Boehm is doing the same thing, is to provide information for the next legislature in the hope of obtaining patient care dollars.

I commend this paper for its inherent quality and to each of you as an instruction guide in setting up a regional obstetrical program.

DR. CARL E. JOHNSON, Rochester, Minnesota. I would like to ask a question about legal liability in the case of a mother and child placed in an ambulance and transported 40 miles in a precarious situation. What is the medicolegal implication if the mother dies en route or the fetus dies in utero en route?

DR. A. WORK, JR., Ann Arbor, Michigan. I noticed that the majority of the patients were admitted for delivery. I would like to know the experience the authors have with those patients who were seen for consultation and then sent back undelivered to their community. What has been the response of the referring physicians in giving such patients follow-up after consultation in the case?

DR. ALFRED A. CARUSO, Kansas City, Missouri. In Kansas City in June, 1978, we added a helicopter service at a local hospital. Have you had any experience with transportation of mothers with helicopter or fixed-wing service?

DR. BOEHM (Closing). To begin with Dr. Nettle's question concerning the secret for obtaining legislative support, I think that there really are no secrets. It just takes perseverance.

The neonatologists in Tennessee were the prime movers originally. We as obstetricians and gynecologists need to become more involved locally in the political arena. Our Perinatal Advisory Committee has set up committees that look for legislative monies and we have certainly learned a great deal from reviewing the experience in other states and how they have obtained legislative money.

Currently, the legislature has deemed our obstetric regionalization program worth approximately half a million dollars and each of our regional centers receives an equal share.

None of this is patient care money but it does help pay for nurses and physicians, for some tests that are being performed in the tertiary center, and for other aspects of perinatal health care in the region.

The other point that needs to be raised is that when one approaches the legislature, it is important to emphasize certain interesting facts. For example, if one baby can be saved from institutionalization in the entire state, the state has been saved more than half a million dollars because that is what it costs for institutionalization of that particular individual. We are using this approach and it does seem to be working. I believe it is important to realize that we as physicians have to become involved in this political arena and not leave this important matter up to individuals who perhaps do not know as much about the medical field as we do.

Second, how cost effective is a Xerox Telecopier Network? We have recently reviewed our first 4 years' experience with the telecopier system and we did not address the cost effectiveness of this program. The important thing about the Telecopier Consultative Network is that it gives the private physician in a smaller community hospital a place to call when the tracing he or she is looking at is confusing. In the middle of the night nurses and doctors call our unit or my home and ask numerous important questions concerning the fetal monitor tracing. We often get into a lengthy discussion concerning the overall management of the case in question.

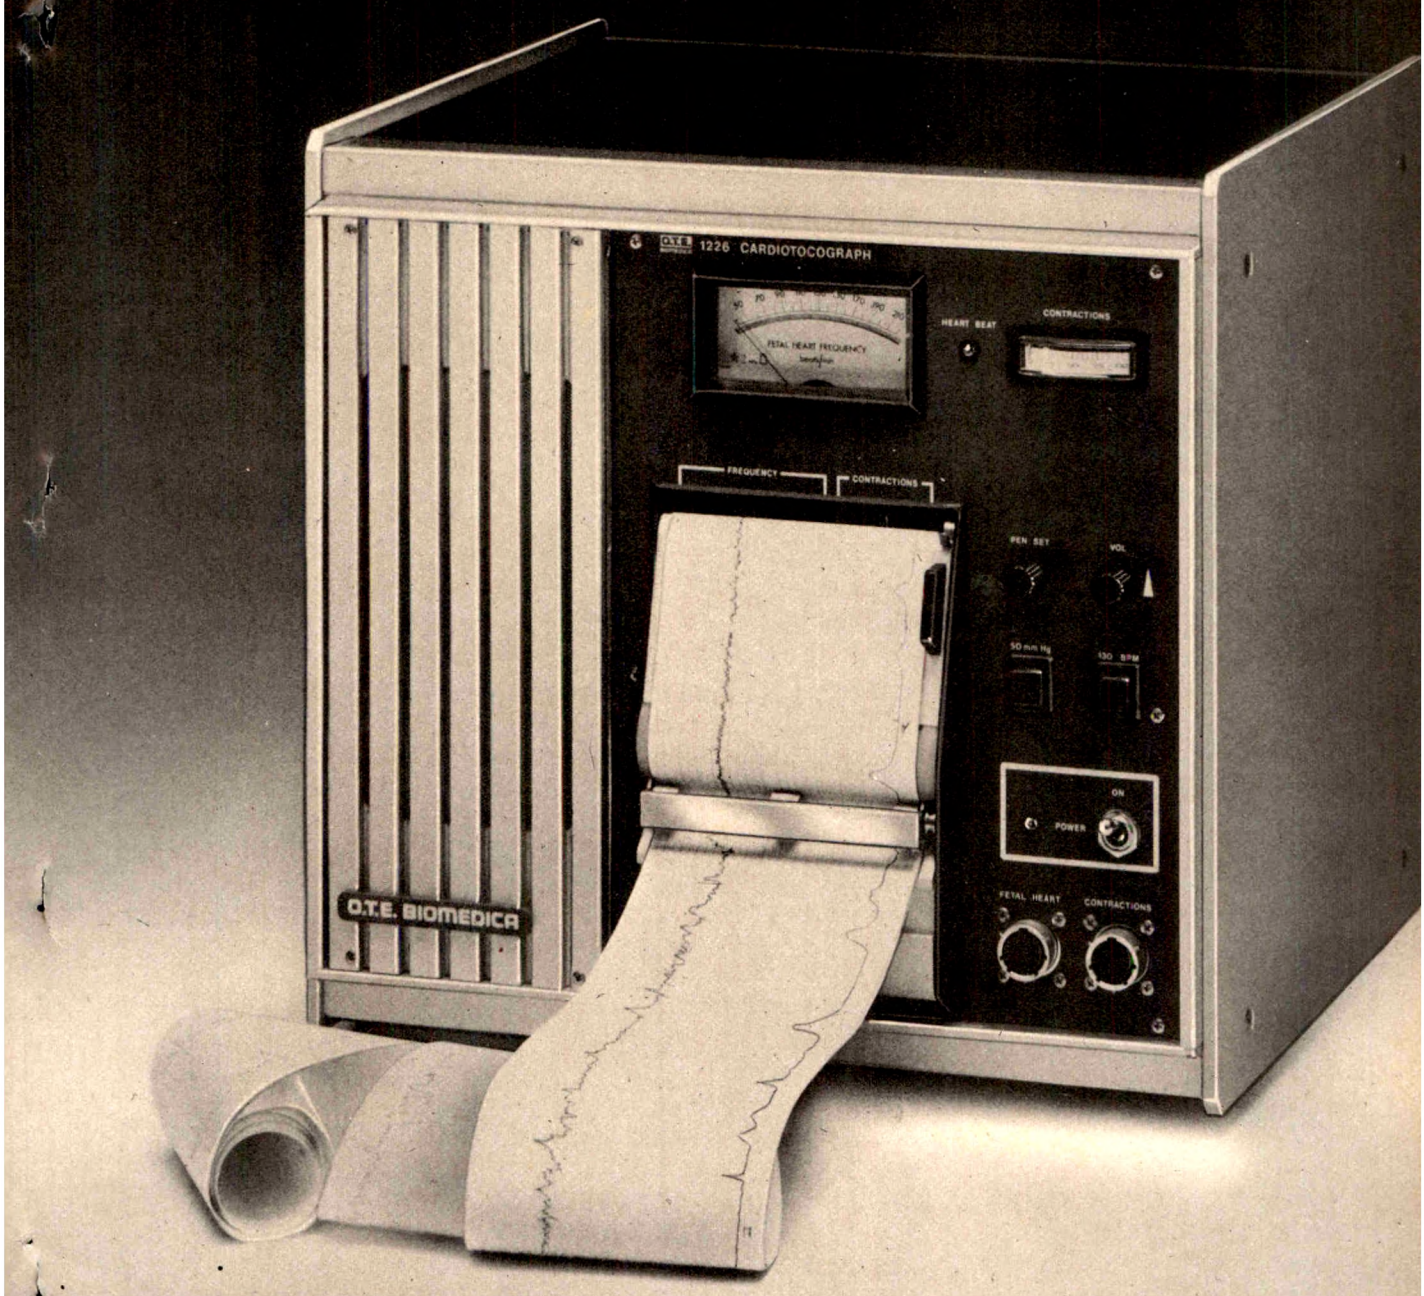
Concerning the problems that have occurred with shifting costs of those unable to pay, we have the same problems as expected in any other area. There is a certain write-off and someday there may come a limit as to how much money we can lose in the fetal intensive care unit. Hopefully upgrading insurance in the near future will help solve that problem. Money, as it relates to the regionalization program, will have to be a prime subject for all of us. I do know that the government is not necessarily the answer. The question in many ways lies with us.

Therefore, we in middle Tennessee have aggressively tried to do this work ourselves. We strongly believe that regionalization is a concept that is healthy and productive. It is what all of us want to do anyway, that is, to give good care, but we need to do it as a team and not as arrogant egotists who are trying to protect our little corner of the world. I believe that patients will respond favorably to this aspect of team care.

Dr. Stevenson commented about the military use and whether or not we have a Friday or Saturday or holiday "dump syndrome" at Vanderbilt. My response is that although my wife occasionally thinks that I am working harder on weekends than on other days, the fact is that this is not the case. We have witnessed a conscientious concern of family practitioners and obstetricians and gynecologists alike in sending patients whom they honestly believe can be better handled in our institution. It is a rare case where a physician sends a patient in merely to get that patient off his back because of the time of day or week.

Second, in regard to the question that concerned the primary physician's privileges at the tertiary center, there are no mechanisms for that at the present time. But, interestingly enough, in our travels around middle Tennessee, we asked physicians if they were interested in coming to Vanderbilt to continue the care at the tertiary center and most responded in a negative fashion, indicating that it would be very difficult for them to travel to Nashville to manage this. Obviously, in a regionalized system within a city, that may not be the case.

The other question of Dr. Stevenson concerned product and quality cost-benefit ratios. I do not think I have time to get into this aspect nor do I think that I could fully answer this very thoughtful question as I believe it is probably the bottom-line question for all of us. At the moment I have a hard time cost-effecting life. I know that sounds trite, but it still needs to be said.



One hundred dollars a day in the hospital for a mother compared to perhaps a thousand dollars a day for the neonate sometimes can be proved to be cost effective. However, with couples wanting so desperately that happy, normal "product," as we all do, I have a hard time in cost-benefiting this type of system and I must admit that even if I did find that it was not cost effective, I do not think from what I have seen that I could stop this type of program.

Concerning Dr. King's comment about the type of patient who is sent in for maternal transport, it is interesting to note that the patients who are referred frequently have adequate coverage and it is not necessarily the indigent type of patient who is referred. In reviewing a number of patients recently, we noted that 16% had 100% coverage; 36% had 80% to 99% coverage; another 20% had 10% to 79% coverage, while only 28% had no coverage at all. Hopefully, these figures will look even better in the years ahead.

Concerning Dr. Johnson's question about legal liability and who is responsible when the mother is sent in and the mother or baby dies in route, my response is that the referring institution is responsible until the patient arrives at the tertiary center.

O.T.E. Biomedica Cardiotocograph you can rely on its simplicity and convenience.

Reliability/operability/convenience/simultaneous detection of fetal heart rate and uterine activity/two application modes, using internal and external transducers/ safety - floating ECG inputs/ease of operation/modular dimensions - expandability.

Flagyl® (metronidazole) 250 mg.

Warning
Metronidazole has been shown to be carcinogenic in mice and possibly carcinogenic in rats. (See *Warnings*.) Unnecessary use of the drug should be avoided. Its use should be reserved for the conditions described in the *Indications* section.

Indications: For the treatment of symptomatic trichomoniasis in both females and males when the presence of the trichomonad has been confirmed by appropriate laboratory procedures (wet smears and/or cultures). Also for the treatment of asymptomatic females when the organism is associated with endocervicitis, cervicitis, or cervical erosion. *T. vaginalis* infection is a venereal disease and therefore, asymptomatic sexual partners of infected patients should be treated simultaneously if the organism is present. The decision to treat an asymptomatic male partner who has a negative culture or smear, or one in whom no culture has been attempted, is an individual one. In any event, the consort should be treated with Flagyl in cases of reinfection. Flagyl is also indicated for acute intestinal amebiasis (amebic dysentery) and for amebic liver abscess.

Contraindications: Evidence or history of blood dyscrasia, active organic disease of the CNS, the first trimester of pregnancy and a hypersensitivity to metronidazole.

Warnings: Flagyl should not be used in the first trimester of pregnancy (see *Contraindications*). Use with discretion during the second and third trimesters of pregnancy and restrict to those pregnant patients not cured by topical measures. Flagyl (metronidazole) is secreted in the breast milk of nursing mothers. It is not known whether this can be injurious to the newborn. If used during lactation, an alternative method of feeding may be elected.

Note: Tumorigenicity Studies in Rodents. Metronidazole has shown evidence of tumorigenic activity in a number of studies involving chronic, oral administration in mice and rats.

Most prominent among the effects in the mouse was the promotion of pulmonary tumorigenesis. This has been observed in all five reported studies in that species, including one study in which the animals were dosed on an intermittent schedule (administration during every fourth week only). The published results of one of the mouse studies indicate increases in the incidence of malignant lymphomas as well as pulmonary neoplasms associated with lifetime feeding of the drug. All these effects are statistically significant.

Two long-term toxicity studies in the rat have been completed. There was a statistically significant increase in the incidence of various neoplasms, particularly mammary tumors, among female rats administered metronidazole over that noted in the concurrent female control groups.

Two lifetime tumorigenicity studies in hamsters have been performed and reported to be negative.

Metronidazole has been reported to potentiate the anticoagulant effect of coumarin and warfarin resulting in a prolongation or prothrombin time. This possible drug interaction should be considered when Flagyl is prescribed for patients on this type of anticoagulant therapy.

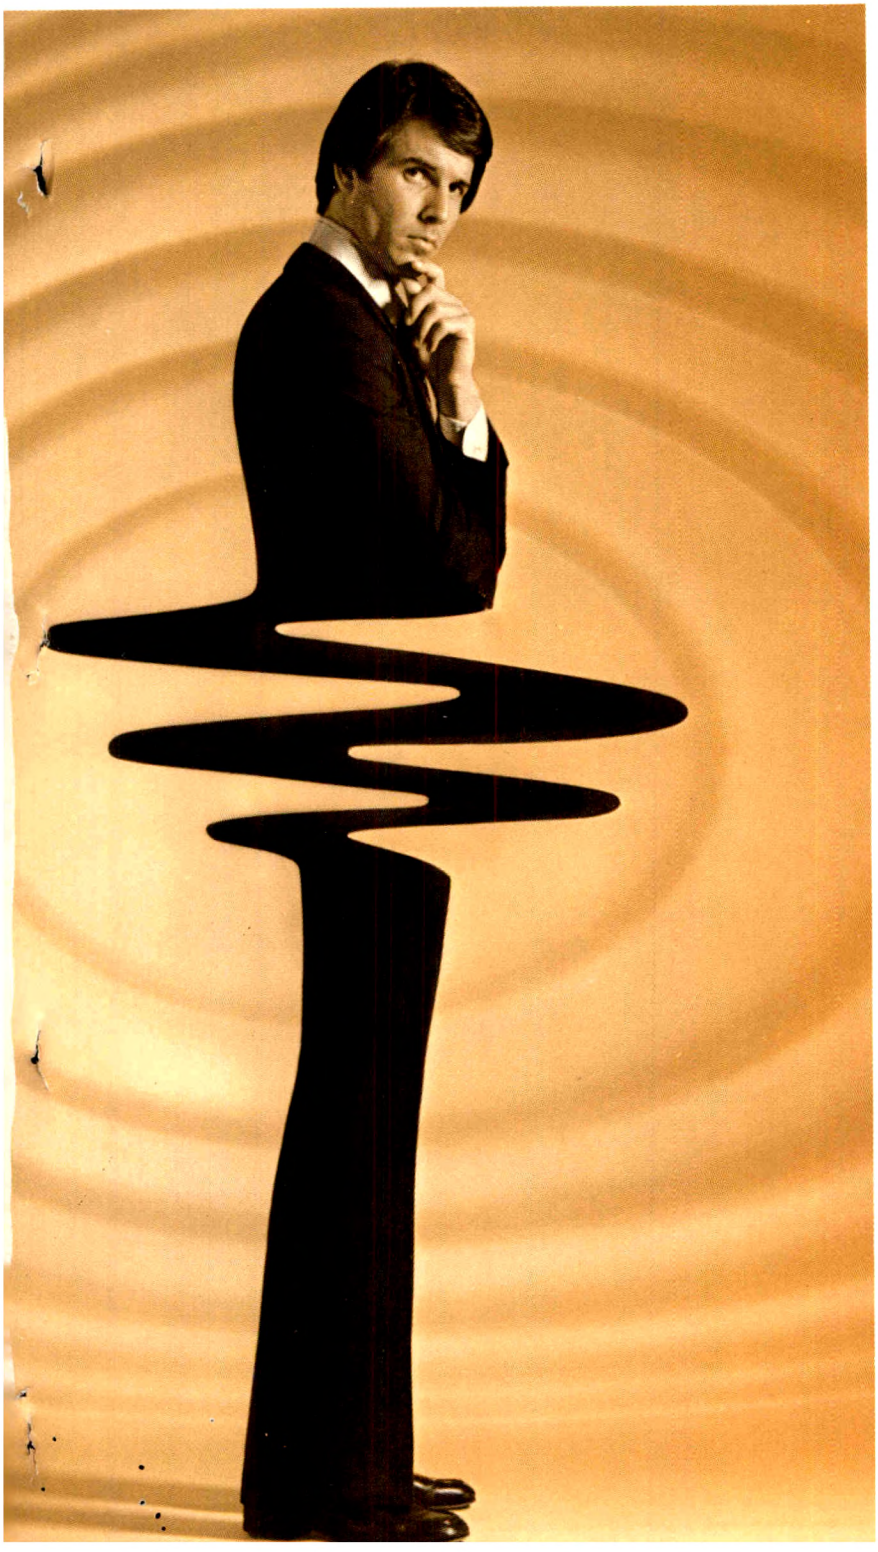
Precautions: Mild leukopenia has been reported during Flagyl use; total and differential leukocyte counts are recommended before and after treatment with the drug, especially if a second course is necessary. Avoid alcoholic beverages during Flagyl therapy because abdominal cramps, nausea, vomiting, headaches and flushing may occur. Discontinue Flagyl promptly if abnormal neurologic signs occur. Exacerbation of moniliasis may occur. In amebic liver abscess, aspirate pus during metronidazole therapy.

Adverse Reactions: Nausea, headache, anorexia, vomiting, diarrhea, epigastric distress, abdominal cramping, constipation, a metallic, sharp and unpleasant taste, furry tongue, glossitis and stomatitis possibly associated with a sudden overgrowth of *Candida*, exacerbation of vaginal candidiasis, an occasional reversible moderate leukopenia, dizziness, incoordination and ataxia, numbness or paresthesia of an extremity, fleeting joint pains, confusion, irritability, depression, insomnia, mild erythematous eruptions, "weakness," urticaria, flushing, nasal congestion, dryness of the mouth, vagina or vulva, pruritus, dysuria, cystitis, a sense of pelvic pressure, dyspareunia, fever, polyuria, incontinence, decrease of libido, proctitis, pyuria and darkened urine have occurred in patients receiving the drug. Patients receiving Flagyl may experience abdominal distress, nausea, vomiting, flushing or headache if alcoholic beverages are consumed. The taste of alcoholic beverages may also be modified. Flattening of the T-wave may be seen in ECG tracings.

Dosage and Administration: ***For Trichomoniasis:*** The recommended dosage for both male and female is one 250-mg. tablet orally three times daily for seven days. When repeat courses of the drug are required, it is recommended that an interval of 4 to 6 weeks elapse between courses and that the presence of the trichomonad be reconfirmed by appropriate laboratory measures. Total and differential leukocyte counts should be made before, during and after retreatment. The male consort should be treated in any event in cases of reinfection.

For Amebiasis: *Adults:* For acute intestinal amebiasis, 750 mg. orally three times daily for 5 to 10 days.

For amebic liver abscess: *Adults:* 500 mg. or 750 mg. orally three times daily for 5 to 10 days.



Children: 35 to 50 mg./kg. of body weight/24 hours, divided into three doses, orally for 10 days.

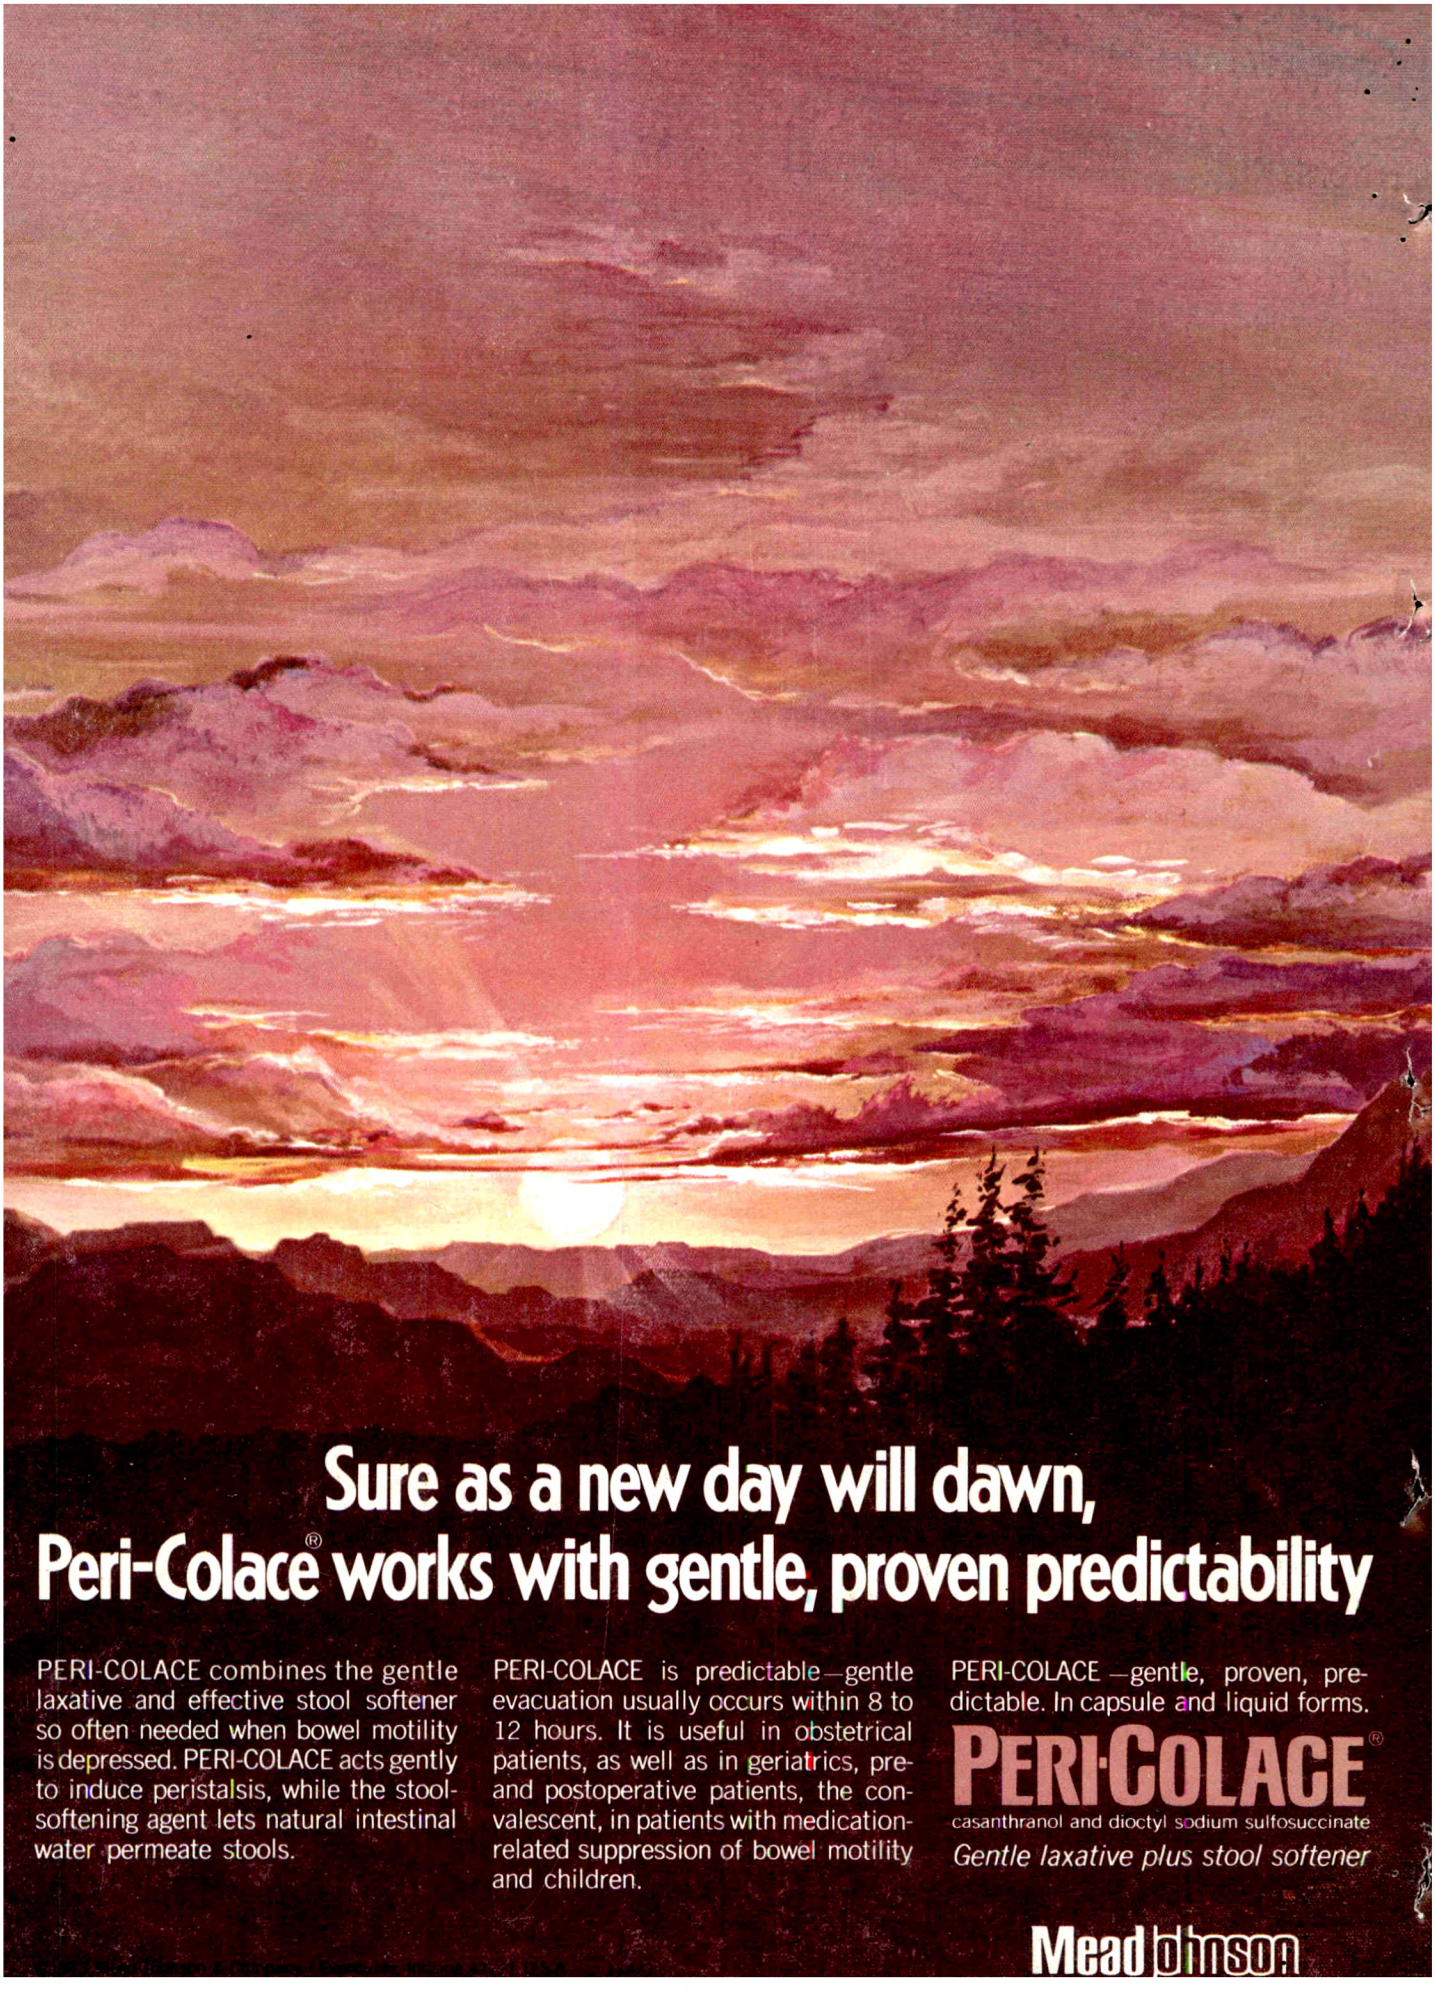
If men suffered from the symptoms of trichomoniasis, they'd appreciate Flagyl®.

(metronidazole)

Women with trichomoniasis have been grateful for the benefits of Flagyl therapy for over a decade. Most men have no symptoms and are not even aware that they have contracted trichomoniasis, so they rarely appreciate Flagyl. Unless both sexual partners are diagnosed and treated simultaneously, reinfection from the consort is a probability (the "ping-pong" effect).

In the female, trichomoniasis is a multiorgan disease. Trichomonads invade the vagina and are often deeply entrenched in the endocervix, Skene's and Bartholin's glands, the urethra and the bladder. Only the systemic action of Flagyl can eliminate trichomonads from these sequestered sites.



In the male, only Flagyl can effectively eliminate trichomonads from the male genitourinary tract.

Thus, for the female Flagyl is the treatment of choice. For the male it is the only choice. And that's something they both can appreciate!

Flagyl®
(metronidazole)
250-mg. tablets

Sure as a new day will dawn, Peri-Colace® works with gentle, proven predictability

PERI-COLACE combines the gentle laxative and effective stool softener so often needed when bowel motility is depressed. PERI-COLACE acts gently to induce peristalsis, while the stool-softening agent lets natural intestinal water permeate stools.

PERI-COLACE is predictable—gentle evacuation usually occurs within 8 to 12 hours. It is useful in obstetrical patients, as well as in geriatrics, pre- and postoperative patients, the convalescent, in patients with medication-related suppression of bowel motility and children.

PERI-COLACE—gentle, proven, predictable. In capsule and liquid forms.

PERI-COLACE®

casanthranol and dioctyl sodium sulfosuccinate

Gentle laxative plus stool softener

Today's teenager expects a lot more than medicine from her doctor.

The plight of today's teenager in these socially turbulent times is often precarious at best. According to a recent national survey, there has been a 30% increase in teenage sexual activity in the last five years.[1] Also, half of all out-of-wedlock births are attributed to teens. Up to two-thirds of these are unwanted, unplanned births.[2] Trapped in the midst of rapidly changing sexual mores, the teenager is further beset by uncertainty, timidity, ignorance, and misinformation.

That's why today's younger patient needs and deserves thorough counseling — underlined by compassion, reassurance, and trust — in many areas. These range from the basic facts of life, in some cases, to more serious subjects like venereal disease. But, no issue is more sensitive, or more in need of physician/patient exploration than that of contraception.

Today, contraceptive counseling often culminates in the selection of a low-dose oral contraceptive like Brevicon. Brevicon offers a rate of efficacy comparable to higher-dose formulations and its incidence of menstrual irregularities is low. In 16,345 cycles among 1,168 patients, there were 0.22 pregnancies per 100 woman years. Breakthrough bleeding occurred in 5.1% of cycles, and amenorrhea in 1.0% of cycles. Dropout rate due to menstrual irregularities during the crucial first three months was 3.4%.

Counseling, compassion, and Brevicon — a good combination for many of today's teenage patients.

Brevicon® tablets **A sign of the times**

(norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)

2. Monthly Vital Statistics Report: Natality Statistics, National Center for Health Statistics, Vol. 26, No. 5, September 1977.

Note: Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. The physician should be fully aware of the prescribing information for this product.

COLLEGE OF MEDICINE LIBRARY

Brevicon® 21-Day Tablets
(norethindrone 0.5 mg. with ethinyl estradiol 0.035 mg.)
Brevicon® 28-Day Tablets
(21 norethindrone 0.5 mg. with ethinyl estradiol 0.035 mg. tablets followed by 7 inert tablets)

ORAL CONTRACEPTIVE (O.C.) AGENTS

INDICATIONS O.C.s are indicated for the prevention of pregnancy. The drop-out rate for medical reasons, as observed in the clinical trials conducted with BREVICON, appears to be somewhat higher than observed with higher dose combination products. The dropout rate due to menstrual disorders and irregularities was also somewhat higher, dropouts being equally split between menstrual disorders and irregularities and other medical reasons attributable to the drug. *DOSE-RELATED RISK OF THROMBOEMBOLISM FROM O.C.s.* Studies have shown a positive association between the dose of estrogens in O.C.s and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The O.C. product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of O.C.s should be started on preparations containing 0.05 mg or less of estrogen.

CONTRAINDICATIONS 1. Known or suspected pregnancy (see Warning No. 5). 2. O.C.s should not be used in women who have or have had any of the following conditions: a. Thrombophlebitis or thromboembolic disorders. b. Cerebral vascular or coronary artery disease. c. Markedly impaired liver function. d. Known or suspected carcinoma of the breast. e. Known or suspected estrogen dependent neoplasia. f. Undiagnosed abnormal genital bleeding.

WARNINGS: Cigarette smoking increases the risk of serious cardiovascular side effects from O.C. use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use O.C.s should be strongly advised not to smoke.

The use of O.C.s is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, liver tumor, gall bladder disease, visual disturbances, fetal abnormalities, and hypertension. Practitioners prescribing O.C.s should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of O.C.s is well established. One British study demonstrated an increased relative risk for fatal venous thromboembolism; two British and three American studies demonstrated an increased relative risk for non-fatal venous thromboembolism. These studies estimate that users of O.C.s are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. CEREBROVASCULAR DISORDERS. Two American studies demonstrated an increased relative risk for stroke, which had not been shown in prior British studies. In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the relative risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the relative risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers. A British long-term, follow-up study reported in 1976 a highly significant association between O.C. use and stroke. Another British long-term, follow-up study had suggested such an association in 1974, but the number of cases was too small to estimate the risk. MYOCARDIAL INFARCTION. An increased relative risk of myocardial infarction associated with the use of O.C.s has been reported, confirming a previously suspected association. One study conducted in the United Kingdom found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an O.C. user or not. O.C.s, however, were found to be an additional risk factor. In terms of relative risk, it has been estimated that O.C. users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. O.C. users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, and about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the number of cigarettes smoked is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. (The estimates are based on British vital statistics which show acute myocardial infarction death rates 2- to 3-times less than in the U.S. for women in these age groups; consequently, actual U.S. death rates could be higher.) The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not been quantified; other synergistic actions may exist. RISK OF DOSE. In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in O.C.s. Preparations containing 0.1 mg or more of estrogen were associated with a higher risk of thromboembolism than those containing 0.05-0.08 mg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been supported by a study in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only O.C.s have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk. ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASE. A large British prospective study estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of O.C.s according to age, smoking habits, and duration of use. The overall excess death rate annually from circulatory diseases for O.C. users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000). The risk is concentrated in older women, in those with a long duration of use, and in cigarette smokers, and may persist after discontinuation of O.C. use. It was not possible, however, to examine the interrelationships of age, smoking, and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of O.C.s) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The findings of this analysis are shown in Table 1 below. The study concluded that the mortality associated with all methods of birth control is low and below that of childbirth, with the exception of O.C.s in women over 40 who smoke. (The rates given for pill only/smokers for each age group are for smokers as a class. For "heavy" smokers (more than 15 cigarettes a day), the rates given would be about double; for "light" smokers (less than 15 cigarettes a day), about 50 percent.) The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The study also concluded that O.C. users who smoke, especially those over the age of 30, have a greater mortality risk than O.C. users who do not smoke.

TABLE 1. *The annual number of deaths associated with control of fertility and no control per 100,000 nonsterile women by regimen of control and age of women are:*

	15-19	20-24	25-29	30-34	35-39	40-44
No method	5.6	6.1	7.4	13.9	20.8	22.6
Abortion only	1.2	1.6	1.8	1.7	1.9	1.2
Pill only—nonsmokers	1.3	1.4	1.4	2.2	4.5	7.1
Pill only—smokers	1.5	1.6	1.6	10.8	13.4	58.9
IUDs only	0.9	1.0	1.2	1.4	2.0	1.9
Traditional contraception only	1.1	1.6	2.0	3.6	5.0	4.2
Traditional contraception and abortion	0.2	0.2	0.3	0.3	0.3	0.2

The risk of thromboembolic and thrombotic disease associated with O.C.s increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hyperlipidemias, obesity, diabetes, or history of preeclampic toxemia and especially by cigarette smoking. Based on the data currently available, the following table gives a gross estimate of the risk of death from circulatory disorders associated with the use of O.C.s:

TABLE 2. *Smoking habits and other predisposing conditions – risk associated with use of O.C.s*

Age	Below 30	30-39	40+
Heavy smokers	C	B	A
Light smokers	D	C	B
Nonsmokers (No predisposing conditions)	D	C,D	C
Nonsmokers (other predisposing conditions)	C	C,B	B,A

A—Use associated with very high risk. C—Use associated with moderate risk.
B—Use associated with high risk. D—Use associated with low risk.

The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four- to six-fold increased risk of post-surgery thromboembolic complications has been reported in O.C. users. If feasible, O.C.s should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. Among patients with thromboembolic disease, the results of retrospective studies suggest the possibility of an increased risk for users who are of blood types A, B, or AB, as compared with those of type O. *Ocular Lesions:* There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of O.C.s. Discontinue O.C. medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions; and institute appropriate diagnostic and therapeutic measures. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of certain adenomas, benign or malignant, such as those of the breast, cervix, vagina, uterus, ovary, pituitary and liver. Certain synthetic progestogens, none currently contained in O.C.s, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. Several retrospective case-control studies have reported an increased relative risk (3.1 to 13.9 times) associating endometrial carcinoma with the prolonged use of estrogens in postmenopausal women who took estrogen replacement medication to relieve menopausal symptoms. One publication reported on the first 30 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on O.C.s. Of the adenocarcinomas found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time O.C.s were first given, polycystic ovaries) nearly all occurred in women who had used a sequential O.C. These products are no longer marketed. No statistical association has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only O.C.s, although individual cases have been reported. Several studies have shown no increased risk of breast cancer to women taking O.C.s or estrogens. In one study, however, while no overall increased risk of breast cancer was noted in women treated with O.C.s, a greater risk was suggested for the subgroups of O.C. users with documented benign breast disease and for long-term (2-4 years) users. One other study indicated an increasing risk of breast cancer in women taking menopausal estrogens, which increased with duration of follow-up. A reduced occurrence of benign breast tumors in users of O.C.s has been well documented. In a prospective study of women with cervical dysplasia, there was an increase in severity and of conversion to cancer *in situ* in O.C. users compared with nonusers. This became statistically significant after 3 to 4 years of use. Nonreversal of dysplasia within the first 6 months of pill use was suggested to be predictive of progression after prolonged exposure. There have been other reports of microglandular hyperplasia of the cervix in users of O.C.s. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with O.C.s. Close clinical surveillance of all women taking O.C.s is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use O.C.s instead of other methods of contraception. 4. *Liver Tumors:* Sudden severe abdominal pain or shock may be due to rupture and hemorrhage of a liver tumor. There have been reports associating benign or malignant liver tumors with O.C. use. This has been reported in short-term as well as long-term users of O.C.s. One study showed that O.C. formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Two studies relate risk with duration of use, the risk being much greater after 4 or more years of use. Although it is an uncommon lesion, it should be considered in women presenting with an "acute abdomen". The tumor may cause serious or fatal hemorrhage. Patients with liver tumors have demonstrated variable clinical features which may make preoperative diagnosis difficult. Some cases presented because of right upper quadrant masses, while most had signs and symptoms of acute intraperitoneal hemorrhage. Routine radiological and laboratory studies may not be helpful. Liver scans may clearly show a focal defect. Hepatic arteriography may be a useful procedure in diagnosing primary liver neoplasm. 5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that O.C.s further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use O.C.s instead of other methods of contraception. Furthermore, a high percentage of women exposed to diethylstilbestrol (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported following use of sex hormones, including O.C.s, in pregnancy. In one case-control study it was estimated that there was a 4.7-fold increased relative risk of limb-reduction defects in infants exposed *in utero* to sex hormones (O.C.s, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In a large prospective study, cardiovascular defects in children born to women who received female hormones, including O.C.s, during early pregnancy occurred at a rate of 18.2 per 1,000 births, compared to 7.8 per 1,000 for children not so exposed *in utero*. These results are statistically significant. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing O.C.s. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping O.C.s is unknown. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if progestogen-only O.C.s are used) and further use of O.C.s should be withheld until pregnancy has been ruled out. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue O.C.s with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available [illegible]

mendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy. 6. *Gall Bladder Disease:* Studies report an increased risk of gall bladder disease in users of O.C.s or estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In another study an increased risk was apparent between 6 and 12 months of use. 7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage of patients on O.C.s. For this reason, prediabetic and diabetic patients should be carefully observed while receiving O.C.s. An increase in triglycerides and total phospholipids has been observed in patients receiving O.C.s. The clinical significance of this finding is unknown. 8. *Elevated Blood Pressure:* An increase in blood pressure has been reported with O.C. use. In some women, hypertension may occur within a few months of beginning O.C. use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two and a half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in O.C. users. Women with a history of elevated blood pressure (hypertension), preexisting renal disease, a history of toxemia or elevated blood pressure during pregnancy, a familial tendency to hypertension or its consequences, or a history of excessive weight gain or fluid retention during the menstrual cycle may be more likely to develop elevation of blood pressure when given O.C.s and, therefore, should be monitored closely. Even though elevated blood pressure may remain within the "normal" range, the clinical implications of elevations should not be ignored and close surveillance is indicated, particularly for women with other risk factors for cardiovascular disease or stroke. High blood pressure may or may not persist after discontinuation of the O.C. 9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of O.C.s and evaluation of the cause. 10. *Bleeding Irregularities:* Breakthrough bleeding, spotting, and missed menses are frequent reasons for patients discontinuing O.C.s. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an O.C. with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of O.C.s. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities. A higher incidence of galactorrhea and of pituitary tumors (e.g., adenomas) has been associated with amenorrhea in former users compared with nonusers. One study reported a 16-fold increased prevalence of pituitary prolactin-secreting tumors among patients with postpill amenorrhea when galactorrhea was present. 11. *Infertility:* There is evidence of impairment of fertility in women discontinuing O.C.s in comparison with those discontinuing other methods of contraception. The impairment appears to be independent of the duration of use of the preparations. While the impairment diminishes with time, there is still an appreciable difference in the results in nulliparous women for the O.C. and non-O.C. groups 30 months after discontinuation of birth control. For parous women the difference is no longer apparent 30 months after cessation of contraception. 12. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. However, in progestogen-only O.C. failures, the ratio of ectopic to intrauterine pregnancies is higher than in women who are not receiving O.C.s, since the drugs are more effective in preventing intrauterine than ectopic pregnancies. 13. *Breast Feeding:* O.C.s given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in O.C.s has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast fed child have not been determined. If feasible, the use of O.C.s should be deferred until the infant has been weaned. **PRECAUTIONS** *GENERAL* 1. A complete medical and family history should be taken prior to the initiation of O.C.s. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, O.C.s should not be prescribed for longer than 1 year without another physical examination being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking O.C.s should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug related. 4. O.C.s may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma or cardiac, hepatic or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving O.C. therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. O.C. users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is unknown. 8. Serum folate levels may be depressed by O.C. therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping O.C.s, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of O.C. therapy when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing O.C.s. For example: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. *DRUG INTERACTIONS* O.C.s may be rendered less effective by virtue of drug interaction with rifampin, isoniazid, ampicillin, neomycin, penicillin V, chloramphenicol, sulfonamides, nitrofurantoin, barbiturates, phenytoin, primidone, analgesics, tranquilizers and antimigraine preparations. O.C.s may alter the effectiveness of other types of drugs, such as oral anticoagulants, anticonvulsants, tricyclic antidepressants, antihypertensive agents (e.g., quanethidine), vitamins and hypoglycemic agents. *CARCINOGENESIS* See Warnings. *PREGNANCY* Pregnancy category X. See Contraindications and Warnings. *NURSING MOTHERS* See Warnings. **ADVERSE REACTIONS** An increased risk of the following serious adverse reactions has been associated with the use of O.C.s (see Warnings): thrombophlebitis, thrombosis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, mesenteric thrombosis, liver tumors, cerebral hemorrhage, hypertension, gall bladder disease, congenital anomalies, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving O.C.s and are believed to be drug related: bleeding irregularities (breakthrough bleeding, spotting, missed menses during treatment, amenorrhea after treatment), gastrointestinal symptoms (nausea, vomiting, bloating, abdominal cramps), dysmenorrhea, infertility after discontinuance of treatment, edema, chloasma or melasma which may persist after drug is discontinued, breast changes (tenderness, enlargement, and secretion), intolerance to contact lenses, change in corneal curvature (steepening) change in weight (increase or decrease), change in cervical erosion and cervical secretion, possible diminution in lactation when given immediately postpartum, cholestatic jaundice, migraine, increase in size of uterine leiomyomata, rash (allergic), mental depression, reduced tolerance to carbohydrates, vaginal candidiasis, prolactin-secreting pituitary tumors. The following adverse reactions have been reported in users of O.C.s, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, impaired renal function.

SO EFFECTIVE YOU'D EXPECT TO WRITE A PRESCRIPTION

SO SAFE YOU DON'T HAVE TO

Preparation H and its principal ingredient—Skin Respiratory Factor (SRF) have been studied *in vitro*.* A group of world renowned wound-healing specialists confirmed that SRF stimulated wound oxygen consumption, epithelialization and collagen synthesis.

The unique Preparation H formula temporarily relieves pain and itching in many cases and actually helps shrink swollen hemorrhoidal tissue due to inflammation. All without anesthetics or steroids.

PREPARATION H®
Clinically tested.
Available in ointment and suppositories.

PREPARATION H ACTIVE INGREDIENTS:
Live Yeast Cell Derivative, supplying 2,000 units Skin Respiratory Factor Per Ounce of Base; Shark Liver Oil 3.0%, supplying Vitamin A.

Fertility restoration surgery improved with Zeiss operation microscope.

Dual stereoscopic viewing

The Zeiss Operation Microscope 7-P/H is designed so two surgeons can work face-to-face. A 1:5 zoom system affords continuous, motorized magnification change. The slim body gives free view of the surgical area. Vertical position guarantees depth of focus over the entire field (not possible with inclined microscopes). The 7-P/H can be rotated through 360° and offers a choice of several working distances. Of course, the superior Zeiss optics are unequaled for sharp definition and color rendition.

Simultaneous TV and still-camera use

The Vertolux P/H fiber optic illumination system is so bright that two recording systems, e.g. TV and still camera, can be used simultaneously via the unique Zeiss-Urban dual camera adapter which attaches to the Zeiss beam splitter. Because the beam splitter functions right through the optical system of the microscope, the field of view is exactly as the surgeon sees it.

For further information on this or other Zeiss microscopes, write to us.

You're looking at the only medical reason to recommend a douche.

Monilial vaginitis before Trichotine

Monilial vaginitis after Trichotine

When douching can enhance therapy of vaginitis, as in the photographs above, it has a definite place in medicine. And such evidence, as described by numerous clinical investigators over the years, is exactly the reason Trichotine® receives extensive professional recommendation.

By clearing away obstructive vaginal discharge, Trichotine affords better access to infected mucosa during topical vaginitis therapy and speeds symptomatic relief when used with systemic agents.

One investigator, for example, found that "relief of itching and leukorrhea is prompt and enhances the results obtained with the specific therapy."[1] In subsequent studies[2,3] of patients with vaginitis, others have confirmed this rapid symptomatic relief.

Further, following surgical procedures such as cervical cryosurgery, douching with Trichotine has "...proved to be an effective adjunct in...reducing vaginal discharge, irritation, discomfort and patient complaints."[4] Similar benefits were reported in cervical cauterization,[5] in acute inflammatory[6] and chronic pelvic disease.[7]

Cleanses better than acid douches/Works differently than iodophor douches.

Alkalinity enhances the detergent action of Trichotine—by lowering surface tension and increasing mucolytic action. This results in more thorough vaginal cleansing than with acid douches.[8,9] And, unlike acid douches, Trichotine won't coagulate and precipitate vaginal debris.[8] Or burn as acid douches tend to do.

Unlike iodophor douches, Trichotine doesn't upset the vaginal flora by introducing broad-spectrum antimicrobials. Its actions are limited to those you expect from an adjunctive douche: mucolytic, antipruritic, detergent and deodorizing.

Trichotine: The more you know about it, the more professional reasons you have to recommend douching.

A low level
of estrogen with
a high level of
patient acceptance

"In deciding which combination drug to initially prescribe it is best to utilize the combination pill with the lowest effective dose and an acceptable level of side effects."

Mishell, D.: Current Status of Oral Contraceptive Steroids, Clin. Obstet. Gynecol. *19*:743-764 (December) 1976.

Choose an oral contraceptive she'll stay with.

- Proven effectiveness with excellent cycle control
- Low dropout rate due to breakthrough bleeding and spotting (based on 2,256 patients)*

Months of use	1	2	3	6	9	12
Discontinuation (cumulative) per 100 woman-years of use	0.7	1.1	2.0	3.0	3.5	4.2

*Data on file, G. D. Searle & Co.

- Minor side effects uncommon
- Low incidence of cramping, nausea, weight gain, breast tenderness, and irritability
- Simplified schedule with calendarized Compack®
- Excellent record of continuation

Please see the next page for a brief summary of prescribing information.

Demulen®

(ethynodiol diacetate 1 mg., ethinyl estradiol 50 mcg.)

...She'll stay with it.

Serious as well as minor side effects have been reported with the use of oral contraceptives. These include thromboembolic disease. The physician should remain alert to the earliest manifestations of any symptoms of serious disease or conditions and discontinue oral contraceptive therapy when appropriate. The physician should be fully familiar with the complete prescribing information for this product.

SEARLE

Indication and usage—For prevention of pregnancy. Pregnancy rate using products with ≥35 mcg. ethinyl estradiol or ≥50 mcg. mestranol is <1/100 woman-years. With ≤35 mcg. ethinyl estradiol, rate is slightly higher; with progestogen-only oral contraceptives (OCs), rate is about 3. Precise comparisons cannot be made. Rates for other methods have been published. Dose-related Thromboembolic Risk—One study showed positive association between OC estrogen dose and thromboembolic risk. Thus, it is prudent and in keeping with good therapeutics to minimize estrogen exposure. Prescribe product containing the least amount of estrogen compatible with acceptable pregnancy rate and patient acceptance. Start new OC users on ≤50 mcg. estrogen.

Contraindications—Thrombophlebitis, thromboembolic disorders, cerebral vascular disease, myocardial infarction or coronary artery disease, or past history of these; known or suspected breast carcinoma, estrogen-dependent neoplasia, or pregnancy; undiagnosed abnormal vaginal bleeding; markedly impaired liver function; past or present, benign or malignant liver tumors.

Warnings

Cigarette-smoking increases risk of serious cardiovascular side effects from OC use. Risk increases with age and heavy smoking (15 or more cigarettes/day) and is quite marked in women over 35. OC users should be strongly advised not to smoke.

OCs are associated with increased risk of several serious conditions including venous and arterial thromboembolism, thrombotic and hemorrhagic stroke, myocardial infarction, visual disorders, hepatic tumors, gallbladder disease, hypertension, fetal abnormalities. Practitioners should be familiar with the available information relating to these and other risks.

1. Thromboembolic disorders and other vascular problems—Increased risk of thromboembolic and thrombotic disease associated with OCs is well established. A British study showed increased relative risk for fatal venous thromboembolism, 2 British and 3 U.S. studies increased relative risk for nonfatal venous thromboembolism. Two U.S. studies showed increased relative risk for stroke, not shown in prior British studies. It was estimated OC users were 2–11 times more likely than nonusers to manifest these diseases without evident cause. In a British study of idiopathic deep vein thrombosis and pulmonary embolism, projected hospitalization rates for ages 16-40 were 47/year/100,000 users and 5 for nonusers. In a British mortality study, overall excess mortality from pulmonary embolism or stroke was 1.3–3.4 deaths/year/100,000 users and increased with age. Cerebrovascular Disorders—In a U.S. study of stroke with and without predisposing causes, risk of hemorrhagic stroke was estimated as 2 times greater and thrombotic stroke 4.0–9.5 times greater in users. Mortality trends in 21 countries indicate that, since OC introduction, changes in mortality from nonrheumatic cardiovascular disease were associated with changes in the prevalence of OC use. The Royal College of GPs reported on its prospective study comparing users and nonusers: "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." They reported more superficial and deep vein thrombosis in users. A 1977 analysis showed a 5-fold increased mortality in users from circulatory diseases, mainly myocardial infarction (MI) and hemorrhagic stroke. Excess mortality was associated with age, smoking and duration of use. In 1976 a British Family Planning Association study found a highly significant association between OC use and stroke though total numbers were small; the increased risk for venous thrombosis and pulmonary embolism was about 4-fold and statistically highly significant. Circulatory disease mortality was significantly greater in users. Myocardial Infarction—An increased risk of MI associated with OC use was reported in Britain, as previously suspected. The morbidity study found the greater the number of risk factors for coronary artery disease (smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia) the higher the MI risk, regardless of OC use. OCs were considered an additional risk factor. The excess rate of fatal MI in Britain was about 3.5/year/100,000 users aged 30–39 and 20 for ages 40–44. (These are based on British vital statistics with acute MI death rates 2–3 times less than the U.S. Similar estimates for U.S. are 25.7 for users aged 30–39 with predispositions vs. 1.5 without; for ages 40–44, 86.2 vs. 5.1.) Excess hospitalization rate for nonfatal MI in Britain was about 3.5/year/100,000 users aged 30–39 and 47 for ages 40–44. Smoking is a major predisposing condition to MI. In terms of relative risk, nonsmoking OC users are twice as likely to have fatal MI as nonsmoking nonusers. Smoking users have a 5-fold greater risk of fatal MI as nonsmoking users, but a 10–12-fold greater risk than nonsmoking nonusers. Amount of smoking is an important factor. In determining importance of these risks, give serious consideration to rates in table below. Importance of other predispositions cited above in determining relative and absolute risks has not been quantified; it is likely the same synergism exists, but perhaps to a lesser extent.

Estimated Mortality Rate from Myocardial Infarction per 100,000 Women/Year

	Aged 30–39		Aged 40–44	
	Users	Nonusers	Users	Nonusers
All smokers	10.2	2.6	62.0	15.9
≥15 cigarettes daily	13.0	5.1	78.7	31.3
<15 cigarettes daily	4.7	0.9	28.6	5.7
Nonsmokers	1.8	1.2	10.7	7.4
Smokers and nonsmokers	5.4	1.9	32.8	11.7

Risk of Dose—Reports of thromboembolism after use of OCs with ≥50 mcg. estrogen received by drug safety committees in Britain, Sweden and Denmark were compared with the distribution expected from market research sales estimates. A positive correlation was found between estrogen dose and reporting of thromboembolism, including coronary thrombosis, in excess of that predicted by sales. OCs with ≥100 mcg. estrogen were associated with higher thromboembolism risk than those with 50–80 mcg. The authors suggested that estrogen quantity may not be the sole factor. Any influence of progestogens was not considered, which may be responsible for certain discrepancies in the data. No significant differences were noted between OCs containing the same estrogen dose nor between ethinyl estradiol and mestranol. Studies on thromboembolic risk with progestogen-only OCs have not been done. Cases have been reported for these OCs and they are not presumed free of excess risk. In a U.S. case-controlled study, relative risk of OC use 1 month before hospitalization for various types of thromboembolism was calculated. If relative estrogenic potency and possible influence of different progestogens are ignored, OCs may be divided into those with <100 mcg. and those with ≥100 mcg. estrogen. For all cases combined, larger doses were associated with only slightly higher relative risk; for idiopathic cases relative risk was doubled with larger doses, but confidence limits overlapped and differences were not significant. Apparently there was no increased risk for cases with predispositions. Thromboembolic risk in users and nonusers increases with age. OCs have been considered an independent risk factor. Excess Mortality from Circulatory Diseases—A U.K. prospective study estimated annual mortality from circulatory diseases for OC users and nonusers according to age, smoking habits and duration of use. Excess mortality was 20/100,000 users (5 for ages 15–34, 33 for ages 35–44, 140 for ages 45–49), the risk being concentrated in older women, long-term users, and smokers. Interrelationships of age, smoking and duration of use could not be examined, nor could effects of continuous vs. intermittent use. Though circulatory mortality was increased 10-fold in users of >5 years, all deaths were in women over age 34. Until more under-35 users of 5+ continuous years are available, size of relative risk for this age group cannot be given. Risk of circulatory disease may have persisted after discontinuance of OCs. One study estimated risk of death with various contraceptive methods, each estimate including risk of method (e.g., thromboembolism for OCs) plus risk due to pregnancy or abortion in cases of method failure. This latter risk varies with effectiveness. It concluded mortality with all methods is low and below that of childbirth, except for OC users over 40 who smoke. Heavy smokers have double the risk of smokers as a class, light smokers about half. Mortality associated with OC use in nonsmokers over 40 is higher than with any other method in that age group. Lowest mortality is with the condom or diaphragm backed up by early legal abortion. Risk of thromboembolic and thrombotic disease associated with OCs increases with age after 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia, and especially cigarette smoking. Based on current data, the chart gives gross estimates of risk of death from circulatory disorders associated with OCs:

Risk is: A—very high, B—high, C—moderate, D—low. Age:	<30	30–39	≥40
Heavy smokers (≥15/day)	C	B	A
Light smokers (<15/day)	D	C	B
Nonsmokers, no predispositions	D	C,D	C
Nonsmokers, with predispositions	C	C,B	B,A

Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary artery disease, myocardial infarction, retinal thrombosis, mesenteric thrombosis). Should any of these occur or be suspected, discontinue OCs immediately. A 4–7-fold increased risk of postsurgery thromboembolism was reported in users; if feasible discontinue OCs at least 4 weeks before elective surgery or during prolonged immobilization and do not resume until at least 4 weeks postsurgery. Thromboembolic risk may be increased for users with blood types A, B or AB. **2.** Ocular lesions—Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OCs. Discontinue if there is unexplained, gradual or sudden, partial or complete loss of vision; proptosis or diplopia; papilledema; or evidence of retinal vascular lesions. Institute diagnostic and therapeutic measures. **3.** Carcinoma—Long-term estrogen in certain animals increases carcinomas such as those of breast, uterus, cervix, vagina, ovary, liver, pituitary. Some synthetic progestogens, none currently in OCs, increase incidence of benign and malignant mammary nodules in dogs. There is now evidence that estrogens increase risk of human endometrial carcinoma. In several case-controlled studies increased relative risk (3.1–13.9 times) associated endometrial carcinoma with prolonged estrogen for menopausal symptoms. Risk was independent of other known risk factors and depended on duration of use and dose. This is supported by increased endometrial cancer incidence since 1969 in 8 U.S. areas with cancer-reporting systems, which may be related to rapidly expanding estrogen use. There is no evidence that natural estrogens are more or less hazardous than synthetics at equi-estrogenic doses. Of the first 30 cases of endometrial carcinoma in OC users under 40, those without predispositions (e.g., irregular bleeding before OCs, polycystic ovaries) occurred nearly always with no-longer-marketed sequential OCs. No statistical association is reported suggesting increased endometrial cancer with combination or progestogen-only OCs, though individual cases have been reported. Studies show no increased breast cancer with OCs or estrogens. However, greater risk was noted in OC users with benign breast disease or long-term (2–4 years) use. Risk of breast cancer with menopausal estrogens rose and further increased with duration of follow-up. Decreased benign breast tumors in OC users is well known. Some studies suggested increased risk of cervical dysplasia, erosion and carcinoma in long-term users; cause and effect is not established. Cervical microglandular hyperplasia has been reported. In summary, there is no confirmed evidence from human studies of increased cancer risk with OCs. Close surveillance is, however, essential. In undiagnosed persistent or recurrent abnormal vaginal bleeding, consider nonfunctional causes and take appropriate diagnostic measures to rule out malignancy. Carefully monitor users with a strong family history of breast cancer or with breast nodules, fibrocystic disease, recurrent cystic mastitis, abnormal mammograms, or cervical dysplasia. **4.** Hepatic adenomas, hepatomas, hamartomas, regenerating nodules, focal nodular hyperplasia, hemangiomas, hepatocellular carcinoma, etc. have been associated with OCs. In 1 study OC formulations with high "hormonal potency" were associated with higher risk. Though benign these hepatic lesions may rupture and cause fatal hemoperitoneum in short- or long-term users. Two studies related risk to duration of use, being much greater after ≥4 years. Consider such lesions in users with abdominal pain, tenderness, mass or shock. About 25% present with abdominal masses; up to half with acute hemoperitoneum. Routine radiologic and lab studies may not be helpful; liver scans may show a focal defect. Hepatic arteriography or CAT may be useful in diagnosis. Hepatocellular carcinoma was noted in a few users. OCs are contraindicated in case of past or present, benign or malignant liver tumors. **5.** Use in or immediately preceding pregnancy, birth defects, malignancy in offspring—Estrogens or progestogens during early pregnancy may seriously damage offspring. Females exposed in utero to DES and other nonsteroidal estrogens may have increased risk of vaginal or cervical cancer. Though OCs may not enhance this risk, monitor such patients carefully. From 30–90% of DES-exposed women develop benign vaginal or cervical adenosis, which could be premalignant. Males so exposed may develop urogenital defects. Other estrogens may mimic DES. Reports relate fetal exposure to female sex hormones and congenital anomalies, e.g., multiple anomalies described by VACTERL for vertebral, anal, cardiac, tracheoesophageal, renal and limb defects. There appears preferential expression by males. There was a 4.7-fold increased risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal pregnancy tests or treatment for threatened abortion). Some exposures were very short, being only a few days. Cardiovascular defects in children exposed to female hormones, including OCs, during early pregnancy occurred at 18.2/1000 births, compared to 7.8 for those unexposed ($P<.05$). Female sex hormones were used for threatened or habitual abortion, but there is considerable evidence estrogens are ineffective and no evidence progestogens are effective. Triploidy and possibly other polyploidy may be increased in abortuses from women becoming pregnant soon post-OC. These almost always abort spontaneously. It is unknown if spontaneous abortion is increased soon after stopping OCs. Safety of OCs in pregnancy has not been demonstrated. Rule out pregnancy in using OCs and always consider it if withdrawal bleeding does not occur. If 2 consecutive periods are missed rule out pregnancy before continuing. If user deviates from regimen, consider pregnancy at first missed period and withhold OCs. If pregnancy is confirmed, apprise patient of potential fetal risks and discuss continuation of pregnancy. Users discontinuing for pregnancy should use alternative contraception for 3 months before attempting to conceive, though this is not based on precise information. Do not use progestogen-only or progestogen-estrogen drugs as pregnancy tests. **6.** Gallbladder disease risk, surgically confirmed, appeared after 2 years' use and doubled after 4–5 years in 1 study; it appeared in 6–12 months' use in another. **7.** Carbohydrate & lipid metabolism—Decreased glucose tolerance occurs in a significant number of users; carefully observe diabetic and prediabetic patients. Triglycerides and total phospholipids may increase. **8.** Elevated blood pressure (BP) occurs in some users in a few months, and degree may relate to progestogen dose. Hypertension prevalence in users is no higher than in nonusers in the first year, but increases with longer exposure; in the 5th year it is 2½–3 times the first year. Age is strongly correlated with hypertension in users. Those with history of elevated BP (hypertension), pre-existing renal disease, history of toxemia or elevated BP in pregnancy, familial tendency to hypertension or its consequences, or history of excessive weight gain or fluid retention during menstrual cycles may be more likely to develop elevated BP on OCs and thus should be monitored closely. Even though elevated BP may be in the "normal" range, do not ignore clinical implications. Follow closely, particularly those with other risk factors for cardiovascular disease or stroke. High BP may or may not persist after stopping OCs. **9.** Headache—Onset or exacerbation of migraine or development of headache of a new pattern that is recurrent, persistent or severe requires stopping OCs and evaluating cause. **10.** Bleeding irregularities—Breakthrough bleeding (BTB), spotting and amenorrhea are frequent reasons for discontinuing. In BTB, as in all cases of irregular bleeding, consider nonfunctional causes. In undiagnosed persistent or recurrent bleeding, rule out pregnancy or malignancy. If pathology is excluded, time or change to another product may suffice. Change to a higher estrogen OC only when necessary as this may increase thromboembolic risk. Those with a history of oligomenorrhea or secondary amenorrhea or without established regular cycles may be anovulatory or amenorrheic after discontinuing. Those with such problems should be so informed and other methods encouraged. Post-use anovulation, possibly prolonged, may occur in women without previous irregularities. Higher incidence of galactorrhea and of pituitary tumors (e.g., adenomas) has been associated with postpill amenorrhea. One study reported 16-fold increased prevalence of pituitary prolactin-secreting tumors in patients with postpill amenorrhea when galactorrhea was present. **11.** Ectopics—In failures with combination OCs, the ratio of ectopic to intrauterine pregnancies is no higher than in nonusers. There may be an increased risk of ectopics after discontinuing. **12.** Breast feeding—OCs may decrease quantity and quality of milk. A small fraction of OC steroids appears in milk. Effects if any on the child are unknown. If feasible defer OCs until after weaning. **13.** Infertility may occur in women discontinuing OCs, which appears independent of duration of use. While impairment diminishes with time, there is still an appreciable difference in nulliparous but not parous women after 30 months; difference is negligible after 42 months.

Precautions—Conduct complete history and physical prior to OC use and annually thereafter. Include breasts, abdomen and pelvis, with BP, pap and lab tests. Pre-existing uterine leiomyomata may enlarge. Mental depression may occur, with positive history, observe carefully and discontinue if serious recurrence. Fluid retention may occur; prescribe cautiously and monitor carefully in convulsive disorders, migraine, asthma, or cardiac, hepatic or renal dysfunction. History of jaundice in pregnancy increases risk of recurrence on OCs; observe carefully and discontinue if jaundice occurs. Steroids may be poorly metabolized in liver dysfunction and should be given cautiously. Tryptophan metabolism may be disturbed and result in pyridoxine deficiency; megaloblastic anemia has been reported. Serum folate may be depressed and may be exacerbated in post-OC pregnancy. Advise pathologist of OC use when submitting specimens. Endocrine and liver function tests may be altered; repeat abnormal tests after stopping for 2 months. These have been observed: increased BSP retention and other abnormalities in liver function tests; increased prothrombin and coagulation factors VII, VIII, IX, X; decreased antithrombin III, increased platelet aggregability; increased thyroid-binding globulin leading to increased circulating total thyroid hormone (PBI, T^4); decreased T^3 uptake, unaltered free T^4; decreased pregnanediol excretion; reduced metyrapone response; increased blood transcortin, corticosteroid, triglyceride, phospholipid; reduced serum folate; impaired glucose tolerance; altered plasma trace minerals. Influence of prolonged OC use on pituitary, ovarian, adrenal, hepatic, or uterine function, or on immune response is not established. OCs may mask onset of climacteric. Information for patients—see patient labeling. Drug interactions—OC effectiveness may be decreased and more BTB occur with rifampicin, isoniazid, ampicillin, neomycin, penicillin V, chloramphenicol, sulfonamides, nitrofurantoin, barbiturates, phenytoin, primidone, phenylbutazone, analgesics, tranquilizers, antimigraines. OCs may alter effectiveness of drugs such as oral anticoagulants, anticonvulsants, tricyclic antidepressants, antihypertensives, vitamins, hypoglycemics.

Adverse Reactions—Increased risk of the following serious adverse reactions has been associated with OCs: thrombophlebitis and thrombosis; pulmonary embolism; myocardial infarction and coronary thrombosis; cerebral thrombosis; cerebral hemorrhage; hypertension; gallbladder disease; benign adenomas and other hepatic lesions, with or without intra-abdominal bleeding; congenital abnormalities. There is evidence of association between the following conditions and OCs, though confirmatory studies have not been done: mesenteric thrombosis; Budd-Chiari syndrome, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following have been reported with OCs and are believed drug related: nausea, vomiting, gastrointestinal symptoms, breakthrough bleeding, spotting, change in menstrual flow, dysmenorrhea, amenorrhea during and after use, infertility post-OC, edema, chloasma or melasma, which may persist post-OC, breast changes (tenderness, enlargement, secretion), weight changes, change in cervical erosion and secretion, endocervical hyperplasia, lactation decrease, cholestatic jaundice, migraine, enlarged uterine leiomyomata, allergic rash, mental depression, reduced carbohydrate tolerance, vaginal candidiasis, change in corneal curvature (steepening), intolerance to contact lenses. The following have been reported and association has not been confirmed or refuted: premenstrual-like syndrome, cataracts, libido changes, chorea, appetite changes, cystitis-like syndrome, headache, paresthesia, nervousness, dizziness, auditory disturbances, rhinitis, fatigue, backache, hirsutism, scalp hair loss, erythema multiforme or nodosum, hemorrhagic eruption, itching, vaginitis, porphyria, impaired renal function, anemia, pancreatitis, hepatitis, colitis, gingivitis, lupus erythematosus, rheumatoid arthritis, pituitary tumors (e.g., adenoma) with amenorrhea and/or galactorrhea after use, endometrial, cervical and breast carcinoma.

Acute overdosage—Serious ill effects have not been reported after large acute doses of OCs in young children, but nausea and withdrawal bleeding might occur.

Important note—Full prescribing information should be consulted prior to use and is available on request.

Demulen® Each white tablet contains ethynodiol diacetate 1 mg. and ethinyl estradiol 50 mcg. Each pink tablet in Demulen-28® is a placebo containing no active ingredients.

It takes a persistent anesthesiologist to get other anesthesiologists to agree on new safety standards.

Meet Colonel James Meyer.

Doctor James Meyer is an nesthesiologist with the U.S. Army. e has been for 19 years. But he's ot your usual anesthesiologist. He one of a small group of men who re developing national and inter- ational safety standards for this mplex specialty. They are trying get anesthesiologists around the orld to agree on these standards. me issues, like agreement on lor coding of equipment, seem mple. However, the most common nesthesia accidents involve ossed oxygen and nitrous oxide pplies. For example, in Germany ygen tanks and related fittings are always painted blue; in North America, blue is the color code for nitrous oxide. The danger of using the wrong gas is increased where field operations involve other such countries or where physicians trained in one country practice in another. Agreement between countries is hard to achieve when national laws need to be changed or when the cost is in millions.

Besides directing a residency training program in anesthesiology, Colonel Meyer is the Army's representative at conferences on safety standards concerning anesthesia-related equipment at national and international standards-setting organizations. He also represents the American Society of Anesthesiologists at the National Fire Protection Association, bringing his expertise to medical equipment and hospital design standards adopted by city, county and state governments, as well as the federal government.

Army Medicine provides the perfect setting for men like James Meyer who wish to participate in programs to advance the quality of medical practice everywhere.

Army Medicine offers opportunities for the student, the resident

and the practicing physician.

If you are a student, you will find that Army Medicine offers fully accredited residencies in virtually every specialty. Army residents generally receive higher compensation and greater responsibility than their civilian counterparts. Graduates of Army residencies, as a group, do particularly well on specialty board certifying examinations.

If you are a resident or a practicing physician, you will discover that Army Medicine offers an attractive alternative to civilian practice. As an Army officer you will receive substantial compensation, extensive annual paid vacations and will participate in a remarkable non-contributory retirement plan. You will also gain the freedom to practice without such non-medical distractions as innumerable insurance forms, malpractice premiums or cash flow concerns.

Army Medicine.
The practice that's practically all medicine.

CHAIRPERSON, Department of Ob/Gyn: Mount Sinai Hospital Medical Center, Chicago, Illinois, is seeking a full-time Chairperson for its Department of Ob/Gyn. Mount Sinai Hospital Medical Center is a 466 bed teaching hospital, located on the near West Side of Chicago with accredited residency programs in all clinical departments. The Hospital is a major teaching affiliate of Rush Medical College.

Candidates must be American Board Certified, and have demonstrated performance and accomplishments in clinical practice, teaching, and administrative roles. Academic rank can be considered at the Professor or Associate Professor level. The Chairperson also assumes the position as President of the Department's Group Practice. Salary arrangements are competitive and negotiable. Mount Sinai Hospital Medical Center is an equal opportunity employer.

Respond with curriculum vitae to Albert I. Rubenstone, M.D., Chairman, Search Committee, c/o Department of Pathology, Mount Sinai Hospital Medical Center, California Avenue at 15th Street, Chicago, Illinois 60608 (312) 542-2417.

OBSTETRICIAN/ GYNECOLOGIST

University trained, Board eligible or certified, to join a growing, federally qualified, multispecialty prepaid group practice in Rochester, New York, situated in attractive new health center. Innovative practice with in-office OR for outpatient surgery, 2 nurse-midwives and full time nurse educator. Medical Group is active in University of Rochester School of Medicine programs. Salary competitive, plus liberal fringe benefits. For further information, send curriculum vitae to: James S. Roberts, M.D., 800 Carter St., Rochester, N.Y. 14621.

EDITORS! REVIEWERS! AUTHORS!

For you . . . a new book that contains virtually everything you want to know about

THE SCIENTIFIC JOURNAL: EDITORIAL POLICIES AND PRACTICES

Guidelines for Editors, Reviewers, and Authors

In 1665 the first scholarly journal was published in France. Since that time, there has been no one source of editorial guidelines for journal editors. This new book now provides you with such a source.

YOU DECIDE YOUR OWN APPROACH!

Presenting the advantages and disadvantages of each specific decision, eminent editors offer you various recommendations, discussions, and opinions concerning the problems you may encounter:

"Because we are aware that there is no 'right' policy on most editorial matters, we have tried not to prescribe rules, but have, instead, explored various facets of the problems that confront the editor in his daily work."

The book is divided into two general sections: editorial policies, which usually require major decisions; and editorial practices, which involve minor decisions, often about format or mechanical style. You'll find essays exploring: the manuscript reviewing system; special types of manuscripts (abstracts, transactions, solicited manuscripts, book reviews). You'll value chapters which cover: information for authors; copyright; errata; references cited; copy-editing; journal cover; etc.

From "the purpose of scientific journals" to "binding practices," this new book contains virtually everything you want to know as editor, reviewer, or author. See for yourself!

By Lois DeBakey, Ph.D. In collaboration with: Paul F. Cranefield, M.D., Ph.D.; Ayodhya P. Gupta, M.D.; Franz J. Ingelfinger, M.D.; Robert J. Levine, M.D.; Robert H. Moser, M.D.; J. Roger Porter, Ph.D.; and F. Peter Woodford, Ph.D. August, 1976. 128 pages, 6″ × 9″. Price, $12.50.

SOUTHERN MEDICAL ASSOCIATION DIAL access

the ModiCon balance

TRADEMARK

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in the 28-day regimen contains inert ingredients.

low hormonal content/high patient acceptability

Low hormonal content, yet highly effective
ModiCon combines a low dose of estrogen (0.035 mg ethinyl estradiol) with a low dose of progestin (0.5 mg norethindrone). In clinical trials, the pregnancy rate in **1,168** patients completing **16,345** cycles was only **0.22** per 100 woman-years.

Good patient acceptability with low incidence of amenorrhea and good cycle control†
With ModiCon, the majority of women who start with it stay with it.

Throughout clinical trials, the total incidence of amenorrhea was only **1.0%.** The average cycle dropout rate during the first three months because of menstrual disorders was only **1.2%.**

ModiCon is available in both 21 and 28-day regimens in the unique DIALPAK* Tablet Dispenser.

See the complete Prescribing Information for this product, a summary of which is on the next page.

ModiCon

†Serious as well as minor side effects have been reported with the use of oral contraceptives. These include thromboembolic disease. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. The physician should be fully aware of the complete Prescribing Information for this product.

MODICON* Tablets

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables, and references. The physician should be thoroughly familiar with the complete prescribing information and patient information before prescribing the product.

- **INDICATION: CONTRACEPTION.** The pregnancy rate in women using conventional combination oral contraceptives (containing 35 mcg or more of ethinyl estradiol or 50 mcg or more of mestranol) is generally reported as less than one pregnancy per 100 woman-years of use. Slightly higher rates (somewhat more than one pregnancy per 100 woman-years of use) are reported for some combination products containing 35 mcg or less of ethinyl estradiol, and rates on the order of three pregnancies per 100 woman-years are reported for the progestogen-only oral contraceptives. Table 1 gives ranges of pregnancy rates reported in the literature for other means of contraception. The efficacy of these means of contraception (except the IUD) depends upon the degree of adherence to the method.

Table 1: Pregnancies Per 100 Women-Years. IUD, less than 1-6; Diaphragm with spermicidal product (creams or jellies), 2-20; Condom, 3-36; Aerosol foams, 2-29; Jellies and creams, 4-36; Periodic abstinence (rhythm) all types, less than 1-47; 1. Calendar method, 14-47; 2. Temperature method, 1-20; 3. Temperature method—intercourse only in postovulatory phase, less than 1-7; 4. Mucus method, 1-25; No contraception, 60-80. **DOSE-RELATED RISK OF THROMBOEMBOLISM FROM ORAL CONTRACEPTIVES:** Two studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral contraceptives be started on preparations containing .05 mg or less of estrogen. **CONTRAINDICATIONS:** Oral contraceptives should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed, abnormal genital bleeding. 7. Known or suspected pregnancy (see WARNINGS, No. 5).

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Four principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. Overall excess mortality due to pulmonary embolism or stroke is on the order of 1.0 to 3.5 deaths annually per 100,000 users and increases with age. **CEREBROVASCULAR DISORDERS:** In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than in nonusers and the risk of thrombotic stroke was 4.0 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION: An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia), the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. The annual excess case rate (increased risk) of myocardial infarction (fatal and nonfatal) in oral contraceptive users was estimated to be approximately 7 cases per 100,000 women users in the 30-39 age group and 67 cases per 100,000 women users in the 40-44 age group. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10-to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent. **Risk of Dose:** In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only oral contraceptives have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk. The risk of thromboembolic and thrombotic disorders, in both users and nonusers of oral contraceptives, increases with age. Oral contraceptive use, however, an independent risk factor for these events. **ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES:** A large prospective study carried out in the United Kingdom estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of oral contraceptives according to age, smoking habits, and duration of use. The overall excess death rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking, and duration of use, nor to compare the effects of continuous versus intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for five or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for five or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. This study reports that the increased risk of circulatory diseases may persist after the pill is discontinued. Another study published at the same time confirms a previously reported increase of mortality in pill users from cardiovascular disease. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of oral contraceptives) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The findings of this analysis are shown in Figure 1 below. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke. (The rates given for pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 cigarettes a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50 percent.) The mortality associated with oral contraceptive use in nonsmokers over 40 is higher than with any other method of contraception in that age group. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia and especially by cigarette smoking. The risk of myocardial infarction in oral contraceptive users is substantially increased in women age 40 and over, especially those with other risk factors. Based on the data currently available, the following chart gives a gross estimate of the risk of death from circulatory disorders associated with the use of oral contraceptives:

SMOKING HABITS AND OTHER PREDISPOSING CONDITIONS—RISK ASSOCIATED WITH USE OF ORAL CONTRACEPTIVES

Age	Below 30	30-39	40+	
Heavy smokers	C	B	A	A—Use associated with very high risk.
Light smokers	D	C	B	B—Use associated with high risk.
Nonsmokers (no predisposing conditions)	D	C,D	C	C—Use associated with moderate risk.
Nonsmokers (other predisposing conditions)	C	C,B	B,A	D—Use associated with low risk.

The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four- to six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2. OCULAR LESIONS. There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue oral contraceptive medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions and institute appropriate diagnostic and therapeutic measures. 3. CARCINOMA. Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in oral contraceptives, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on oral contraceptives. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time oral contraceptives were first given, polycystic ovaries), nearly all occurred in women who had used a sequential oral contraceptive. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only oral contraceptives. Several studies have found no increases in breast cancer in women taking oral contraceptives or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with oral contraceptives, found an excess risk in the subgroups of oral contraceptive users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of oral contraceptives has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of

Figure 1. Estimated annual number of deaths associated with control of fertility and no control per 100,000 nonsterile women, by regimen of control and age of woman.

	15-19	20-24	25-29	30-34	35-39	40-44
No method	5.5	5.2	7.1	14.0	19.3	21.9
Abortion only	2.3	2.5	2.5	5.2	9.8	6.6
Pill only-nonsmokers	1.3	1.4	1.4	2.2	4.5	3.1
Pill only-smokers	1.5	1.6	1.6	10.8	13.4	58.9
IUDs only	1.1	1.2	1.2	1.4	1.6	1.4
Traditional contraception only	1.1	1.4	1.9	3.7	4.7	4.0
Traditional contraception and abortion	0.3	0.4	0.4	0.8	1.4	0.8

4. HEPATIC TUMORS. Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study showed that oral contraceptive formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of oral contraceptives. Two studies relate risk with duration of use of the contraceptive, the risk being much greater after four or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time. 5. USE IN OR IMMEDIATELY PRECEDING PREGNANCY, BIRTH DEFECTS IN OFFSPRING, AND MALIGNANCY IN FEMALE OFFSPRING. The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be on the order of 1 to 4 in 1000 exposures. Although there is no evidence at the present time that oral contraceptives further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including oral contraceptives, in pregnancy. One case control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if the progestogen-only oral contraceptives are used), and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy. 6. GALLBLADDER DISEASE. Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives and estrogens. In one study, an increased risk appeared after two years of use and doubled after four or five years of use. In one of the other studies, an increased risk was apparent between six and twelve months of use. 7. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. An increase in triglycerides and total phospholipids has been observed in patients receiving oral contraceptives. The clinical significance of this finding remains to be defined. 8. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in patients receiving oral contraceptives. In some women hypertension may occur within a few months of beginning oral contraceptive use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two and a half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in oral contraceptive users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. Hypertension that develops as a result of taking oral contraceptives usually returns to normal after discontinuing the drug. 9. HEADACHE. The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of oral contraceptives and evaluation of the cause. 10. BLEEDING IRREGULARITIES. Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Postuse anovulation, possibly prolonged, may also occur in women without previous irregularities. 11. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. 12. BREAST FEEDING. Oral contraceptives given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of oral contraceptives should be deferred until the infant has been weaned. **PRECAUTIONS: General:** 1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another physical examination being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by oral contraceptive therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping oral contraceptives, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. **INFORMATION FOR THE PATIENT: (See Patient Package Insert). DRUG INTERACTIONS:** Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and ampicillin. **CARCINOGENESIS, PREGNANCY, NURSING MOTHERS: See CONTRAINDICATIONS and WARNINGS. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS): Thrombophlebitis. Pulmonary embolism. Coronary thrombosis. Cerebral thrombosis. Cerebral hemorrhage. Hypertension. Gallbladder disease. Liver tumors. Congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis. Neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea, usually the most common adverse reaction. Vomiting, occurs in approximately 10% or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Dysmenorrhea. Amenorrhea during and after treatment. Temporary infertility after discontinuance of treatment. Edema. Chloasma or melasma which may persist. Breast changes: tenderness, enlargement, and secretion. Change in weight (increase or decrease). Change in cervical erosion and cervical secretion. Possible diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Increase in size of uterine leiomyomata. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome. Cataracts. Changes in libido. Chorea. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. (ORTHO-NOVUM 1/50□21 and ORTHO-NOVUM 1/50□28 contain tartrazine. Allergic reactions have been reported with the ingestion of this dye in some patients.) **ACUTE OVERDOSE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Information for authors

Submission of contributions. Manuscripts should in general be sent to a particular Editor according to the following plan: If it is from the southeastern quadrant of the United States or from Canada, or if it has been presented before one of the official sponsoring societies, to Dr. Brewer; if from the northeastern quadrant (including Ohio), or if it is a Clinical Opinion or a Letter to the Editors, to Dr. Zuspan; if from the north central states, any of the United States west of the Mississippi, Hawaii, Alaska, or abroad, to Dr. Quilligan.

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. Therefore, all manuscripts must be accompanied by the following written statement, signed by one author: "The undersigned author transfers all copyright ownership of the manuscript (title of article) to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

All articles published in this JOURNAL must be contributed to it exclusively. Articles previously published in another language are not acceptable.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority.

Articles dealing with human experimentation cannot be accepted unless the experiment was approved by the author's local Human Experimentation Committee.

Statements and opinions expressed in the articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantee, warrant, or endorse any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

Manuscripts. Manuscripts should be typewritten on one side of the paper only, with double spacing and liberal margins. The original and one copy of the manuscript are required. References should be placed at the end of the article. They should include name of author(s), article title, name of periodical, volume, page, and year. Name of periodical should conform to that shown in latest *List of Journals Indexed in Index Medicus*. For reference style see current issue of JOURNAL. Authors are encouraged to limit references to *16, except* for Communications in Brief, limited to *2,* Current Investigation and Clinical Opinion, limited to *6,* and Current Developments, for which there is *no* limit. Illustrations accompanying manuscripts should be numbered, provided with suitable legends, and marked lightly on the back with the author's name. Authors should indicate on the manuscript the approximate position of tables and text figures.

Tables should be typed on separate sheets of paper, not in the text, with one table to a page. They should be numbered in sequence and each must be referred to at an appropriate point in the text. Captions of the tables should be brief, yet indicate clearly the purpose or content of each table. Rows and columns in the table should precisely define the nature of the data in each. Abbreviations in tables should be used as little as possible and if abbreviations are used they should be explained in a footnote to the table.

An abstract of 50 to 150 words, to be published as an introduction, should accompany each manuscript and should be typed on a separate sheet of paper.

A footnote should be included which gives the name and complete mailing address of the person to whom reprint requests and correspondence should be sent.

A Guide to Writing for the American Journal of Obstetrics and Gynecology may be obtained from the Publisher on request.

Illustrations. A reasonable number of halftone illustrations will be reproduced free of cost to the author, but special arrangements must be made with the Editors for color plates, elaborate tables, or extra illustrations. Original drawings or graphs should be drawn with black India ink. Typewritten or freehand lettering is not acceptable. All lettering must be done professionally. **Do not send original art work, x-ray films, or ECG tracings.** Glossy print photographs are preferred, for good black and white contrast is essential.

Announcements. Announcements of meetings must be received by Dr. Brewer at least 2½ months prior to the time of the meeting. Such announcements should concern major meetings and other significant activities. Announcements of symposia or seminars for which fees are charged are not published in the scientific pages of the JOURNAL but may be submitted for paid advertisements, if desired.

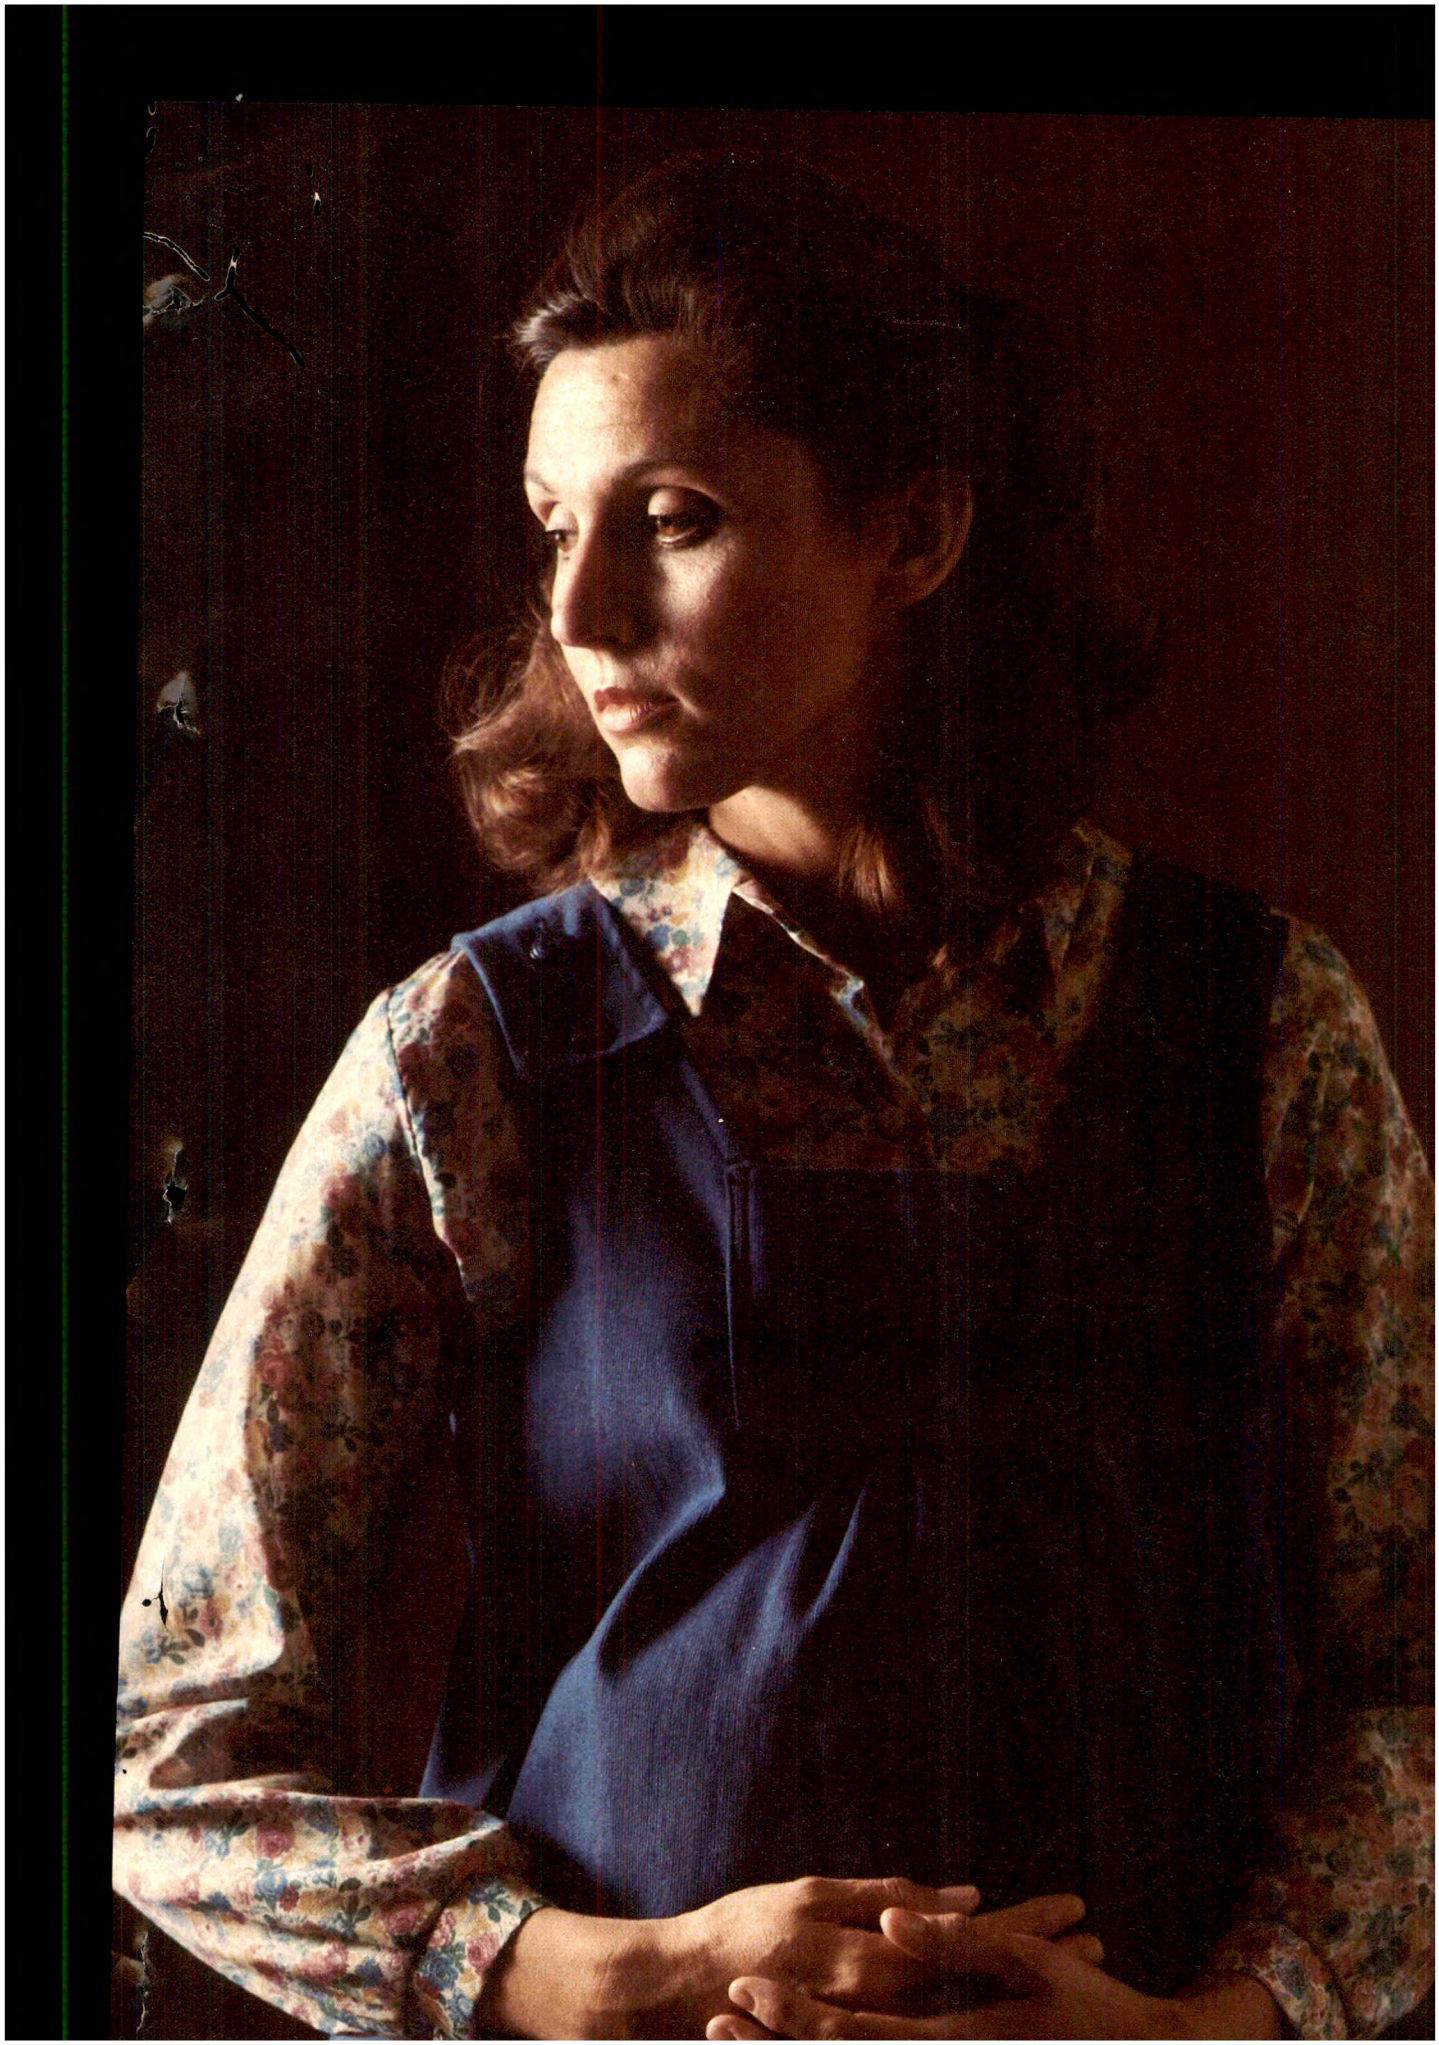
Letters to the Editors. A brief Letter to the Editors commenting upon some article which has appeared in the JOURNAL will be considered for publication. The writer of the original article will have an opportunity to reply to unfavorable comments. A brief case presentation of special interest in the form of a Letter to the Editors will also be considered for publication. All such letters should be sent to Dr. Zuspan.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie.

Reprints. Reprints of articles must be ordered from the Publishers, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63141, who will send their schedule of prices. Individual reprints of an article must be obtained through the author.

How to determine fetal well-being, accurately, in your office.

For the first time, you can perform fetal non-stress testing (NST) conveniently and safely in the privacy of your office, with the Corometrics 110 Antepartum Monitor. Think of it—a test location reassuring to your patient and a modality far easier and less costly than the oxytocin challenge test.



Convenience for you and your patient. The 110 frees you from battling testing schedules and eliminates waiting for data to arrive—the average test lasts 12 minutes. Included as a regular part of your prenatal care program, the 110 can economically and reliably help you provide better patient care.

NST—a noninvasive, efficient and reliable test method. The Corometrics 110 monitors FHR accelerations, associated with fetal movement, which indicate fetal well-being. Non-stress testing is comfortable for both mother and fetus. A reactive NST pattern demonstrates fetal well-being more reliably than any other test.*

The Corometrics 110 Antepartum Monitor. It adds a more personal touch to your practice. For more information, contact: Corometrics Medical Systems, Inc., 61 Barnes Park Road North, Wallingford, Connecticut U.S.A. 06492, (203) 265-5631.

**Routine Fetal Heart Rate Monitoring in the Antepartum Period*—Barry S. Schifrin, Gerard Foye, Jack Amato, Richard Kates & Jarleth McKenna. Presented at the District VIII Meeting ACOG, Honolulu, October 10, 1978. Accepted for publication—Obstetrics and Gynecology.

"Nonspecific" vaginitis is often masked
"Nonspecific" vaginitis
...Often masked by previsit and routine douches, candidiasis and trichomoniasis.[1]
...Often chronic—in a recent clinical study of 5,000 consecutive cases of chronic vaginitis, the chief cause was undiagnosed H. vaginalis vaginitis, followed by candidiasis and trichomoniasis.[1]
1. Fleury, F.J.: Obstet. Gynecol. News 12:1,25, Aug. 15, 1977.
2. Gardner, H.L., and Kaufman, R.H.: Benign Diseases of the Vulva and Vagina, St. Louis, The C.V. Mosby Company, 1969, p. 191.

When you unmask "nonspecific" vaginitis you may find H. vaginalis

Sultrin
TRADEMARK

Triple Sulfa Cream/Vaginal Tablets

effective against H.vaginalis— the cause of over 90% of "nonspecific" vaginitis[2]

Effective
Based on a review by the National Academy of Sciences/National Research Council, SULTRIN was rated as "effective" against *H. vaginalis.*

Prompt symptomatic relief
Patients can experience relief of embarrassing itching and malodorous discharge. Within the same time, most patients can also achieve marked clinical improvement.

Versatile adjunct in other vaginitides
SULTRIN is also effective in treating H.V. vaginitis concomitant with trichomoniasis and candidiasis.

Convenient choice of dosage forms
SULTRIN comes as a soothing, nonstaining and esthetically pleasing cream or convenient vaginal tablets.

Composition: SULTRIN Cream contains sulfathiazole 3.42%, sulfacetamide 2.86%, sulfabenzamide 3.7%, and urea 0.64%. Each SULTRIN Tablet contains sulfathiazole 172.5 mg, sulfacetamide 143.75 mg, and sulfabenzamide 184.0 mg.

Indications: SULTRIN Cream and Tablets are indicated for treatment of *Haemophilus vaginalis* vaginitis. They may also be used as a deodorant for saprophytic infection following radiation therapy.

Contraindications: Sulfonamide sensitivity and kidney disease.

Dosage: SULTRIN Cream: One applicatorful intravaginally twice daily for 4 to 6 days. The dosage may then be reduced one-half to one-quarter.
SULTRIN Tablets: One tablet intravaginally before retiring and again in the morning for ten days. This course may be repeated if necessary.

Supplied: SULTRIN Cream is available in 2.75 oz. (78 g) tubes with the ORTHO* Measured-Dose Applicator.
SULTRIN Tablets are available in packages of 20 foil-wrapped tablets with vaginal applicator.

The progestogen in oral contraceptives: But certainly

Norgestrel, the progestogen that distinguishes Ovral and Lo/Ovral.

Today, many physicians are concerned about choosing a suitable estrogen level for their oral contraceptive patients.

The effects of any combination oral contraceptive, however, are largely the result of the synergistic activity between estrogen and progestogen. So it seems wise to choose the progestogen carefully, too.

Norgestrel, the progestogen in Ovral and Lo/Ovral, has many properties worth examining.

Distinctive because it is non-estrogenic and does not add estrogen. Unlike other progestogens in current use, norgestrel has been shown in biological assays to be free from inherent estrogenicity and does not convert to estrogen *in vivo*. So the delicate estrogen-progestogen balance in Ovral and Lo/Ovral remains undisturbed.

It helps maintain a sound endometrium in combination with ethinyl estradiol. Even at very low doses, norgestrel demonstrates a pronounced ability to help support the integrity of the endometrium—a primary function of progestogen in oral contraceptives.

A highly effective estrogen antagonist. Norgestrel displays marked anti-estrogenic activity at the cervical level. It thickens the cervical mucus during the 3-week cycle of therapy and may therefore act as a secondary contraceptive mechanism.

Norgestrel and ethinyl estradiol: together they usually mean patient confidence, comfort and compliance. In separate clinical trials, overall effectiveness with Ovral over an 8 year period was 99.3 percent; with Lo/Ovral over a 4 year period, 99.7 percent.[1] Both Ovral and Lo/Ovral also offered excellent cycle control and a minimum of common side effects.* The drop-out rate due to breakthrough bleeding for Ovral was only 0.5 percent; for Lo/Ovral, only 1.4 percent.
50 mcg Ovral® and 30 mcg Lo/Ovral®: distinguished by norgestrel.

*Serious as well as minor adverse reactions have been reported following the use of all oral contraceptives. The physician should remain alert to their earliest manifestations and in the event of serious adverse reactions, should avoid any oral contraceptives. Contraindications, Warnings, Precautions, Adverse Reactions, etc. in the accompanying IN BRIEF should be carefully considered.

1. Based on life table method.

See important information on following page.

Wyeth Laboratories
Philadelphia, Pa. 19101

OVRAL®
Each tablet contains 0.5 mg norgestrel with 0.05 mg ethinyl estradiol.

LO/OVRAL®
Each tablet contains 0.3 mg norgestrel with 0.03 mg ethinyl estradiol.

Copyright© 1979, Wyeth Laboratories Div. of AHPC, N.Y., N.Y. All rights reserved.

IN BRIEF:

Indications and Usage—OVRAL® and LO/OVRAL® are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OC's) as a method of contraception.

Contraindications—OC's should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5).

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gall bladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with use of OC's is well-established. Three principal studies in Great Britain and 3 in the U.S. have demonstrated increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OC's are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION (MI)—An increased risk of MI associated with use of OC's has been reported, confirming a previously suspected association. These studies, conducted in the UK, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing MI, regardless of whether the patient was an OC user or not. OC's, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to MI) are about twice as likely to have a fatal MI as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal MI compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, amount of smoking is also an important factor. In determining importance of these relative risks, however, baseline rates for various age groups must be given serious consideration. Importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; quite likely the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse-reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to dose of estrogen in OC's. Preparations containing 100 mcg or more of estrogen were associated with higher risk of thromboembolism than those containing 50-80 mcg. Their analysis did suggest, however, that quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the U.S.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the UK estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OC's according to age, smoking habits, and duration of use. Overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), risk being concentrated in older women, in those with long duration of use, and in cigarette smokers. It was not possible, however, to examine interrelationships of age, smoking, and duration of use, nor to compare effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess magnitude of relative risk for this younger group.

Available data from a variety of sources have been analyzed to estimate risk of death associated with various methods of contraception. Estimates of risk of death for each method include combined risk of contraceptive method (e.g. thromboembolic and thrombotic disease in the case of OC's) plus risk attributable to pregnancy or abortion in event of method failure. This latter risk varies with effectiveness of method. The study concluded that mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OC's in women over 40 who smoke. Lowest mortality is associated with condom or diaphragm backed up by early abortion. Risk of thromboembolic and thrombotic disease associated with OC's increases with age after about 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia, and especially cigarette smoking.

Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A 4- to 6-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OC's should be discontinued at least 4 weeks before surgery of a type associated with increased risk of thromboembolism or prolonged immobilization.

2. *Ocular Lesions*—There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with use of OC's. Discontinue OC's if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma*—Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in OC's, have been noted to increase incidence of mammary nodules, benign and malignant, in dogs. In humans, 3 case-control studies have reported an increased risk of endometrial carcinoma associated with prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OC's. Of cases found in women without predisposing risk factors (e.g., irregular bleeding at the time OC's were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These are no longer marketed. No evidence has been reported suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only OC's. Several studies have found no increase in breast cancer in women taking OC's or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women on OC's, found an excess risk in subgroups of OC users with documented benign breast disease. Reduced occurrence of benign breast tumors in users of OC's has been well-documented. In summary, there is at present no confirmed evidence from human studies of increased risk of cancer associated with OC's. Close clinical surveillance of all women on OC's is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms should be monitored with particular care if they elect to use OC's.

4. *Hepatic Tumors*—Benign hepatic adenomas have been found to be associated with use of OC's. One study showed that OC's with high hormonal potency were associated with higher risk than lower potency OC's. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users. Two studies relate risk with duration of use of OC's, the risk being much greater after 4 or more years' use. While hepatic adenoma is rare, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women on OC's. Relationship of these drugs to this type of malignancy is not known.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring*—Use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have increased risk of developing in later life a form of vaginal or cervical cancer ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence now that OC's further enhance risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OC's. Furthermore, 30 to 90% of such exposed women have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with use of other estrogens, it cannot be presumed they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with use of sex hormones, including OC's, in pregnancy. One case-control study estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OC's, hormonal withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some exposures involved only a few days. Data suggest that risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OC's. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OC's is unknown. It is recommended that, for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing OC's. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at time of first missed period, and further use of OC's should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and advisability of continuation of the pregnancy should be discussed. It is also recommended that women who discontinue OC's with intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this. The administration of progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease*—Studies report increased risk of surgically confirmed gallbladder disease in users of OC's and estrogens. In one study, increased risk appeared after 2 years' use and doubled after 4 or 5 years' use. In one of the other studies, increased risk was apparent between 6 and 12 months' use.

7. *Carbohydrate and Lipid Metabolic Effects*—Decrease in glucose tolerance has been observed in a significant percentage of patients on OC's. For this reason, prediabetic and diabetic patients should be carefully observed while on OC's. Increase in triglycerides and total phospholipids has been observed in patients on OC's; clinical significance of this finding remains to be defined.

8. *Elevated Blood Pressure*—Increase in blood pressure has been reported in patients on OC's. In some women, hypertension may occur within a few months of beginning OC's. In the 1st year of use, prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. Prevalence in users increases, however, with longer exposure, and in the 5th year of use is 2½ to 3 times the reported prevalence in the 1st year. Age is also strongly correlated with development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure on OC's. Hypertension that develops as a result of taking OC's usually returns to normal after discontinuing the drug.

9. *Headache*—Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of OC's and evaluation of the cause.

10. *Bleeding Irregularities*—Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing OC's. In breakthrough bleeding, as in all cases of irregular vaginal bleeding, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another OC may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase risk of thromboembolic disease.

Women with past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuing OC's. Women with these preexisting problems should be advised of this possibility and encouraged to use other methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy*—Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding*—OC's given in the postpartum period may interfere with lactation and decrease quantity and quality of breast milk. Furthermore, a small fraction of the hormones in OC's has been identified in the milk of mothers on OC's; effects, if any, on the breast-fed child have not been determined. If feasible, defer OC's until infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OC's. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Pap smear and relevant laboratory tests. As a general rule OC's should not be prescribed for longer than 1 year without another physical examination.

2. Under influence of estrogen-progestogen preparations, pre-existing uterine leiomyomata may increase in size.

3. Patients with history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while on OC's should stop OC's and use an alternate method to try to determine whether the symptom is drug-related.

4. OC's may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency.

5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while on OC's. If jaundice develops, OC's should be discontinued.

6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution.

7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. Clinical significance is undetermined.

8. Serum folate levels may be depressed by OC's. Since the pregnant woman is predisposed to development of folate deficiency and incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OC's, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency.

9. The pathologist should be advised of OC therapy when relevant specimens are submitted.

10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OC's: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling.

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and ampicillin.

Carcinogenesis—See Warnings on carcinogenic potential of OC's.

Pregnancy—Category X. See Contraindications, Warnings.

Nursing Mothers—See Warnings.

Adverse Reactions—An increased risk of these serious adverse reactions has been associated with use of OC's (see Warnings): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies. There is evidence of an association between the following conditions and use of OC's although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients on OC's and are believed to be drug-related. Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea, amenorrhea during and after treatment, temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement, and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening), intolerance to contact lenses.

The following adverse reactions have been reported in users of OC's, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OC's by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

OBSTETRICS

Induction of labor following intrauterine death with intra-amniotic hyperosmolar urea and prostaglandin $F_{2\alpha}$: Evaluation of placental endocrine function and changes in coagulation parameters

G. SHER, F.A.C.O.G., M.R.C.O.G. (LOND.), F.C.O.G. (S.AFR.)

Chapel Hill, North Carolina

A practicable and reliable method for inducing labor in patients whose pregnancies are complicated by intrauterine death of the fetus is described. The method involves the intra-amniotic instillation of 30 mg of prostaglandin $F_{2\alpha}$ with 60 gm of urea. Twenty patients had pregnancies ranging between 22 and 41 weeks and the estimated duration of fetal death ranged between two and eight weeks. Delivery was achieved within 24 hours in all cases. Side effects and complications were minimal. Plasma human placental lactogen (hPL) and progesterone concentrations, as well as several blood coagulation parameters (i.e., plasma fibrinogen, blood platelet count, and serum fibrin degradation products (FDP) concentrations), were measured immediately prior to induction of labor. The latter (i.e., coagulation factors) were repeated at parturition. The presence of residual viable placenta prior to induction did not influence the induction-delivery interval. No statistically significant alterations in blood coagulation parameters that could be attributed to the specific method of induction employed were noted. (AM. J. OBSTET. GYNECOL. 134:493, 1979.)

IN MOST CASES, spontaneous labor and delivery follow within about two weeks of intrauterine death of the fetus.[1] In the event that this fails to occur, the obstetrician is often faced with the decision of whether or not to induce labor and thereby expedite delivery. The psychological distress to which a mother carrying a dead fetus is subjected, coupled with a time-related risk of the development of disseminated intravascular coagulation (DIC)[2, 3] makes urgent delivery not only desirous but, on occasion, imperative. The introduction of prostaglandins and their subsequent application (via the intravenous,[4, 5] intra-amniotic,[6] intrauterine–extra-amniotic,[3] and vaginal[6, 7] routes) for the management of pregnancies complicated by intrauterine death of the fetus heralded a new era in the treatment of this condition.

In 1976, the author reported on the management of 14 pregnancies (ranging between 17 and 35 weeks ges-

tation) complicated by intrauterine death of the fetus that were managed by a single amniotic injection of 30 mg of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) and 60 gm of urea. Delivery resulted within 17 hours in all cases.[8] Complications were rare.

This larger study was undertaken in an effort to support the previous findings and to ascertain the extent to which this form of management would influence major blood coagulation parameters (i.e., plasma fibrinogen concentration, blood platelet count, and serum fibrin degradation products (FDP) concentrations) and the extent to which residual placental survival (evaluated by the measurement of plasma human placental lactogen [hPL] and progesterone concentrations) would influence induction-delivery interval in pregnancies complicated by intrauterine death of the fetus managed with intra-amniotic urea and prostaglandin. The study was conducted at the Groote Schuur Hospital, which is the teaching institution of the University of Cape Town School of Medicine, South Africa.

Patients, methods, and materials

Twenty patients with intrauterine death of the fetus were investigated. Death was diagnosed by clinical signs and symptoms and confirmed radiologically and/or by ultrasound examination. All fetuses were judged to have been dead for longer than 2 weeks. Details of each patient are presented in Table I.

Plasma concentrations of hPL and progesterone were measured immediately prior to commencing the intra-amniotic infusion of urea and $PGF_{2\alpha}$. Plasma fibrinogen concentrations (measured by the Haanen method[9, 10]), blood platelet count, (in parallel on the Coulter counter), and serum FDP (measured by hemagglutination inhibition) were measured in specimens of blood obtained both prior to induction and at the time of delivery (Table I). All patients were premedicated with diazepam. The abdomen was prepared as for a routine amniocentesis, using a strictly aseptic technique. A selected area of skin was infiltrated with 10 ml of a 1% Xylocaine solution. Thereafter, a No. 18 Tuohy needle was introduced transabdominally into the uterine cavity. About 100 ml of amniotic fluid was drained off, whereupon an epidural catheter was introduced into the amniotic sac through the Tuohy needle. Subsequent aspiration of amniotic fluid through the cannula reconfirmed its correct location. Sixty grams of urea, dissolved in 70 ml of normal saline solution, was introduced under pressure into the amni-

otic sac through the catheter. This was followed by the injection of a broad-spectrum antibiotic (usually 500 mg of ampicillin) via the same route. A test dose of 5 mg of $PGF_{2\alpha}$ was then injected, followed in five minutes by 25 mg of $PGF_{2\alpha}$, if no side effects occurred. The catheter was then removed and a dressing was applied to the puncture site.

Results

All patients were delivered within 24 hours of commencing the procedure (the mean induction-delivery interval was 13.2 hours). One patient (Case 3), who exhibited evidence of DIC and secondary hyperfibrinolysis, received augmentation of an intravenous infusion of oxytocin (5 Mu/min) for a period of four hours.

Only 4 of the 20 patients had received prenatal care. Fifteen fetal deaths presumably occurred during the third trimester. The estimated duration of fetal death was greater than 28 days in three patients (Cases 3, 7, and 11). In only 50% of cases could a probable cause of intrauterine death be determined.

The following complications could be attributed to the method of induction employed:

1. *Nausea and/or vomiting and/or diarrhea.* Three patients had these complications (Cases 5, 9, 17).
2. *Postpartum hemorrhage.* Two patients had postpartum hemorrhage (Cases 1 and 3). In Case 1, the hemorrhage was due to retention of part of the placenta following delivery. Case 3 had a postpartum hemorrhage due to persistent uterine atony and an associated coagulopathy.
3. *Retention of the placenta.* Two patients had partial or complete retention of their placentas. In Case 1, as described previously, partial retention of the placenta was associated with postpartum hemorrhage. In Case 15, no postpartum hemorrhage occurred, but manual removal of the placenta was necessary.
4. *Transient pyrexia.* Cases 14 and 18 experienced transient pyrexia (less than 38° C) which resolved spontaneously within 24 hours without prompting the use of antibiotics.

The results of plasma fibrinogen, serum FDP, and platelet count measurements, immediately prior to induction and at the time of delivery, follow: no statistically or clinically significant alteration occurred in plasma fibrinogen or blood platelet counts during induction and delivery, and in most patients FDP concentrations increased during labor. This is in consonance with the "physiologic" effect known to occur in labor.

Plasma hPL and progesterone concentrations prior to induction indicated a functional placenta in 12 of the 20 patients studied (Cases 1-6, 8, 9, 14, 15, 17 and 19).

Induction to abortion time was similar in those patients with a nonfunctional placenta (14.0 hours) to those with evidence of residual functional placenta (12.3 hours). The patient with DIC appeared to have a functional placenta. Concentrations and changes in fibrin degradation products were similar in patients with and without functional placentas (Table I).

Comment

In the past, difficulties associated with achieving successful induction of labor in patients with prolonged intrauterine death of the fetus led many obstetricians to favor an expectant approach to management. In most instances, the patient was given psychological support and was assured that labor would ultimately ensue. Apart from the mental anguish experienced by such patients, there was a risk that when a dead fetus was retained in utero for longer than 4 weeks, 25% would develop DIC.[11, 12] These considerations prompted efforts aimed at inducing labor in patients whose pregnancies were so complicated. The realization that amniotomy carries a high risk of aerobic and anaerobic infection[13] and that the infusion of oxytocin is often unsuccessful in pregnancies complicated by fetal death prompted attempts to sensitize the uterus with quinine and/or estrogens[14] prior to induction of labor with oxytocin. Although intra-amniotic hypertonic saline was advocated for the management of pregnancies complicated by fetal death, this method was associated with the development of severe DIC and hyper-natremia.

The intra-amniotic instillation of $PGF_{2\alpha}$ in combination with urea is not associated with an escalation of DIC. Neither does the induction-delivery interval appear to be influenced by the presence of residual functional placental tissue. The one patient who had DIC had the syndrome prior to induction. There were no significant changes in plasma fibrinogen concentrations, blood platelet counts, or serum FDP concentrations over the induction period. And there was no difference in the value of these blood coagulation parameters between the patients with or without evidence of functional residual placenta. The induction to abortion time, complications, and side effects were similar in patients with evidence of functional placenta and those without such evidence. The method, which requires only a single intra-amniotic instillation, appears to be both practicable and highly reliable.

As mentioned earlier, prostaglandins have effectively been administered via the intravenous, intrauterine extraovular, intra-amniotic, and vaginal routes.[3, 5–7] The intrauterine extraovular method is effective but is associated with a relatively high complication rate. This limits the clinical applicability of this method. Appropriate doses of intra-amniotic prostaglandin result in satisfactory abortion rates and a clinically acceptable incidence of side effects. However, the concomitant use of urea permits one to use a lower dose of $PGF_{2\alpha}$ and eliminates the need for repeated intra-amniotic instillations, while the same degree of effectiveness is achieved in association with a low complication rate. Although vaginal administration is convenient, absorption is inconsistent and overt vaginal bleeding often occurs. The convenience of the vaginal route of administration does, however, warrant further investigation into this method of management.

A special protective problem that may occur with the use of urea and prostaglandin $F_{2\alpha}$ in this setting is the occurrence of hypertonic injury when the urea is inadvertently injected into tissue such as the myometrium. This can be avoided by paying meticulous attention to suggested technique, i.e., withdrawal of amniotic fluid prior to injection of urea and prostaglandin and the injection of these agents via a correctly placed polythene catheter that will not be displaced by uterine contractions.

DIC and secondary hyperfibrinolysis have been shown to be associated with a degree of uterine atony that is relatively resistant to oxytocics and results in postpartum hemorrhage[16] (Case 3). Likewise, patients with severe abruptio placentae associated with serum FDP concentrations in excess of 320 μg/ml have been shown to experience severe antepartum uterine atony that is refractory to oxytocin infusion.[17]

The assistance of Dr. M. Katz (Department of Gynecologic Endocrinology-University of Cape Town), Dr. P. Jacobs (Department of Hematology-University of Cape Town), and Dr. W. Brenner (Department of Obstetrics and Gynecology-University of North Carolina School of Medicine) is acknowledged.

Information for authors

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. Therefore, all manuscripts must be accompanied by the following written statement, signed by one author: "The undersigned author transfers all copyright ownership of the manuscript (title of article) to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

Sexual behavior and response in relation to complications of pregnancy

RICHARD P. PERKINS, M.D.
Albuquerque, New Mexico

A detailed written questionnaire survey of 155 puerperas is reviewed. Sexual and obstetric data were examined for possible associations leading to premature or low-birth-weight infants. Among 25 patients delivering premature infants (16 with babies weighing less than 2,500 grams), no significant association could be made between coitus, orgasm, and/or other sexual experiences and the proximity to the onset of labor. Orgasmic patients appeared to have a consistently lower percentage of early deliveries. No particular method of sexual gratification was unique except that masturbation was consistently associated with a lower risk of prematurity throughout various stages of gestation. Speculations are advanced to explain these observations. Sexual activity appears to be safe throughout pregnancy in almost all patients. Ruptured membranes on admission may be associated with recent sexual stimulation without orgasm. (AM. J. OBSTET. GYNECOL. 134:498, 1979.)

IT IS a prevalent opinion that sexual behavior and response during pregnancy may in some way be related to certain untoward gestational complications. Data to substantiate this opinion are scanty and inferential. As yet, no prospective study has been published which is designed to address and resolve this issue. Most standard texts and (we suspect) most physicians confronting these issues are silent or skeptical regarding the safety of normal sexual activity in pregnancy, particularly in the latter weeks or in situations where an increased risk of premature delivery is recognized.

Previous reports attempting to address this issue have dealt with the recognized association between orgasmic response and uterine contractility,[1] or have attempted to show heightened sexual behavior and response in patients ultimately delivering premature infants.[2] The matter of the association between sexual activity and spontaneous rupture of membranes has been suspected by many, but no reports attempting to resolve this issue have appeared.

In an attempt to shed a little more light on this important but poorly explored area of human behavior, relevant portions of a large study recently completed on sexual behavior and pregnancy were reviewed. A highly detailed analysis of the study as a whole is in preparation and will be extensively reported later.

Material and methods

The study was conducted over a brief time period on the postpartum unit at the University of Colorado Medical Center in late 1976. An elaborate questionnaire was distributed to the patients in order to study many aspects of their personal and sexual lives before and during pregnancy. All patients were invited to participate in the study, and only those who were physically unable to contribute or who were non-English speaking were excluded. The questionnaire was explained to the patients and the terminology made clear to avoid confusions in interpretation. The patients were assured of anonymity and that they would not be questioned further regarding the particulars of their responses except if they wished further investigation. The questionnaire was administered by a female professional skilled in psychological techniques and interpersonal relationships. Obstetric data was added from the mothers' and babies' charts prior to removal of the identifying cover sheet. Results were then coded and subjected to statistical analysis.

A total of 190 questionnaires were distributed. Twenty-four patients declined to participate. Some of these patients discarded their questionnaires and

0002-9378/79/130498+08$00.80/0 © 1979 The C. V. Mosby Co.

others completed only nonsensitive portions. A total of 172 questionnaires were available for review at the conclusion of the study and, of these, 17 were sufficiently incomplete to preclude useful data analysis. The remaining 155 questionnaires were subjected to analysis.

The ages of the respondents varied widely. Of those studied, one was less than 16 years of age. Of the remainder, 61 were age 16 to 20, 56 were age 21 to 25, 33 were age 26 to 35, and 4 were over 35. A total of 97 (62.6%) listed their occupation as "housewife," 11 (7.1%) as "student," 18 (11.6%) as "full-time employed," 13 (8.4%) as "part-time employed," and 16 (10.3%) as "unemployed."

Fifty-one patients (32.9%) were in their first pregnancy. In addition, 78 (50.3%) had never experienced a prior viable birth.

Racial distribution of the population was as follows: black—14 (9.0%), Chicano (Mexican-American)—19 (12.3%), white—120 (77.4%), and "other"—2 (1.3%).

Forty-one (26.5%) listed their religion as Catholic, 2 (1.3%) as Jewish, 73 (47.1%) as Protestant, 27 (17.4%) as "no preference," and 10 (6.5%) as "other."

With regard to marital status, 117 (75.5%) described themselves as married, 18 (11.6%) as single, 7 (4.5%) as divorced or separated, and 13 (8.4%) as "common law" status.

By education background, 3 (1.9%) had received no more than an eighth grade education. One hundred twelve (72.3%) had completed some or all of a high school education, and 39 (25.2%) had been educated beyond the high school level.

In surveying the sexual status of the population, many aspects of sexual behavior and response before and during pregnancy were studied. Patients were asked to characterize the frequency of utilization of seven major sexual behavior patterns before pregnancy, during the first three months, during the middle of pregnancy, and during the last two months. These behavior patterns were: intercourse with simultaneous genital stimulation by the partner, intercourse with simultaneous self-stimulation, intercourse alone, noncoital genital stimulation by partner's hand, noncoital genital stimulation by partner's mouth or tongue, "other" noncoital genital stimulation, and masturbation (characterized as self-stimulation with partner absent, to mitigate negative responses to the emotionally charged terminology). Patients were asked to provide some response to the utilization of each technique from 0 to 100% of the times sexual stimulation occurred.

In addition to the above, patients were asked to indicate in each case whether or not orgasm occurred at least 50% of the times such stimulation was experienced. By this means, the frequency of orgasmic response to various techniques could be determined in addition to the frequency of utilization of various techniques before and throughout pregnancy.

Other relevant determinations subjected to analysis for the purposes of this report included the incidence of rupture of membranes prior to admission to the hospital (whether or not the patient was in labor), the time interval between the patient's last sexual experience and the onset of labor, the incidence of prematurity (defined as the birth of an infant determined to be less than 38 weeks gestational age), and the incidence of low-birth weight infants (less than 2,500 grams).

In order to determine the relative incidence of the production of perceptible uterine irritability by various sexual events, the patients were asked to characterize the association between uterine contractions at various stages of pregnancy and coitus with orgasm, coitus without orgasm, orgasm without associated coitus, and other sexual stimulation without orgasmic response. By this means, it was hoped that the relative contributions of coital stimulation, noncoital stimulation, and orgasm to the production of perceptible uterine activity could be ascertained.

All data derived were subjected to analysis through the Statistical Package for the Social Sciences, utilizing modified chi-square differentiations.

Results

Since some patients did not respond to each and every question asked, evaluation will be limited to those patients in whom a response was available. After careful analysis of the frequency of events among nonresponders it was determined to our satisfaction that missing responses, even were they to occur in incriminating categories, would not change the overall results or conclusions significantly.

A total of 13 patients (8.4%) had never been orgasmic. These patients will therefore be consistently included in the nonorgasm study group. The distributions of these patients were as follows: black—4/14, Chicano—2/19, white—7/119; Catholic—2/41, Protestant—7/73, "no preference"—4/27; age 16 to 20—10/61, age 21 to 25—2/55, age 26 to 35—1/33; married—8/123, unmarried—5/31; high school education—12/111, beyond high school—1/39. These differences were found not to be of major statistical significance and not important in relation to other data to be reported below.

Sex and onset of labor. Of the total population, 20 patients reported the onset of labor within 24 hours of their last sexual experience (regardless of its nature)

Table I. Correlation of events with time of labor onset after last sexual experience

	Interval			
	No data	*<24 hr.*	*>24 hr.*	*p*
Membranes on admission:				
Ruptured	5	8	34	NS

Premature rupture	0	17	<0.05
No premature rupture	8	24	
No orgasm occurred:			
Premature rupture	8	17	<0.005
No premature rupture	3	49	
p_2	<0.005	NS	

p_1 = Variables of interval to labor onset and ruptured membranes.

p_2 = Variables of habits or orgasmic response and ruptured membranes.

Of the remainder, 30 patients reported either no sexual experience within two months of delivery or did not respond to the question. One hundred four patients had had at least one sexual experience between 24 hours and 60 days from the onset of labor, and these were relatively uniformly distributed.

Since it seemed unreasonable to assume an association between sexual stimulation and the onset of labor if the interval exceeded 24 hours, the population was then studied in relation to labor onset before and after the 24 hour period. The response to the sexual stimulation last experienced was related to the time of labor onset as was the presence or absence of an association

Table III. Orgasmic response by stages of pregnancy, habits, and incidence of premature delivery (orgasmic women only)

with premature rupture of membranes (defined as rupture prior to hospital admission) and gestational age and weight at delivery. The results are shown in Table I.

It can be seen that there is no association between the interval between the last experience and the onset of labor and the status of the membranes on admission with the presence or absence of orgasmic response with that experience or with birthweight. An association is noted between the gestational age at delivery and the proximity of the last experience to labor onset. The significance of this will be discussed later.

Table II explores the association of these various events with each other. It can be seen from this display that (as shown by p_1) there is no statistical difference among those experiencing coitus and noncoital sexual stimulation and the incidence of premature membrane rupture among those experiencing labor onset before and after 24 hours. As shown by p_2, there is also no difference among those with labor onset within and after 24 hours and the incidence of ruptured membranes between those experiencing coitus and noncoital stimulation.

As is also shown in Table II, there is a significant ($p < 0.05$) difference in the incidence of membrane rupture prior to admission among those experiencing orgasm during their last sexual exposure when such exposure occurred more than 24 hours prior to the onset of labor when compared with those experiencing onset less than 24 hours (there being no patient admitted with premature ruptured membranes and a sexual interval less than 24 hours who had experienced orgasm with that event). Among those who did *not* experience orgasm with their last experience, however, a significantly greater number ($p < 0.005$) were admitted with ruptured membranes if their last experience had been less than 24 hours prior to labor onset than those with stimulation occurring more than 24 hours before labor. In addition, among those who labored within 24 hours of their last experience, a significantly greater number ($p < 0.005$) were admitted with ruptured membranes if orgasm had *not* occurred than if it had. The difference among those with labor onset greater than 24 hours after their last experience was not significant.

When the population was studied by the presence or absence of a prior birth, no differences were noted in the incidences or significances of these various comparisons.

Among the total population, 34 patients claimed at some time to have prevented orgasm. Of these, 21 claimed this in the last two months due to: fear of hurting baby (8), fear of starting labor (2), told not to have sex or orgasm (7), orgasm was painful (5), "other" reasons (4).

Prematurity and sexual behavior. Since the population was given identical choices to describe various sexual techniques and response throughout various stages of pregnancy, it was possible to follow the trends of behavior and responsiveness throughout the various stages and to explore the possible association between these patterns and the production of a premature infant. Of the total population, 27 patients (17.4%) produced an infant assessed at less than 38 weeks gestational age. Data on 25 patients were complete enough for study. Utilizing this information, and studying only women with orgasmic performance in the past, the association between orgasm by various types of stimulation and the incidence of prematurity is shown in Table III.

It can be seen from this display that the incidence of the utilization of all techniques of stimulation declines throughout pregnancy. It will also be seen, however, that at all stages of pregnancy there is either no association between orgasmic response (>50% of the time) and the production of a premature infant or that when such association exists, the incidence is significantly lower among orgasmic than among nonorgasmic mothers. Although in most cases numbers are quite small, it is presumed that were there a consistent cause-and-effect relationship between orgasmic response and the production of premature labor, the differences demonstrated would at least have been in the nature of a

Table VI. Association of habits and response with perceived uterine contractions at various stages of pregnancy

Behavior and response	*Contractions noted (%)*			*None (%)*
	First 3 mo.	*Middle*	*Last 2 mo.*	
Coitus and orgasm	10.4	10.4	16.3	70.1
Coitus, no orgasm	2.0	9.0	13.5	78.1
Orgasm, no coitus	3.2	7.1	12.3	82.5
No orgasm, other stimulation	1.3	3.2	9.0	88.4

Approximate percentage contributions of various stimuli to uterine contractions in last two months, from data above: coitus, 4.5%; orgasm, 3.0%; sexual arousal, per se (includes natural uterine irritability, unknown quantity), 9.0%.

trend toward an association between orgasm and prematurity. If anything, the trend is clearly away from such an association. The percentages displayed are those of the incidence of prematurity within that patient group. Even such a potent stimulus as masturbation (presumably clitoral in most cases), which is acknowledged to produce the most intense physical response,[3] showed no association with prematurity. The relative decline in such behavior in the population was less than that of other techniques.

Table IV illustrates prematurity rates (in patient numbers) by sexual habits used in the last two months of pregnancy. It can be seen that there are no significant differences in incidences of prematurity as related to the utilization or nonutilization of the various techniques. Table V further explores orgasmic response in relation to these factors and their relationship to sexual habits. Again, no significant associations between orgasmic response and the production of premature infants can be seen, with the exception that a significantly greater percentage of patients who are orgasmic with masturbation were delivered of mature infants when compared with those delivered of premature infants. Incidentally noted, but not surprising to those understanding female sexuality, a significant percentage of women in the study engaged in masturbation without the achievement of orgasm. By standards traditionally applied to the male, some might find this surprising. Patients orgasmic with masturbation actually were delivered of a significantly greater number of term infants than were women not orgasmic by this method.

Sexual habits and response were also explored in relation to their possible association with the production of low-birth weight infants. Although this bears considerable relation to prematurity, a possible association between sexual response and the production of growth retardation is also implied. Table IV also illustrates the

relative numbers of patients delivering babies weighing less than 2,500 grams in relation to various sexual habits throughout pregnancy. It will be seen that there is no statistical difference in the incidence of the utilization of various techniques and birth weight by these two standards. Table V further illustrates a lack of association between orgasmic response and the production of low–birth weight infants, with a borderline significant association between orgasm with masturbation and ostensibly normally grown babies. There appears clearly to be no association established between sexual techniques, responsiveness, and apparent normal growth.

Sexual behavior and uterine contractility. Table VI illustrates patient responses to the inquiry regarding the association between sexual behavior and perceived uterine contractions. It can be seen that throughout pregnancy, coitus with orgasm was more often associated with perceived uterine contractions at various stages than with other stimuli. It will also be seen that in the last two months, the uterus appeared more intrinsically irritable to stimuli of all sorts. Since 9.0% of patients perceived uterine contractions in association with sexual stimulation other than coitus but without orgasmic response, this was felt to represent an association with sexual arousal in a nonspecific sense, and to include coincidental uterine irritability perceived by the patient as associated with this behavior. Utilizing this assumption and using the exclusion of either coitus or orgasm by the other descriptive categories, one can derive a tenuous mathematical presumption regarding the contribution of coitus, orgasm, and baseline sexual arousal (including intrinsic uterine irritability) upon the incidence of perceived uterine contractions among respondents in the last two months. These are shown also in Table VI. If these assumptions bear any relationship to fact, coitus would then appear to consitute a stronger stimulus to uterine contractions than orgasm.

When the population is viewed by age, prior pregnancies, and prior births, no significant differences in intrinsic uterine irritability by any of these factors were noted; in general, however, parous patients perceived a greater incidence of uterine irritability than nulliparous patients. Because of the design of this questionnaire, however, it was impossible to distinguish nonresponders from those who did not experience contractile responses.

Comment

Because of the small numbers involved in the study, it is not intended that persuasive conclusions be drawn from the information presented. The study, however, does not suffer from the same potential for criticism to which similar studies in the past might be subjected. The population was selected without regard to obstetric data and control subjects used were not retrospectively matched. No confrontation interviewing was used, and answers therefore are assumed to be fairly frank and honest.

Goodlin[4] has been a proponent of the concept that orgasmic response and premature labor may be linked. In a later retrospective study,[5] he attempted to support the concept by noting an increased frequency of orgasm among patients who were delivered of premature infants compared with those delivered at term. After recognizing that the two groups were in some ways not comparable, in that the premature group was shown to be at greatly increased risk on the basis of a priór preterm delivery incidence three times that of the control subjects, the authors concluded that the effects were "additive." This mathematical speculation is unsupported. Noting that orgasmic frequencies were higher "after 32 weeks gestation" in the group delivering prematurely, they failed to recognize that, *at the same stage,* similar rates might have been found among the control subjects. The choice of a study interval of 50 hours from orgasm to the onset of labor raises questions regarding the reasons for the choice of this unlikely number and what advantage it played in fostering the premise.

Wagner and associates[2] studied a group of patients delivering prematurely out of a larger study with a format similar to ours. The use of a small number of "matched" control subjects appeared to show a greater degree of orgasmic activity among the prematurely delivering mothers at all stages of pregnancy; but when compared with the entire population, the differences were minimal, and the population as a whole was far from representative, being primarily white, married, and privileged. In all studies, also, it is hard to know how much "heightened consciousness" may be operating among mothers of threatened premature newborn infants, because self-scrutiny as to possible connections between their behavior and the unfortunate outcome is common.

The information from this study fails to establish any convincing connection between sexual habits with or without orgasmic response and such adverse obstetric events as premature labor, premature rupture of membranes, or low–birth weight infants. Although a significant association exists between a last sexual experience less than 24 hours prior to labor onset and delivery of an infant less than 38 weeks' gestational age, no association can be established with orgasmic response and rupture of membranes. It is possible that what is displayed is the recognized greater frequency of

sexual activity in earlier gestation than is found at term. Also, orgasmic response was actually more frequent among those delivering at term. Although one cannot support any contentions based upon these data, were one to draw any conclusion from the information, one would be forced to observe that sexual activity with orgasmic satisfaction may be associated with a better pregnancy performance than the alternative. Unfortunately, there were not a sufficient number of patients who were not sexually active in the latter part of pregnancy to form an adequate group to study from this perspective. An association is also noted between ruptured membranes and recent sexual activity without orgasmic response.

Because of the fact that information relative to sexual behavior and response in early pregnancy was derived by patient recollection, the possibility for inaccuracies exists. It is felt that this cannot be resolved, except to say that with the size of the data base such inaccuracies should be statistically minimized. In addition, the incidence of spontaneous nocturnal orgasmic (REM sleep) events was not sought. Finally, the possible contribution of seminal prostaglandins to uterine irritability would seem unlikely, since there would be no reason to presume the lack of seminal deposition during vaginal coitus among a population pregnant, and Table VI displays no difference in irritability with coital behavior except in the factor of maternal orgasm. The specific incidence of coitus without intravaginal ejaculation, however, was not sought.

Although other data from this study not presented in detail in this report do show a decline in overall sexual activity, interest, orgasmic response, orgasmic intensity, and attitude toward sexual activity progressively throughout pregnancy, patients generally reported a very low incidence of a decline of positive feelings regarding sex or their partners as a result of this pregnancy. Sexual activity declined at a lesser rate than did the patient's interest in such activity, suggesting that most patients maintained a willingness to participate out of regard for the needs of their partners. Only a small number of patients reported a decline in their partner's interest that was in excess of their own, and these patients generally increased masturbatory activity, apparently in compensation. These factors suggested a relatively low level of physical and emotional frustration in the population in relation to opportunities available. It will be interesting to study the incidence of premature labor arising in patients presumably oppressed by unrequited sexual frustration, since some authorities feel that premature labor may be more frequent among patients under stress. Based upon all these presently unsupportable presumptions, it may be surmised that, in the absence of adequate sexual satisfaction in the presence of need, patients might be more predisposed to premature labor than those engaged in regular, satisfying sexual relationships. These presumptions will be explored in the larger analysis of the study now in preparation.

Finally, miscellaneous observations regarding sexual behavior and response at various stages of pregnancy failed to establish a trend of events leading to premature delivery. The comparative use of anesthesia was not related to sexual factors. Despite the slight increase in the number of patients of low parity among the nonorgasmic women, analysis of variance showed no differences in the lengths of the first and second stages of labor among orgasmic versus nonorgasmic women. A more detailed assessment of the possibility that sexual behavior and response may determine labor and delivery performance will be forthcoming in the larger study analysis at a later date.

In summary, based on the information presented here, we would conclude that normal sexual activity has no demonstrated major adverse influence on gestation, and that, in the absence of obvious complications (such as bleeding, ruptured membranes, or threatened premature labor), there exists no contraindication to the pursuit of normal sexual activity throughout pregnancy. Orgasmic women appear, if anything, to be advantaged. Since recommendations against sexual activity, except in addressing a risk that the patient acknowledges or has previously experienced, are rarely followed, and since sexual proscription may impose additional stresses on patient-partner relationships already drawn taut, it would seem advisable that restrictions not be suggested without just cause. In addition, it should be the physician's responsibility to review this area with the couple and to provide them with helpful observations regarding problems in physical and mental adjustments to be faced in connection with sexual behavior in pregnancy. The ease and comfort with which a given physician approaches this area may serve to establish early in the professional relationship a meaningful dialogue for the identification of relationship dysfunctions which later arise. The obstetrician is in an unique position as a potential case-finder in marital discord, and pregnancy is a window on the strengths and weaknesses of the entire relationship. To fail to recognize and respond to such opportunities in a perceptive and professional way relegates the practitioner to the status of an obstetric technician.

The author wishes to recognize the invaluable assistance of Mr. Judith Hirsch, graduate student in Psychology, University of Colorado, for her indispensible

role in the administration of this study. Gratitude also extends to W. Charles Lobitz, Ph.D., for his advice in the study design. We are grateful also to Richard H. Jones, Ph.D., University of Colorado Department of Biostatistics,and his associates for the initial statistical conceptualization and for financial assistance in completing the basic data analysis. Special thanks goes to Mr. Joseph Dixon, Research Computer Services, Milton S. Hershey Medical Center of the Pennsylvania State University, for his invaluable assistance in the completion of the programming and his patience with the author's ignorance.

The efficacy of prophylactic antibiotics in cesarean section

STANLEY A. GALL, M.D.

Durham, North Carolina

The objective of this investigation was to determine the effectiveness of cefazolin-cephalothin administration as a prophylactic regime in patients undergoing cesarean section. The study was to randomized, double-blind, placebo-controlled investigation. Cefazolin, 1.0 gm, or placebo was administered intramuscularly on call to the operating room, and cephalothin, 2.0 gm, or placebo was administered intravenously at 6, 12, and 24 hours postoperatively. Ninety-five patients were included in the study with 49 in the placebo group and 46 in the drug group. Nineteen patients developed 28 infections in the placebo group while eight patients developed eight infections in the drug group ($P = <0.05$). Eight patients in the placebo group developed infections at two or more sites whereas no patient in the drug-treated group developed multiple infections. No infant developed infection and no overgrowth of bacteria occurred. This study supports the concept of preoperative antibiotic administration being beneficial to the obstetric patient. (AM. J. OBSTET. GYNECOL. 134:506, 1979.)

THE EFFICACY and safety of the use of preoperative antibiotics in patients undergoing cesarean section has been studied for more than ten years with the first publication in 1968.[1] However, the scientific basis for the rational use of preoperative antibiotics was proposed in an earlier study by Burke.[2] Unfortunately the principles developed by Burke for preoperative antibiotics were ignored to some degree in subsequent studies. Mead[3] has summarized nine publications since 1969 concerning preoperative antibiotics in patients undergoing cesarean section. This summary indicated a febrile morbidity rate of 51% and a pelvic or wound infection rate of 30% in patients receiving a placebo, whereas the patients receiving the preoperative antibiotic had a febrile morbidity rate of 21% and a pelvic or wound infection rate of 11%. In spite of these data Mead[3] cautioned against the use of chemoprophylaxis in cesarean section.

The objectives of this investigation were to evaluate the safety and effectiveness of cefazolin-cephalothin administration as a prophylactic regimen in patients undergoing cesarean section.

Material and methods

This study included patients who were admitted to Duke University Medical Center for repeat cesarean section or who developed a need for cesarean section while in labor. The study was a prospective randomized, double-blind, placebo-controlled investigation. Patients who demonstrated evidence of clinical infection had ruptured membranes of greater than 12 hours on admission, had received antibiotic therapy during the 48 hours period prior to surgery, or who demonstrated renal or hepatic disease were excluded from investigation. The patients were administered cefazolin,* 1.0 gm, or placebo intramuscularly on call to the operating room and cephalothin,† 2.0 gm, or placebo intravenously at 6, 12, and 24 hours after the first antibiotic or placebo drug.

Preoperatively and on the third postoperative day all patients were evaluated by complete blood count urinalysis, and blood urea nitrogen.

All patients had a five-minute preoperative scrub with providine iodine as a surgical scrub.

The evaluation of the patients receiving the active drug and placebo was based on illness, serious infections, wound healing, and the number of postop-

erative days in the hospital. Illness was defined as a temperature elevation of 38.0° C or greater on any two days excluding the first 24 postoperative hours or other signs of obvious infection. A wound infection was diagnosed when either cellulitis extending greater than 2 cm from the line of incision, purulent exudate in the subcutaneous or subfascial planes, intraperitoneal abscess, or peritonitis was present. Serious infections included wound infections, endometritis, parametritis, pelvic cellulitis, pelvic abscess, septicemia, and septic thrombophlebitis.

The drug and placebo groups were also evaluated by the effect on the bacterial flora of the infant. The first ten infants delivered were evaluated for bacterial overgrowth by comparing the bacterial flora obtained from the external auditory canal and distal nares immediately upon delivery and upon discharge from the nursery.

Cefazolin concentrations were determined from maternal serum, umbilical cord serum, and amniotic fluid obtained at the time of delivery.

Patients who were determined to be febrile or who had obvious signs of infection were evaluated with cultures from indicated sites of infection including blood, endometrial cavity, urine, and wound. Appropriate therapy was subsequently instituted. The code pertaining to the patient's medication was broken if requested by the attending physician.

Cultures of the endometrium were taken for aerobic and anaerobic organisms after insertion of a sterile speculum and cleansing of the cervix with a sterile dry sponge. A sterile swab was inserted into the endometrium and placed in an anaerobic specimen collector.* The swab was streaked on 5% blood agar, 5% sheep blood agar, and solid agar with phenyl ethyl alcohol and vancomycin-kanamycin added and placed in an anaerobic chamber at 37° C. The swab was also streaked on chocolate agar, 5% sheep blood agar, MacConkey's agar, and solid agar with colistin–nalidixic acid. The swab was placed in a chopped meat–carbohydrate broth. The aerobic cultures were incubated at 37° C.

Aerobic cultures were examined at 18 and 72 hours of incubation. Identification was carried out according to standard techniques.[4]

Anaerobic cultures were examined daily. At 72 hours of incubation, colonies were inoculated to chopped meat–carbohydrate broth. After an additional 72 hours they were used to innoculate anaerobic API strips† and for gas chromatography. The Virginia Polytechnic Institute Manual was used as reference for anaerobic bacteria.[5]

Results

There were no significant differences in the clinical characteristics of age, racial distribution, parity, number of catheterizations, or length of time of indwelling catheter between the two groups. Analysis of the results of the complete blood count, urinalysis, and blood urea nitrogen in the two groups showed no differences. In addition minor side effects such as a rash or pruritus or major reactions such as anaphylaxis were not observed.

Ninety-five patients were included in the study with 49 in the placebo group and 46 in the cefazolin-cephalothin group. Twenty of the 49 patients (40.8%) in the placebo group developed at least one postoperative infection while 8 of 46 (17.4%) of patients in the drug group became infected. The group of 20 patients receiving the placebo who became infected had 28 diagnosed infections while only eight infections occurred in the antibiotic-treated group (Table I).

The type and site of the infections which were diagnosed showed significant differences. These are listed in Table II. Eight patients in the placebo group had infections at two or more sites while no patient in the drug group developed multiple infections.

The bacterial organism and site of culture is presented in Table III. The pathogenic organisms in 9 of

No infection	7.56 ± 0.97	7.93 ± 1.20

*Standard deviation.

14 (64.4%) of placebo group patients and four of five (80%) antibiotic group patients developing endometritis were anaerobic bacteria. Anaerobic organisms were responsible for septicemia in three of four (75%) patients in the placebo group.

The average length of postoperative hospital stay was used as a measure of comparison of the two groups. No significant differences were noted (Table IV).

No differences were present in the patient groups when length of surgery or length of time from onset of surgery to delivery of the infant were compared. As the time interval between the administration of cefazolin and delivery increased the infection rate decreased (Table V).

No infant developed a superinfection and in no infant did the administration of the preoperative antibiotic interfere with routine pediatric cultures or assessment. The ten infants who were cultured upon delivery and discharge from the nursery showed no difference in bacterial flora.

The influence of primary versus repeat cesarean section and socioeconomic status is shown in Table VI. When infectious illness of primary versus repeat cesarean section was compared, no significant differences were observed in those patients receiving the prophylactic antibiotic (16.0% versus 19.0%) or the placebo (43.3% versus 36.8%).

The concentrations of cefazolin in maternal blood, cord blood, and amniotic fluid at the time of delivery and the length of time from administration of the drug to delivery of the infant is listed in Table VII. The concentration of cefazolin in maternal blood at 60 minutes varied from 30 to 60 μg/ml while cord blood concentrations were less than 25% of the maternal con-

centration and the amniotic fluid concentrations were extremely low or negative.

Comment

The prevention of serious postoperative infections in patients undergoing cesarean section is of increasing concern. As obstetricians have become more concerned with the infant outcome, the cesarean section rate in this country has doubled. Serious bacterial infections such as wound infections, endometritis, parametritis, pelvic cellulitis, pelvic abscess, septicemia, and septic thrombophlebitis need to be differentiated from noninfectious febrile illness due to atelectasis or drug reactions. The prevention of urinary tract and pulmonary infections by prophylactic antibiotics does not have rational scientific basis. Six of the eight patients in the drug-treated group developed infections which could be considered serious whereas 18 of 20 patients in the placebo group developed serious infections. Therefore 6 of 46 (13.0%) patients who received preoperative antibiotics and 18 of 49 (36.8%) patients who received a placebo developed serious postoperative infections. The presence of four patients who developed septicemia in the placebo group is alarming but no instance of septicemia occurred in the antibiotic group.

The timing of the administration of the prophylactic

Table VIII. Cefazolin prophylactic study—cesarean section: Postoperative antibiotics

Drug group		*Placebo group*	
Ampicillin	96.0 gm	Ampicillin	223.0 gm
Kanamycin	9.5 gm	Kanamycin	26.1 gm
Penicillin G	136.2 mg	Penicillin G	100 mg
Macrodantin	3.5 gm	Macrodantin	2.2 gm
Sulfisoxazole	30.0 gm	Sulfisoxazole	41.0 gm
		Cefazolin	38.8 gm
		Cephalothin	33.0 gm
		Clindamycin	45.0 gm
		Cephalexin	47.5 gm

antibiotic seems to be of a critical nature. Burke[2] has shown that if the antibiotic is administered subsequent to the arrival of the bacteria in the operative site the patient will not benefit. It is seen that the most appropriate length of time from antibiotic administration to delivery is less than one hour (Table V). This would be consistent with excellent antibiotic concentrations in maternal serum at the time of delivery (Table VIII). Most other studies which use prophylactic antibiotics in cesarean section have not measured antibiotic concentrations,[1, 6–10] but Weinstein and associates[11] measured placental transfer of clindamycin and Gentamicin when they were used in a prophylactic regimen. In a companion article Gibbs and Weinstein[12] found clindamycin-gentamicin to be no more effective than a regimen of ampicillin-kanamycin.

Criticism has been forwarded that the use of prophylactic antibiotics markedly increases the total amount of antibiotics patients will receive. Ledger and colleagues[13] showed that patients in their placebo group received considerably more antibiotics and this is also seen for this study (Table VIII).

Prolonged rupture of membranes (PRM) prior to delivery is thought to increase the maternal morbidity rate. Gibbs and colleagues[8] showed prophylactic antibiotics to be effective whether or not membranes were ruptured. In the present study patients were specially excluded if membranes were ruptured more than 12 hours prior to admission. This exclusion was deemed to be necessary because at some time after 12 hours of PRM, chorioamnionitis and endometritis will develop and therapeutic antibiotics should then be used rather than a prophylactic regimen. Patients manifesting frank chorioamnionitis should be treated with full-dose Penicillin or cephalosporin plus an aminoglycoside and clindamycin. The impact of antibiotic therapy in patients with prolonged premature rupture of membranes is beyond the scope of this research. Four patients developed the need for cesarean section after admission with PRM more than 12 hours and were included in the study. Two patients were treated in each group but none of the four developed an infection. Sixteen patients had PRM less than 12 hours with eight in each group. Three infections occurred in each of the drug and placebo groups.

The endometrial cultures were obtained by passage of a sterile swab through a cleansed cervix. It is recognized this is not a totally satisfactory method for obtaining a culture from the endometrium; however, a bacteriologically sterile technique is unavailable at this time.

This study shows a significant decrease in the incidence of all infections and in the incidence of serious infections when a prophylactic regimen of cefazolin-cephalothin was used. No adverse effects to mother or infant due to the drugs were observed. Cultures of the infant at the time of delivery and discharge from the nursery showed no difference whether or not the mother received an antibiotic. The choice of cefazolin seemed to be excellent as a preoperative antibiotic because only small amounts were found in umbilical cord serum and negligible amounts were present in amniotic fluid. This is probably due to the high protein binding of cefazolin.

This study supports the concept of preoperative administration of an effective antibiotic in high dosage for a short period of time as being beneficial to the obstetric patient undergoing cesarean section.

The drugs were provided by Eli Lilly & Co., Indianapolis, Indiana.

Abnormalities among offspring of oral and nonoral contraceptive users

HÉCTOR E. ORTIZ-PÉREZ, M.D.
ABELARDO FUERTES-DE LA HABA, M.D., D.P.H., F.A.C.O.G.
ISHVER S. BANGDIWALA, PH.D., F.A.S.A.
CARLOS A. ROURE, M.D.
San Juan, Puerto Rico

An analysis of 223 children born between 1961 and 1965 to 5,465 women in a controlled experiment at the University of Puerto Rico School of Medicine, regarding the use of oral and nonoral contraceptives, failed to reveal any statistical differences in birth weight and physical abnormalities between the two contraceptive groups. The mean birth weight for the oral group was 7 pounds, 4.1 ounces, whereas for the nonoral group it was 7 pounds, 5.4 ounces. Abnormal physical findings were 10.7% for the oral group and 16.7% for the nonoral group. A comparison is also made between the two groups with respect to incidence of abnormalities by socioeconomic class and by sex of the child, as well as by the number of pregnancies and age of the mother. No significant differences were noted between the groups as an indication of the effect of oral contraceptives. (AM. J. OBSTET. GYNECOL. 134:512, 1979.)

SINCE the development of oral contraceptives, many questions have appeared, opening the way to research and debate between scientists and lay people. Many sectors of our society wonder about their possible effects on women and their offspring. Suspicions regarding a potentially teratogenic role for "the pill" have been voiced for several years but reports have been conflicting, as may be observed in reviewing the literature up to 1976.

At the University of Puerto Rico Medical Sciences Campus, a controlled experiment is being carried out with over 10,000 women, about half of them using oral contraceptives and the remaining using nonoral (vaginal) methods. Several parameters have been studied since the beginning of the experiment in 1961 and the results of the comparison between the oral and control groups have been published.[1-3]

The present report deals with the description of some findings of a study with regard to the presence of some congenital abnormalities in children whose mothers have been using two kinds of contraceptive methods, oral and nonoral. Birth weights of the children from the two groups of women are compared. The variables are also compared by sex of the child and socioeconomic condition of the mother as well as by age at the time of delivery and number of pregnancies of the mother.

Material and methods

The subjects of this study were offspring of women belonging to the University of Puerto Rico Maternal Health Study Program which was designed in 1961 to study the incidence of genital and breast cancer in women who were using progestational agents. Women admitted to the study program met basic minimum qualifications such as: age 21 to 39 years, at least one normal pregnancy, and no prior use of oral contraceptives or of intrauterine contraceptive devices (IUDs). Each candidate before admission to the program agreed to use the contraceptive to be prescribed.

Once a woman was found to be eligible and prior to her physical examination, she was assigned at random to the experimental* (oral contraceptive) or control group (vaginal contraceptive), which she was to follow throughout the experiment.

The 5,465 women of the present study were admitted to one of the clinics in the project between 1961 and 1965. With randomization procedure 2,741 women (50.16%) were assigned to the oral contraceptive group and 2,724 (49.34%) were assigned to the control group. A comparison of several socioeconomic characteristics such as age, education, family income, occupation, parity, etc., of the randomly assigned subjects to our two groups showed that both groups were almost identical and therefore comparable.[3]

The next step was to identify the mothers who had offspring after admission to the study. These were mostly voluntary pregnancies, since there were no cases of contraceptive failure among either of the groups. During the period 1961 to 1965, 229 children were born to these women. Of these 229 children, 223 were included in the study; the remaining six subjects had moved with their families to other communities and therefore were lost to follow-up. Of the 223 children included in the analysis, 210 were alive and 13 had died at the time of the study.

The subjects of the present study (223) were distributed as follows: 103 children (44 boys and 59 girls) were in the group whose mothers used oral contraceptives and 120 (65 boys and 55 girls) were in that of women using nonoral contraceptives. The average age at the time of study was 6.1 years for the 96 living children of the study group and 6.2 years for the 114 living children of the control group.

Each living child was referred to a pediatrician who performed a complete physical examination and recorded a detailed history including birth weight. For the dead children the data were obtained from autopsy records or death certificates. A comparison between groups was made by variables of the child and mother using appropriate statistical analysis. A 5% level of probability was used as the criterion for significance tests.

Results

Birth weight. From the two groups (103 oral and 120 nonoral) only three birth weights for oral and one for nonoral groups were not available for the birth weight study. Thus the analysis included 100 subjects for the oral group and 119 for the nonoral group. The mean weight at birth for the oral group was 7 pounds, 4.1 ounces, and for the nonoral group it was 7 pounds, 5.4 ounces, with a standard deviation of 24.6 ounces for the oral group and 24.3 ounces for the nonoral group (Table I). From these values it can be observed that the difference (1.32 ounces) between the mean birth weights of the two groups is not significant at the 5% level as indicated by the t test.

Abnormal physical findings. Table II shows the number of abnormalities found during physical examination of children in both groups. In the oral group 11 abnormalities were found among the 103 children whereas in the nonoral group 20 of 120 children showed some abnormalities. The percentages of abnormalities were 10.7% for the oral group and 16.7% for the nonoral group. The total chi-square value is 1.660 with one degree of freedom, which indicates that the difference between observed frequency and expected frequency is not significant at the 5% level, that is, the difference between the percentages of abnormal cases in both groups could be considered to have occurred by chance and therefore the incidence is almost the same in both. On an average it was 13.9%. A list of the different abnormalities found in each case study is given in Table III.

Table IV shows the abnormal physical findings by socioeconomic groups according to standards previously established for the experimental subjects.[3] Data for 210 children were available for this variable. In the upper class no abnormalities were found in either group. The middle-class group included 10 cases from the oral group and 14 cases from the nonoral group, and for the low class one abnormal case was found in the oral group and three in the nonoral group. The percentages of abnormalities for the middle class thus were 13.7% and 15.1% for the oral and nonoral groups,

Table IV. Number of children with abnormalities by socioeconomic level for oral and nonoral groups

Socio-economic level	*Oral*		*Nonoral*		*Total*	*Significance of difference*
	Normal	*Abnormal*	*Normal*	*Abnormal*		
High	5	0	4	0	9	
Middle	63	10	79	14	166	
Low	17	1	14	3	35	
Total	85	11	97	17	210*	
Abnormal (%), high class	–	–	–	–	–	NS at 5%
Abnormal (%), middle class	–	13.7	–	15.1	14.5 (average)	NS at 5%
Abnormal (%), low class	–	5.6	–	17.6	11.4 (average)	NS at 5%

$\Sigma\chi^2 = 3.510$ with 6 degrees of freedom—not significant at 5% level; NS = Not significant.
*For 13 subjects, the socioeconomic level of the mother could not be obtained.

respectively. The low class indicated 5.6% for the oral and 17.6% for the nonoral group. The total chi square for the differences between observed and expected frequencies was 3.510 with six degrees of freedom. The difference between observed frequency and expected frequency is therefore not significant at the 5% level in this case either. Thus the percentages in both cases are considered almost the same with an average of 0.% for upper class, 14.5% for middle class, and 11.4% for low class. The difference between these three groups at individual socioeconomic classes was also insignificant at the 5% level as indicated in Table IV.

A comparison between groups was also made with reference to sex. In the oral and nonoral groups there were 10 and 13 cases, respectively, with abnormal physical findings in the boys and one and seven cases for the girls. The percentage of abnormal boys in the oral group was 21.7% whereas for the nonoral group it was 20.0%. The difference, however, is not significant at the 5% level, as indicated in Table V. The percentage of abnormal girls in the oral group was 1.8%, whereas for the nonoral group it was 12.7% which, as indicated in Table V, is a significant difference at the same level.

In the two groups under study the distribution of mothers by age, as presented in Table VI, showed that the average age of the mothers of the 103 children in the oral group was 31.5 years while that of the mothers of the 120 children in the nonoral group was 32.0 years. The difference between the two averages is not significant.

The mean ages of mothers of the normal and abnormal children in the two groups also failed to show any statistical difference, indicating that age is not an

†$\chi^2 = 4.59$ (not significant at 5% level).

important factor affecting the children of our study with any abnormality.

The data were also analyzed for the 223 children as to their position in the family raised by the mother. The rank or the position thus was equivalent to the number of pregnancies incurred by the mother as of this childbirth. Table VII shows the data for the two groups, oral and nonoral, of the mothers of these children. It was observed that the distribution of the mothers according to the number of pregnancies was fairly similar in both groups. When the number of pregnancies of mothers in cases of the normal and abnormal children is compared, the distribution in either group is similar, as indicated by the chi-aquare test. Thus the observed frequencies, although apparently different, are not statistically different from their respective expected value.

Table VIII shows the 13 dead children with their ages at the time of death and the cause of death as reported in autopsies and death certificates. As can be seen clearly none of the deaths can be attributed to the use of oral contraceptives. Moreover, the three dead children who demonstrated congenital anomalies (vertebral, anal, cardiac, tracheal, esophageal, renal, and

limbs) belonged to the group of nonoral contraceptive users.

Comment

By the introduction of contraceptive drugs, a major breakthrough in the problem of human population control seems to have been achieved. A large sector of the female population is now dependent upon the "pill" as an effective means of birth control.

There are, however, controversies as to the "pill's" other effects. Janerich and associates[4, 5] have reported congenital limb reduction defects associated with maternal oral contraceptive exposure with a preponderance in male offspring. Nora and Nora[6, 7] have also reported various cases of fetal abnormalities (vertebral, anal, cardiac, tracheal, esophageal, renal and limbs in the offspring of contraceptive users also with a preponderance among male children. However, these reports associate fetal anomalies with the use of six steroids during early stages of gestation, contrary to our study in which oral contraceptives were used prior to conception. Although both groups agree in their conclusions, their studies have been retrospective to the present time and neither can be taken as conclusive.

Reports have also been made in the literature of masculinization of the female fetus with the use of progestins during the first trimester of fetal life as a test for pregnancy.[8, 9]

Other authors believe that since the great majority of pregnancies preceded by use of oral contraceptives do not result in a defective offspring, some maternal predisposition is probably necessary before malformations occur. Some experimental animals have been used to induce congenital malformation with high doses of estrogen/progestin. But, on the basis of the effect of dosage, it is possible that the use of higher doses of contraceptive drugs would produce a higher frequency of abnormalities, as has been found with other established chemical mutagens.[5, 10–15] The fact remains that such high doses of contraceptive drugs are not at all in use by any human population, and efforts have been made to minimize the applied dose of the steroids to the lowest and safest possible levels. As stated earlier, our experimental group at the University of Puerto Rico received a total daily steroid dose of 5.75 mg (estrogen/progestin) and ranged from one to 29 cycles prior to pregnancy.

Still other authors like Klinger and associates[16] and Yasuda and Miller[17] have found no evidence that prior use of oral contraceptives alters the risk of chromosomally abnormal offspring or can be a cause of "transposition of the great vessels" in man.[16, 17]

In a study carried out by Fuertes-de la Haba and colleagues,[1] cell culture for chromosome studies was conducted in the oral and nonoral groups. No significant difference was found between groups.

Conclusion

As shown by our data in this report there is no statistical evidence whatsoever that the use of contraceptive pills affects the birth weight or causes fetal abnormalities in the offspring. The percentage of abnormalities in both groups was almost the same. The difference in incidence did exist between socioeconomic groups and a particular sex group in the percentage of abnormalities in general, although a consistent difference was observed between oral and nonoral groups in these variables. This may indicate that the preponderance of abnormalities in male children could have been influenced by sex or socioeconomic differences and not

by the use of contraceptive drugs, since the incidence differed between sex and socioeconomic groups but was the same between the oral and nonoral groups.

No correlation could be established between either the abnormalities found in our study group and the mother's age at the time of delivery of these children or the position of the children in relation to their siblings.

Although the reports in the literature have not been conclusive and since further studies on the use of sex steroids during pregnancy have to be done, it is our opinion that the use of these steroids should be avoided during early stages of gestation or if there is any doubt as to the existence of a breakthrough pregnancy.

The effect of chlorotrianisene as postpartum lactation suppression on blood coagulation factors

JENNIFER R. NIEBYL, M.D.
WILLIAM R. BELL, M.D.*

DAVID A. BLAKE, PH.D.
NORMAN H. DUBIN, PH.D.
THEODORE M. KING, M.D., PH.D.
Baltimore, Maryland

Coagulation changes and increased risk of thromboembolic disease may occur in association with estrogen administration. The puerperium is also a high-risk period for thromboembolism, and estrogen administration at this time may increase this risk. Patients with congenital deficiency of antithrombin III have recurrent venous thromboembolic disease, suggesting that low levels of this factor may be associated with "hypercoagulability" states. We studied 50 postpartum patients who received chlorotrianisene (Tace) or placebo for lactation suppression in a prospective, double-blind, randomized fashion. Antithrombin III values were significantly lower on the third day post partum in the treated group compared to the placebo group ($p < 0.05$). In addition, our clinical data from a total of 99 patients support the previous evidence that estrogens delay rather than prevent breast engorgement. Thus, with questionable benefit and a possible increased thromboembolic risk, it would appear prudent to discontinue the practice of estrogen administration for lactation suppression. (AM. J. OBSTET. GYNECOL. 134:518, 1979.)

VARIOUS estrogenic drugs have been used routinely for the suppression of postpartum lactation, to prevent the pain, discomfort, and milk leakage associated with excessive breast engorgement. Diethylstilbestrol (50 mg orally over 9 days, tapered dosage) and chlorotrianisene (Tace, 72 mg every 12 hours for 2 days) have been shown to suppress lactation compared to placebo during the immediate postpartum period.[1] However, these estrogens are no more effective than placebo if one- to four-week postpartum evaluations are done, as many patients have rebound engorgement.[1] Thus estrogens may delay rather than prevent postpartum lactation.

In addition, coagulation changes and increased risk of thromboembolic disease may occur in association with estrogen administration. It is well known that changes in blood coagulation factors occur during pregnancy. Several clotting factors increase in pregnancy: Factor VII and Factor X (Owren's P&P test), antihemophiliac factor (Factor VIII), fibrinogen, plasminogen, and antiplasmin.[2] There is also a decrease in fibrinolysis during pregnancy.[2] so that pregnancy has been considered a hypercoagulable state.

Three large retrospective studies[3–5] have shown that the incidence of puerperal thromboembolism was higher in women who received estrogen for lactation suppression compared with those who did not. In one study,[3] there was a tenfold increase in thromboembolism in low-parity women age 25 and older who were not lactating compared to those who were, and all eight cases of pulmonary embolism were in women who received estrogen for lactation suppression. In another

study,[4] inhibition of lactation by ethinylestradiol was associated with a threefold increase in thromboembolism. Other risk factors were age greater than 25, parity greater than three, or operative delivery. When inhibition of lactation is combined with any of these the risk of thromboembolism is further increased.[4, 5] Among women aged more than 35 years who have an operative delivery, inhibition of lactation with estrogen is accompanied by a tenfold increase in the incidence of puerperal thromboembolism.[4] Post partum, thromboembolic complications have been frequently associated with the use of oral contraceptives.[6]

Antithrombin III, otherwise known as heparin cofactor, is a naturally occurring inhibitor of Factor X. It is an alpha$_2$ globulin with a molecular weight of 60,000. Patients with congenital deficiency of this factor have recurrent venous thromboembolic disease.[7] and so a low level of this factor has been thought to be possibly associated with "hypercoagulability" states. Levels of antithrombin III have been shown to be decreased in women in the third trimester of pregnancy,[8-11] in women taking stilbestrol or quinestrol for lactation suppression,[8, 9, 11] in women taking estrogenic oral contraceptives,[10, 12, 13] and in postmenopausal women taking conjugated estrogens.[14]

Chlorotrianisene (Tace), a synthetic estrogen, has not been previously evaluated for its effect on coagulation factors. We studied hematologic and coagulation properties of blood in postpartum, nonlactating patients receiving chlorotrianisene compared with those receiving placebo.

Material and methods

All patients who had undergone vaginal delivery and who elected lactation suppression were candidates for the study. The study was approved by the Joint Committee on Clinical Investigation of the Johns Hopkins Hospital, and permission according to the Helsinki Declaration was obtained from each patient. Patients with a history of past thromboembolic disease, coagulation disorders, or who were receiving drugs of any kind on a regular basis were excluded from the study. Patients were assigned to receive chlorotrianisene or placebo according to a table of random numbers. Chlorotrianisene, 72 mg, or identical-appearing capsules containing corn oil as placebo were started within four hours post partum and were administered every 12 hours for four doses. Patients received no other drugs except for codeine and propoxyphene during the postpartum period. All patients had breast support and ice packs as needed.

Venous blood was sampled prior to administration of the first capsule and again on the third and eighth postpartum days. Determination of hematocrit, white blood cell count, and platelet count were performed by standard techniques.

Blood for coagulation studies was collected into 3.8% trisodium citrate (1:9V/V) in glass tubes. Plasma was prepared by centifugation of the whole blood for ten minutes at 1,100 g at 20° C. Prothrombin times were measured on fresh plasma, using an acetone-dried rabbit brain preparation (normal control, 16 seconds). The partial thromboplastin time was determined by the macrotechnique of Miale using Thromboflax Reagent (Ortho Diagnostics, Raritan, New Jersey) (normal control value 80 to 100 seconds). The plasma fibrinogen concentrations were measured by both the techniques of Clauss, and Ratnoff and Mensie. The normal range is 220 to 400 mg/dl of plasma. Antithrombin III values reported below were determined immunologically by the electrophoretic immunoassay of Laurell with modifications of the technique as described by Mammen.[15] The normal value for nonpregnant women is 200 + 20 μg/ml. Antithrombin III was also assayed for its biologic functional activity by the method of Gitel and Wessler.

Progesterone was measured by radioimmunoassay following the procedure of Abraham and associates and estradiol was measured similarly using an antiserum made against estradiol 17β-6-carboxymethyloxine-thyroglobulin.

The age, race, and parity of the patients were recorded as was the occurrence of temperature elevation. Patients were examined by one of three observers. Breast size was measured in centimeters with a tape measure from the midline to the anterior axillary line bilaterally. Congestion, secretion, and pain were recorded on a scale of 0 to 4. For purposes of analysis, mild or no engorgement or pain were combined (0, 1, 2 on the scale) and moderate or severe engorgement or pain (3 or 4 on the scale) were combined. Daily use of analgesics for breast pain was recorded, and one week post partum the patients were asked if they were satisfied with the study drug given.

Results

A total of 50 patients were studied and had blood drawn on the day of delivery and two days later; 26 received placebo and 24 received chlorotrianisene. The mean age in the treated group was 21 years and in the placebo group 20 years. Seventy-five percent of the treated and 85% of the placebo patients were black. Fifty-eight percent in both groups were nulliparous. Twelve of the treated group and 13 of the placebo group returned for evaluation on the eighth postpartum day.

Table I. Effect of chlorotrianisene on postpartum hematologic factors

Hematologic factors	*Tace and placebo*	*Day 1*	*Day 3*	*Day 8*
Hematocrit (%)	Chlorotrianisene	35.5 ± 0.7*	34.4 ± 1.0	38.2 ± 1.0*
	Placebo	33.3 ± 0.7	31.9 ± 0.9	34.9 ± 0.7
White blood count	Chlorotrianisene	14.9 ± 0.9	11.4 ± 0.8†	7.3 ± 0.6†
(x 10^3)	Placebo	15.1 ± 0.8	11.6 ± 0.5†	7.6 ± 0.5†
Platelet count	Chlorotrianisene	215 ± 10	226 ± 11*	312 ± 11*†
(x 10^3)	Placebo	247 ± 16	269 ± 11	370 ± 26†
Antithrombin III	Chlorotrianisene	201 ± 18	183 ± 14*	189 ± 13
(μg/ml)	Placebo	189 ± 11	224 ± 14	226 ± 13
Prothrombin time	Chlorotrianisene	100%	100%	100%
(% standard)	Placebo	100%	100%	100%
PTT	Chlorotrianisene	72.5 ± 2.1	73.4 ± 5.4	78.8 ± 3.4
(sec.)	Placebo	72.5 ± 3.5	69.5 ± 2.3	74.3 ± 3.4
Fibrinogen	Chlorotrianisene	350 ± 19	415 ± 30	362 ± 32
(mg%)	Placebo	368 ± 27	384 ± 21	344 ± 38

*$p < 0.05$ (t test) versus placebo of same day.
†$p < 0.05$ (t test) versus Day 1 of same group.

Table II. Clinical data (99 patients)

	Day 3		*Day 8*		*Day 3 or Day 8*	
Clinical data	*Chlorotrianisene (N = 53)*	*Placebo (N = 46)*	*Chlorotrianisene (N = 25)*	*Placebo (N = 21)*	*Chlorotrianisene (N = 53)*	*Placebo (N = 46)*
Fever 100.4° F	4%	4%	—	—	—	—
Breast engorgement moderate or severe	9%	11%	16%	5%	17%	13%
Percentage using analgesics for breast pain	8%	7%	8%	10%	9%	9%
Percentage of patients satisfied with drug	—	—	88%	90%	—	—

The laboratory values are recorded in Table I. On Days 1 and 8 the hematocrit was significantly higher in the treated group, but the mean values for both groups were in the normal range. The platelet counts were not statistically different on the day of delivery, but were significantly lower in the treated group on the third and eighth postpartum days, also all in the normal range.

There was no significant difference in the values for antithrombin III on the day of delivery. On Day 3 the concentration decreased in the chlorotrianisene group and increased in the placebo group for a statistically significant difference ($p < 0.05$). On Day 8 the trend remained but the concentration difference was not significantly different. The differences were thus due to failure of the treated group to develop postpartum elevations of the platelet count and antithrombin III values as were observed in the placebo group. The levels of antithrombin III were the same with both techniques employed.

There was no difference between the placebo and treated groups on Days 1, 3, and 8 for the following tests: white blood cell count, prothrombin time, partial thromboplastin time, fibrinogen (results were the same with both techniques employed), estradiol, and progesterone. Estradiol and progesterone concentrations decreased dramatically with time post partum as shown in Fig. 1, without differences between the treated and control groups.

An additional 49 patients were evaluated clinically but did not have blood drawn. Table II summarizes the clinical aspects of the total 99 patients. Fifty-three received chlorotrianisene, and 46 received placebo; 25 treated patients and 21 placebo patients returned for evaluation on the eighth postpartum day.

The incidence of fever of 100.4° F or greater on the third postpartum day was 4% in each group, and 9% versus 11% in the treated and placebo groups, respectively, had moderate or severe breast engorgement at that time. On the eighth postpartum day, only 5% of placebo-treated patients had moderate or severe breast engorgement compared to 16% of the chlorotrianisene-treated patients. Including moderate or severe breast engorgement occurring at any time post partum, 17% of treated patients and 13% of placebo patients were affected. There was no significant difference among any of these groups by chi-square analysis. Eighty-eight percent of treated patients and 90% of

placebo patients stated that they were satisfied with the medication given. The utilization of mild analgesics for breast pain during the postpartum period was 8% in the chlorotrianisene group and 7% in the placebo group. There was no clinical evidence of thrombophlebitis in any patient.

Comment

Evidence is accumulating that estrogen administration carries a risk of thromboembolic disease. We observed a statistically significant decrease in antithrombin III levels on the third postpartum day in patients who received chlorotrianisene, 72 mg every 12 hours for the first two days post partum, compared to those who received placebo. This finding is consistent with previous reports of decreased antithrombin III in women receiving diethylstilbestrol post partum,[8, 9, 11] in women on oral contraceptives,[10, 12, 13] and in postmenopausal women receiving estrogens.[14]

Following parturition there was a rapid fall in plasma progesterone and estradiol which was independent of chlorotrianisene treatment. Coincident with this rapid decrease in steroid hormones was a rise in antithrombin III in untreated women, and chlorotrianisene administration prevented the rise in antithrombin III in the treated patients. Platelets also rose post partum in the placebo group. Chlorotrianisene administration did not prevent the rise in platelet count, but on Days 3 and 8 the levels were significantly less than in the placebo group, a change not previously related to estrogen therapy. Although the differences are statistically significant, the values remain in the normal range and may not be of biologic significance. The fall in white blood cell count post partum was not influenced by chlorotrianisene administration.

The lower values for antithrombin III in the treated group are not as low as those reported for families with reported increase in thromboembolic disease,[7] as in these families the antithrombin III levels are reduced to 40 to 50% of normal (90 to 100 μg/ml). The values found in this study remained in the normal range and again may not be of biologic significance.

In addition, our results add support to the previous reports questioning the efficacy of estrogen for postpartum lactation suppression,[1] as the overall incidence of breast engorgement was the same in both groups. Our study showed increased delayed breast engorgement in the treated group, suggesting that estrogens

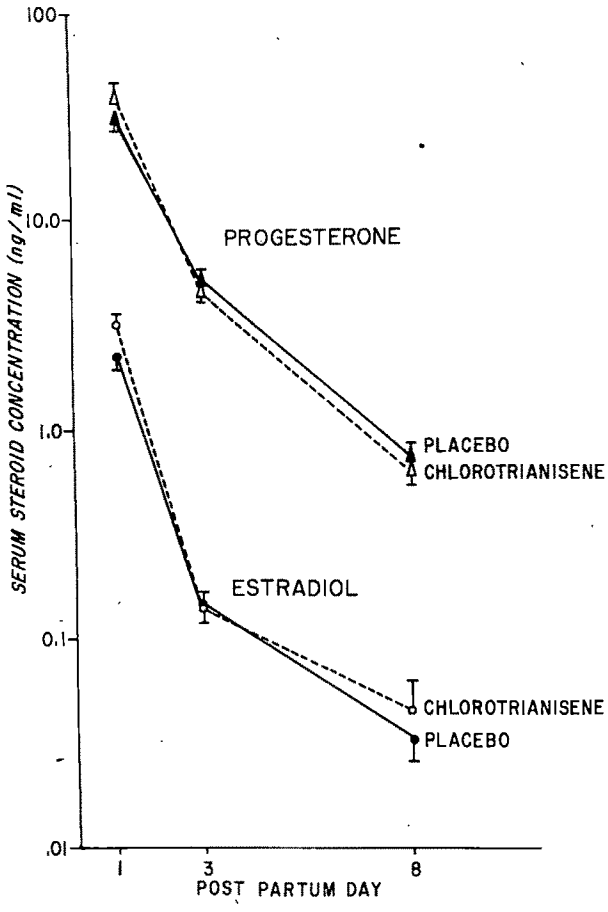

Fig. 1. Serum progesterone (△) and estradiol (○) decrease post partum and are not influenced by administration of chlorotrianisene.

postpone rather than prevent the engorgement. A recent study[16] showed increasing prolactin levels in women receiving stilbestrol post partum, compared to falling prolactin levels in patients receiving placebo. It thus appears that estrogen prevents the action of prolactin at the level of the breast, but when the estrogen is discontinued the prolactin levels are higher and probably contribute to rebound engorgement.

Thus with questionable benefit, if there is a possible thromboembolic risk with the use of estrogens, the risk-benefit ratio would clearly point to discontinuation of estrogen administration for this indication.

The expert technical assistance of Christine Helinski, Patricia Egner, Virginia DeSeau, Daniele Cornell, and Nancy Baros, and the excellent secretarial help of Shelia Rogers are gratefully acknowledged.

Compare your invasive fetal heart rate recording with Roche Fetasonde® recording

We did! Roche indirect fetal heart rate recording can be as good as a standard invasive fetal heart rate recording. This will allow you to monitor most of your patients non-invasively most of the time. Don't be limited to a monitor that does not have that capability when a viable alternative is available.

The Roche 2106 Fetal Monitor is proven useful in virtually all antepartum patients:

- Accuracy approaching internal monitoring.
- Beat-to-beat heart rate variability.
- Complete internal monitoring capability—the 2106 can be used for all patients all the time.

The non-invasive fetal monitor Roche Fetasonde®

OBSTETRICIAN/ GYNECOLOGIST

Immediate opening for academically oriented obstetrician/gynecologist for Beth Israel Ambulatory Care Center (BIAC)—a nationally known hospital based primary care program. Will work with teams of physicians, midwives and mental health workers with responsibility for service, research, and teaching OB/ GYN house staff and medical students.

Competitive income, excellent benefits, and academic appointment at Harvard Medical School. Address all inquiries to Emmanual A. Friedman, MD, Chief, Department of Obstetrics and Gynecology.

Beth Israel Hospital

330 Brookline Ave., Boston, Mass. 02215
An Equal Opportunity Employer

FACULTY POSITIONS

There are currently openings for full-time faculty in Obstetrics and Gynecology who have Board certification or eligibility. Teaching, research and patient care interests important. Special training and expertise in maternal and fetal medicine, reproductive endocrinology, gynecologic oncology or ambulatory care is desired. Academic rank and salary are dependent on qualifications. If interested, please send curriculum vitae and bibliography to:

William N. Spellacy, M.D.
Professor and Head
Department of Obstetrics & Gynecology

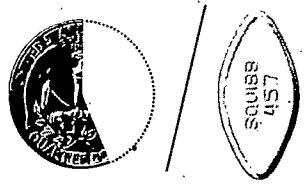
Good reasons to look at MYCOSTATIN® Vaginal Tablets (Nystatin Vaginal Tablets U.S.P.) again

Little or no resistance



"Repeated subculture of *Candida albicans* in increasing concentrations of nystatin results in little or no development of resistance..."[1] No occurrence of *in vivo* resistance as a general rule.

Virtually nontoxic and nonsensitizing

The manual application option

The fact that a vaginal tablet can be inserted *without* an applicator offers an important option when such a method is deemed advisable by the physician.

Economy

Your patients can save substantially compared to the cost of Miconazole Nitrate Cream or Clotrimazole Vaginal Tablets.*

Mycostatin® Vaginal Tablets

Nystatin Vaginal Tablets U.S.P.

[1]Goodman & Gilman, *The Pharmacological Basis of Therapeutics*, 5th Ed, 1975, p. 1236.
*Based on manufacturers' published prices to retailers.

See following page for brief summary.

MYCOSTATIN® Vaginal Tablets
Nystatin Vaginal Tablets U.S.P.

MYCOSTATIN® VAGINAL TABLETS
Nystatin Vaginal Tablets USP

DESCRIPTION: Mycostatin Vaginal Tablets (Nystatin Vaginal Tablets USP) are provided as diamond-shaped compressed tablets containing 100,000 units of nystatin dispersed in lactose with ethyl cellulose, stearic acid, and starch.

INDICATIONS AND USAGE: This product is effective for the local treatment of vulvovaginal candidiasis. Confirm diagnosis by KOH smears and/or cultures prior to therapy. Rule out Trichomonas and *H. vaginalis* by appropriate laboratory methods since these pathogens do not respond to nystatin.

CONTRAINDICATIONS: Contraindicated in patients with a history of hypersensitivity to any of the components of the tablets.

PRECAUTIONS: General—Discontinue therapy if sensitization or irritation is reported during use.

Laboratory Tests—Repeat microbiological studies to confirm diagnosis and rule out other pathogens before instituting another course of antimycotic therapy if there is a lack of response to nystatin vaginal tablets.

Usage in Pregnancy—No adverse effects or complications have been attributed to nystatin in infants born to women treated with nystatin vaginal tablets.

ADVERSE REACTIONS: Nystatin is virtually nontoxic and nonsensitizing and is well tolerated by all age groups, even on prolonged administration. Rarely, irritation or sensitization may occur (see Precautions).

For full prescribing information, consult package insert.

HOW SUPPLIED: Available in packages of 15 and 30 individually foil wrapped tablets with applicator and in Unimatic®cartons of 50 single-dose packs per carton—each cello-protected single-dose pack consists of one individually foil wrapped tablet, one applicator, and one "Instructions for the Patient" leaflet.

19TH ANNUAL REVIEW COURSE IN OBSTETRICS AND GYNECOLOGY

OCTOBER 22–26, 1979

(Monday–Friday, 8:00 A.M.—5:30 P.M.)

37 and 1/2 credit hours, Category 1, A.M.A.'s Physician's Recognition Award 65 Cognates from the American College of Obstetricians and Gynecologists

FEE $325 (Resident's Fee $200)

Robert S. Neuwirth, M.D., Ralph Richart, M.D., Raymond L. Vande Wiele, M.D., Associates and Guest Lecturers

Survey of the major clinical and pathological problems pertaining to the female reproductive system. Emphasis will be placed on the diagnosis and management of obstetrical and gynecological disorders, including infertility, endocrine problems and malignant diseases, in the light of modern advances in basic knowledge and clinical practice. A review of gynecologic patho ogy will be included. The course will be divided as follows: gynecologic oncology, perinatal medicine, gynecology and obstetrics, reproduction control behavior and endocrine disorders. Each lecture will be followed by brief discussion.

For application contact:

Dr. Elizabeth C. Gerst, Director
Continuing Education Center
630 West 168 St., N.Y., N.Y. 10032
(Telephone: 212-694-3682)

GROUP PRACTICE OPPORTUNITIES PACIFIC NORTHWEST

Rapid growth in the metropolitan area of Portland, Oregon has created immediate openings in the Department of Obstetrics and Gynecology. We are seeking obstetrician/gynecologists and/or perinatologists to join an active service with over 3,700 deliveries per year, a high risk intensive care nursery and complete fetal monitoring equipment.

Northwest Permanente, P.C. is a professional medical corporation which provides health care services to the 220,000 members of the Kaiser Foundation Health Plan of Oregon. Through its association with Kaiser Foundation Health Plan, a federally qualified HMO, Northwest permanente, P.C. operates nine outpatient clinics and two full service hospitals.

The medical practice is varied and professionally stimulating offering the physician a pure practice free of business and administrative concerns. A comprehensive salary and benefits package including a sabbatical program, malpractice coverage, three weeks vacation and one week educational leave to start, life, medical/dental and disability insurance along with two excellent retirement programs is provided. The physician is eligible for ownership participation after two years of service.

Portland, Oregon, on the Columbia and Willamette Rivers, is a city with a moderate climate located in a stable, prosperous economic region of the beautiful Northwest. Outdoor recreational facilities are superb and include excellent skiing, backpacking, fishing and boating opportunities. The Environmental Protection Agency, in a recent study, selected Portland as the "most livable city" in the United States.

Please send a curriculum vitae with your initial response to Marvin P. Goldberg M.D., President, Northwest Permanente, P.C., 1500 S. W. 1st Avenue, 11th Floor, Portland, Oregon, 97201.

FETUS, PLACENTA, AND NEWBORN

Acceleration of the fetal heart rate

CARL WOOD, M.B., B.S., F.R.C.S., F.R.C.O.G., F.A.G.O.
ADRIAN WALKER, B.Sc., M.Sc., PH.D.
ROBERT YARDLEY, M.B., B.S.
Melbourne, Victoria, Australia

Acceleration of the fetal heart rate during contractions was usually followed by deceleration, and evidence is presented to show that it results from increased sympathetic drive and may be associated with fetal tissue hypoxia. However, the presence of accelerations are not serious and merely warn the obstetrician of the possibility of the occurrence of subsequent decelerations. The mechanism thought most likely to produce accelerations is uterine compression of the umbilical vein during contractions. (AM. J. OBSTET. GYNECOL. 134:523, 1979.)

ACCELERATION of the fetal heart rate (FHR) during contractions is stated to be "not an adverse pattern," indicating good reflex responsiveness of the fetal circulation, the mean fetal pH in association with this change being normal (7.34 ± 0.03).[1] However, Paul[2] states that the clinical significance of acceleration during contractions is unclear, that the change is mediated through the sympathetic division of the autonomic resources system, and that it may be an early response to the stresses of labor. Accelerations may also occur before labor in the absence of contractions and these have been described by Schifrin[4] as a reactive pattern. Their appearance has been used as a positive indicator of good health of the fetus, over 700 fetuses with a reactive pattern having no serious problem in subsequent labor. The mechanism producing acceleration before and during labor may be different so that evidence of good health in one group may not be applicable to the other, but with the exception of Paul's[2] slight uncertainty, opinions favor the view that accelerations are not important clinically. We wish to present some data associated with accelerations in the human fetus and to discuss this in the light of other evidence, including study of the sheep fetus.

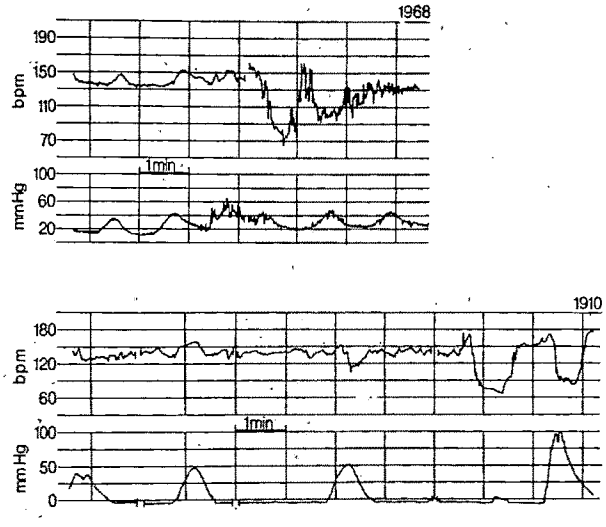

Fig. 1A. FHR uterine pressure recordings from two patients showing transition from transient accelerations or biphasic change to decelerations.

From the Department of Obstetrics and Gynecology, Monash University, The Queen Victoria Memorial Hospital.

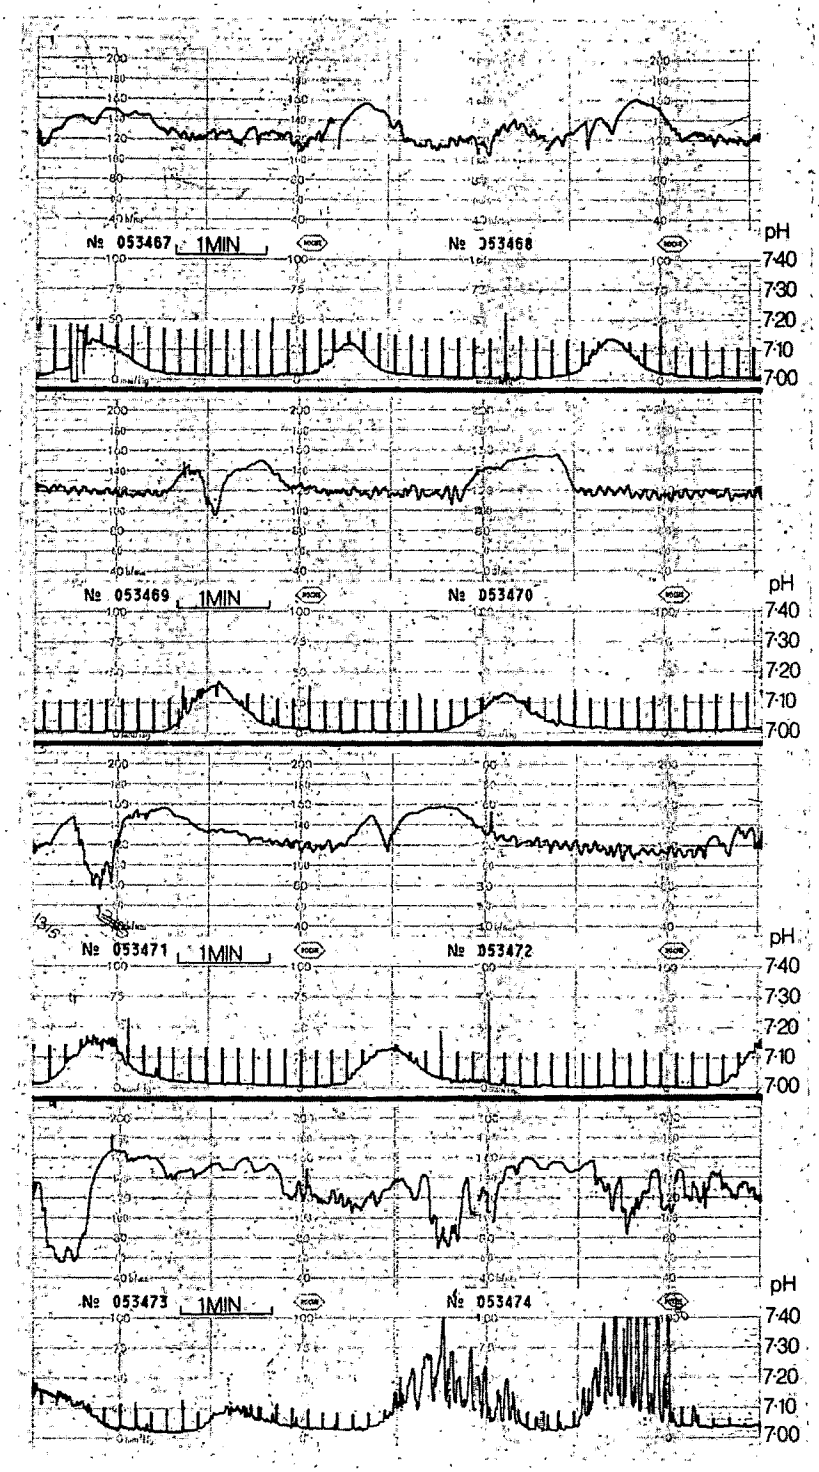

Fig. 1B. FHR, uterine pressure, and scalp tissue pH-(measured by the height of the vertical lines on the pressure trace) recording from patient showing transition from accelerations to biphasic change and decelerations. The scalp tissue pH has declined from 7.20 to 7.10 during the time of change in FHR pattern.

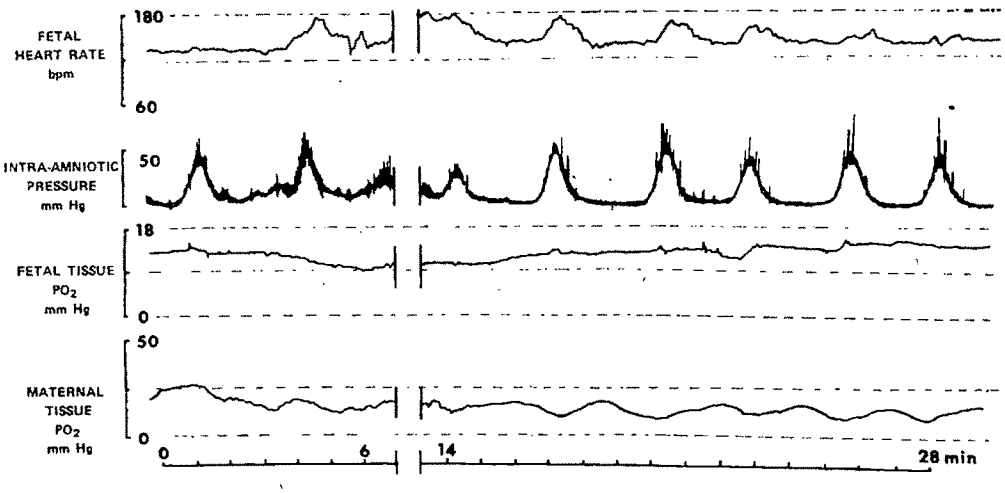

Fig. 2. Prolonged fall in fetal scalp Po_2 accompanied by marked rises in fetal heart rate with uterine contractions. As the magnitude of the accelerations diminshes, fetal tissue Po_2 returns to the basal level. (From Walker, A., Maddern, L., Day, E., Renou, P., Talbot, J., and Wood, C.: Fetal scalp tissue oxygen tension measurements in relation to maternal dermal oxygen tension and fetal heart rate, Br. J. Obstet. Gynaecol. **78**:1, 1979, published by Headley Bros.)

Material and methods

The records of 100 consecutive patients whose FHR was monitored by the fetal intensive care unit were examined for the appearance of accelerations. These were defined as an increase in FHR of more than 20 beats per minute in relation to a uterine contraction. All were patients whose fetuses were at increased risk because of the presence of obstetric complications such as hypertension, proteinuria, antepartum hemorrhage, fetal growth retardation, and low urinary estriol excretion. Patients received intramuscular Demerol, 100 to 150 mg, as an analgesic during the first stage of labor and nitrous oxide and oxygen mixtures during the second stage.

Results

FHR accelerations were present in 14 of the patients. In only three were accelerations not accompanied by other changes. The FHR traces of the remaining 11 patients showed both accelerations and decelerations. The accelerations always preceded the development of decelerations and in some instances the trace showed a gradual progression from accelerations, to acceleration and deceleration (biphasic change), to decelerations alone (Figs. 1A and 1B).

In the same 100 patients there were 11 with decelerations alone, nine beginning in the early-mid phase of the contraction cycle, and three in the late phase of the contraction cycle (one had both early-mid and late decelerations).

The occurrence of accelerations in association with decelerations was highly significant (Table I).

Overall comparison of two groups, accelerations + decelerations, and decelerations alone showed no difference in terms of age, parity, gestational length, length of labor, type of delivery, Apgar score, and fetal weight (Table II). The three patients with accelerations alone were not different from the remaining 11 of this group who had both accelerations and decelerations.

Comment

The reason for the association between accelerations and decelerations is very unlikely to be due to chance ($P < 0.001$) and the most likely explanation is that a single process causes both. As accelerations precede decelerations it is also likely that the acceleration represents an early stage of a physiologic or physiopathologic process which would support Paul's[2] view that it may be an early response to some stress.

Three pieces of evidence may throw light on the significance of the accelerations. Maternal injection of a beta-blocking drug abolished accelerations in relation to the contraction cycle in all of the eight fetuses.[3] This shows that the acceleration is proabably related to increased sympathetic drive. Studies of fetal tissue Po_2 show correlation between FHR accelerations and falls in fetal scalp tissue Po_2 (Figs. 2 and 3).[5] When the heart rate change is biphasic, the tissue Po_2 begins to fall at the time of the acceleration, suggesting that the acceleration represents an early stage of a hypoxic process.

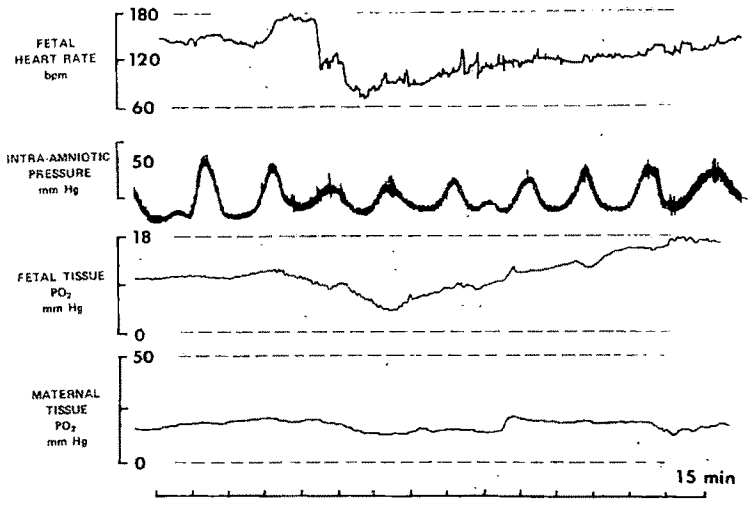

Fig. 3. Large fall in fetal scalp tissue Po_2 associated with a spontaneous biphasic change in fetal heart rate. The patient, who suffered from the supine hypotensive syndrome, was turned from the supine to the right lateral position at the 10 minute mark of this record. Note that the fall in tissue Po_2 began at the time of the acceleration and became more marked during the deceleration. (From Walker, A., Maddern, L., Day, E., Renou, P., Talbot, J., and Wood, C.: Fetal scalp tissue oxygen tension measurements in relation to maternal dermal oxygen tension and fetal heart rate, Br. J. Obstet. Gynaecol. **78**:1, 1979, published by Headley Bros.)

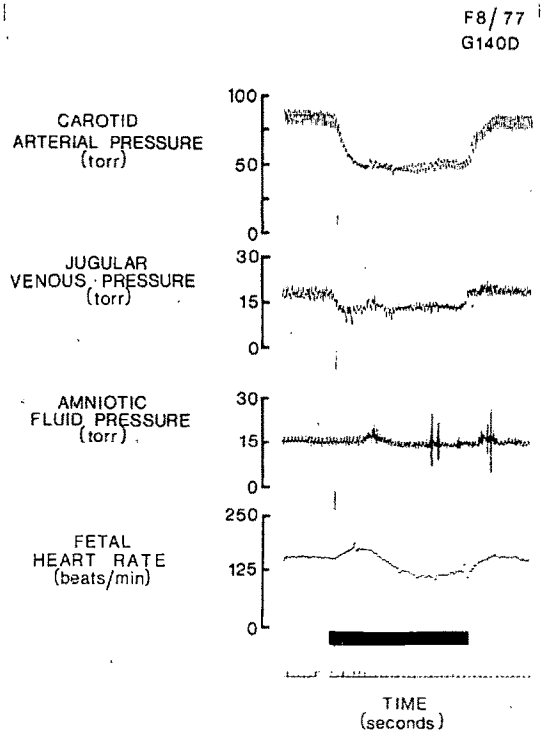

Fig. 4. Illustration of a bidirectional change in heart rate following brief inferior vena caval occlusion (bar) in a near term fetal lamb. Note that heart rate first increases (+20 beats/minute) then decreases (−45 beats/minute) from the baseline level in association with falls in both venous and arterial pressures. Caval occlusion was effected by inflating a balloon cuff which had been implanted around the vessel 30 days prior to the experiment.

Table I. Association between accelerations and decelerations

Accelerations	*Decelerations*	
	Yes	*No*
Yes	10	3
No	11	76

$\chi^2 = 28$; $p < 0.001$.

Table II

	Accelerations + decelerations	*Decelerations*
Age	21 ± 2.1	22 ± 2.5
Parity	1.7 ± 0.4	1.4 ± 0.3
Gestational length	283 ± 16	287 ± 13
Length of labor	8.1 ± 2.5	9.6 ± 3.4
Mode of delivery:		
Spontaneous	11	6
Forceps	2	4
Cesarean section	1	1
Fetal weight (gm)	3,310 ± 327	3,421 ± 285
Apgar score (1 minute)	7.2	7.2

Comparison of groups by χ^2 test and Student's t test showed no significant differences.

The final evidence concerns the biphasic change of FHR which occurs in the sheep fetus following brief inferior vena caval occlusion (Fig. 4). The fall of venous and arterial pressure occurs during both the acceleration and deceleration and could be expected to be as-

sociated with a reduction in cardiac output and, at least in some areas of the body, a fall of fetal tissue Po_2.

The hypothesis suggested from the observation and evidence cited is that accelerations are most likely a result of a reduction of venous return to the heart, perhaps from cord compression. The acceleration results from sympathetic stimulation as they are abolished by the action of a beta-blocking drug. The transient reduction in fetal scalp tissue Po_2 which occurs during accelerations cannot be assessed quantitatively, and judging from the case histories, in particular the fetal and neonatal status, the presence of accelerations have no clinical significance except to warn the obstetrician that decelerations may subsequently occur. The accelerations, however, are distinct from the transient increase of FHR, and reactive patterns described by Schifrin[4] which occur in the antepartum period in the absence of uterine contractions.

Other explanations of the data are possible and may involve any circulatory stress which initially would stimulate the sympathetic nervous system and then subsequently stimulate the parasympathetic system when the stress is more severe. However, none seems as likely to occur in utero as restriction of venous return resulting from uterine compression of veins, most likely the umbilical vein.

Assessment of fetal lung maturity: A comparison of the lecithin/sphingomyelin ratio and the tests of optical density at 400 and 650 nm

W. N. SPELLACY, M.D.
W. C. BUHI, M.S.
A. C. CRUZ, M.D.
S. R. GELMAN, M.D.
K. R. KELLNER, M.D., PH.D.
S. A. BIRK, R.N., B.S.
Gainesville, Florida

Seventy-eight amniotic fluid samples were obtained by transabdominal amniocentesis and were analyzed for their L/S ratio and optical density at 400 and 650 nm. The L/S ratio was considered to be mature if the values were greater than 2.0. The optical density of the fluids decreased with prolonged refrigeration. With freshly centrifuged samples, the OD_{650} reading of greater than 0.15 gave the best correlation with the mature L/S ratio. There were 3.8% false positive results and 14.1% false negative results. The study confirms that the OD_{650} test on fresh amniotic fluid is a rapid and inexpensive way to determine fetal maturity. All samples with values of less than 0.15 must, however, also be tested for their L/S ratio since some of the infants with these values may also be mature. (AM. J. OBSTET. GYNECOL. 134:528, 1979.)

A MAJOR PERINATAL MORBIDITY and mortality problem is the immaturity of neonates' lungs and their resultant respiratory distress. The introduction of amniotic fluid measurements of the lecithin to sphingomyelin (L/S) ratio by Gluck and associates[1] in 1971 provided obstetricians with an accurate means of assessing fetal lung maturation. The proper application of this test to women who are being considered for elective termination of pregnancy should eliminate the large number of iatrogenic cases of prematurity that occur.[2] When maternal and/or fetal diseases require early delivery, this test can give an accurate prediction of the neonatal risks of the intervention which is critical information for making the correct decisions. One problem with the new L/S test has been a technical one of getting accurate laboratory determinations at the smaller obstetric units. In order to overcome this problem simpler tests have been developed. Recently Sbarra and co-workers[3] have suggested that reading the optical density at 400 and 650 nm gave a good correlation with the L/S ratio. The purpose of this report is to compare the optical density test reading at both 400 and 650 nm with the classic amniotic fluid L/S ratio test. The results show that significant false negative errors can occur with the simple OD test and especially if the fluid is refrigerated for long periods before testing.

Methods

Seventy-eight fresh amniotic fluid samples were selected for study. All of the fluids were obtained by transabdominal amniocentesis from women who were considered for delivery for medical reasons and where there was a question of fetal maturity. The medical reasons included hypertension, diabetes mellitus, Rh sensitization, intrauterine growth retardation, and previous cesarean sections. All of the patients signed an informed consent and all had ultrasound localization of the placenta and optimal amniocentesis site before the

L/S ratio >2.0 Mature	11 (14.1%) False negative	30 (38.5%)

procedure. No fetal or maternal complications were encountered. The fluids which were highly pigmented or which contained blood or meconium were excluded since these substances are known to affect the L/S ratios.[4] The fluids were centrifuged within two to three hours of collection for 10 minutes at 3,000 rpm (2,500 × g) at 4° C in an International Model PR 600 centrifuge. The supernate was removed and divided into two aliquots. One aliquot of each sample was analyzed in duplicate for its L/S ratio by means of a modified thin-layer chromatographic technique.[5] The absorbance of the other aliquot was determined at wave lengths of 400 and 650 nm by means of a Beckman Model 25 DB recording spectrophotometer against distilled water within two hours of centrifugation.

Finally an experiment was performed to see the effects of prolonged refrigeration of amniotic fluids on the initial optical density. Four amniotic fluids were centrifuged as described and the optical density at 650 nm was read. The fluids were then placed in a refrigerator at 4° C and a repeat centrifugation and OD reading at 650 nm was done daily over a five-day period of time.

The paired sample results were analyzed with the aid of a computer and calculations were made of the correlation coefficients and the false negative and positive rates for the OD using an L/S ratio of 2.0 and above as indicating fetal lung maturity. Probability values were taken from two-tailed tables and only values of less than 0.05 were considered significant.

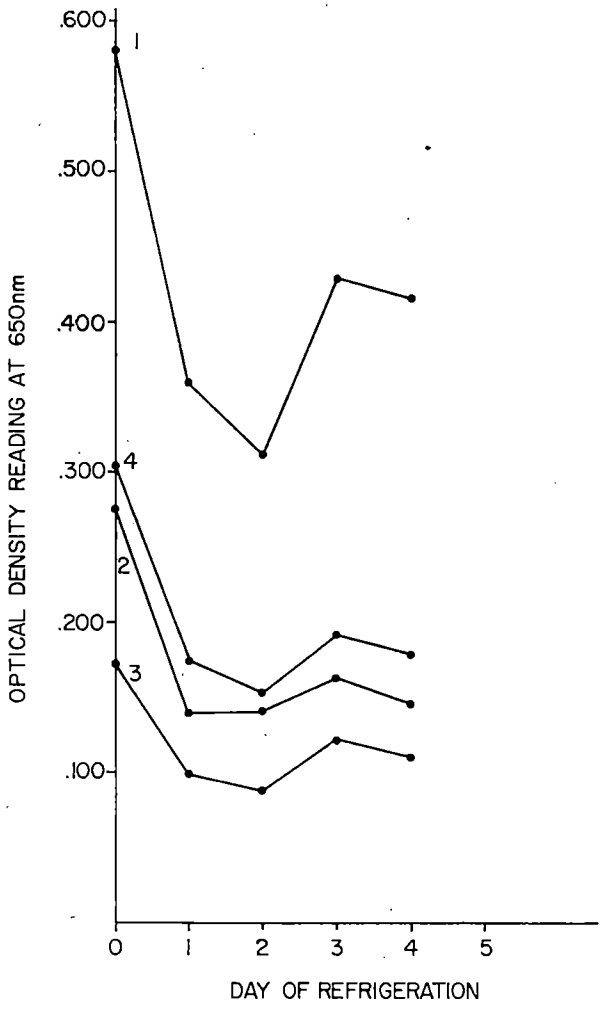

Fig. 1. The effect of prolonged refrigeration of amniotic fluids on the optical density reading at 650 nm (N = 4).

Results

A comparison of the L/S ratio and the OD at 400 nm and 650 nm results is seen in Tables I and II. Since Sbarra and colleagues[3] have used the OD reading of 0.15 or greater at 650 nm as an index of fetal maturity, this same value was studied here. The results show that the 650 nm values give an excellent prediction of the L/S ratio. The correlation coefficient for the L/S ratio and OD_{400} was 0.55 and for the OD_{650} it was 0.49 and both were statistically significant ($p < 0.05$). It can be seen that the false negative rate is 14.1% and the false positive rate is 3.8% for the 650 nm reading at 0.15.

When the OD reading at 0.28 or greater at 400 nm was used as an index of fetal maturity, the false positive rate was 22.1% and the false negative rate was 5.2%. When the OD_{400} reading of 0.35 or more was used, the false positive rate was 9.1% and the false negative rate was 14.3%.

The effects of prolonged refrigeration of amniotic fluids are seen in Fig. 1. It is clear that the optical density falls during the first two days and this is probably due to flocculation of the fluid proteins. This fall could bring a "mature" fluid to an "immature" reading at both wave lengths.

Comment

The need for a simple, rapid, reliable, and reproducible test of fetal lung maturity is well known to perinatologists. It has been established that the L/S ratio test does give an accurate prediction for most obstetric patients with the exception of those infants of mothers with diabetes mellitus.[5, 6] The L/S ratio test is somewhat complicated to perform, however, and it takes several hours to obtain the results. As a consequence some smaller obstetric services do not have the test available. Other simpler tests of fetal lung maturation have been developed and the one most widely tested has been the "shake" or "bubble" or "foam stability" test. Critical studies comparing that test with the L/S ratio show that the results can be quickly determined but there is a high false positive and false negative rate of interpretation.[7]

In 1976 Sbarra and co-workers[3] reported that the simple measurement of amniotic fluid optical density gave a good index of the L/S ratio. They originally suggested an OD of 0.28 or higher at 400 nm indicated fetal lung maturity with one false negative and no false positive results.[3] Because pigments such as bilirubin, meconium, and hemolyzed blood interfered at that wave length, they did their subsequent investigations at 650 nm.[3, 8-9] In an expanded study of 100 amniotic fluids they showed that the OD_{650} reading of 0.15 or higher gave a false negative rate for predicting a mature L/S ratio of 6% while the false positive rate was zero.[8] A later study of 300 amniotic fluids showed a 98% accuracy for prediction of the L/S ratio over two by measuring an OD at 650 nm of more than 0.15.[9] This method was also studied by Copeland and associates[10] on 87 amniotic fluids and they were less enthusiastic for although there were no false positive values, the false negative rate was 41%. A similarly disappointing set of results was found by Moodley and colleagues[11] on 127 fluids. They found a false negative rate of 32% and a false positive rate of 3% in attempting to predict a mature L/S ratio by the OD reading at 650 nm.[11] The results were better at 400 nm OD reading with a false positive rate of 6% and a false negative rate of 17%.[11]

Finally, Arias and co-workers[12] determined the OD_{400} (reading at 0.3), OD_{650} (reading at 0.15), and L/S ratio on 102 amniotic fluid samples. They noted a false positive rate of 18.1 and 11.0% and a false negative rate of 23.5 and 34.6% for the OD_{400} and OD_{650}, respectively.[12] Their conclusions were that the errors of the OD were too great to make the procedure at all applicable for perinatal assessments.[12]

Their high false negative rates might have been due to prolonged refrigeration of the fluids for it was shown in this study that that lowers the optical density. In addition, earlier studies have shown that the speed of centrifugation will affect the L/S ratio as low speeds give higher ratios than faster speeds. In this study it was noted that high centrifugation speeds gave lower absorbance. Therefore different investigators might get different results simply because of their speed of centrifugation.

The present study extends those observations and shows that prolonged refrigeration can lower the OD results. Also comparing the two OD readings the 650 nm gave the better results. With the OD_{650} reading of 0.15 the false positive rate for predicting a mature L/S ratio remains low (3.8%); however the false negative rate is still disturbingly high (14.1%). These figures suggest that the OD test cannot be the sole perinatal fetal maturation test but it can be used as a preliminary screening procedure. If a fetus is retained in utero during a high-risk pregnancy when it is really mature it could be damaged or die. This could happen in the 14.1% of the cases where the result is a false negative. Therefore, in order to avoid this problem all fluids with a negative OD_{650} reading must be further checked with an L/S ratio. The OD_{650} test is inexpensive and rapid and the information derived is valuable if the results are positive. When critical decisions such as referral to a tertiary care unit or premature delivery are to be made, it seems that the most sophisticated fetal maturity test possible must be available. As more studies are done, it may turn out that tests which are even more complicated than the L/S ratio such as the phosphatidyl glycero and phosphatidyl inositol measurements are the ones we will need for backup rather than the simpler ones such as the optical density determinations.[13] Further studies in this area are underway.

The authors would like to thank Mrs. M. Rountree for her help in these studies and Ms. E. Wells for her help in preparing the manuscript.

Antepartum fetal testing

I. The oxytocin challenge test

M. ISMAIL BARRADA, M.D.
LAURA E. EDWARDS, M.D.
ERICK Y. HAKANSON, M.D.
St. Paul, Minnesota

Two hundred seventy-eight high-risk patients were managed by a comprehensive assessment of the anatomic, biochemical, and functional environment of the fetoplacental unit utilizing predetermined guidelines. Decisions to terminate pregnancy were reserved for patients who demonstrated a positive OCT. Perinatal outcome in patients with positive OCT's was significantly worse than in patients who did not have a positive OCT. Patients with suspicious OCT's frequently had positive OCT's and were more likely to bear growth-retarded infants, whereas negative OCT's in general were associated with a favorable outcome. Correlation of estriol excretion with the OCT and perinatal outcome was inconsistent. There were a total of four prenatal deaths, all of which were considered unpreventable. (AM. J. OBSTET. GYNECOL. 134:532, 1979.)

A COMPREHENSIVE approach to the antepartum assessment of the intrauterine environment consists of adequate evaluation of the anatomic, biochemical, and functional status of the fetoplacental unit. In this institution, anatomic assessment involves routine ultrasound cephalometry during early gestation.[1] Biochemical tests include 24 hour urinary estriol determinations,[2] and amniotic fluid analysis for both the L/S ratio[3] and spectrophotometric analysis in instances of Rh isoimmunization.[4] Functional evaluation involves electronic monitoring of the fetal heart rate (FHR) for periodic changes in response to oxytocin-induced uterine contractions, the oxytocin challenge test,[5] and for accelerations in response to fetal movements,[6] a "nonstress" test.

With this information provided the task would be primarily to determine whether the intrauterine environment has been sufficiently compromised to warrant termination of the pregnancy, and then to select the appropriate time for intervention.

The present study was undertaken in order to evaluate the role of the functional methods of assessing the pregnancy at risk for fetal compromise and will be reported in two parts: Part I describes the experience and pregnancy outcome in patients who have undergone an oxytocin challenge test (OCT) and Part II describes the experience with a standardized nonstress test (NST).

Material and methods

During the interval between January, 1974, and July, 1977, a total of 420 OCT's were performed on 278 patients who were considered at risk for a compromised fetoplacental unit.

Patients selected for this test were admitted to the labor and delivery ward and were positioned at a comfortable recumbancy (approximately 30 to 40 degrees) with a slight left tilt. A continuous recording of the fetal heart rate (FHR) and uterine activity was accomplished by means of a Roche Fetal Monitor, Model Number 2102 or 2104. Maternal vital signs, including blood pressure, pulse, and temperature, were recorded at the outset and the blood pressure at periodic intervals for the duration of the test.

Oxytocin was administered with a Harvard constant-rate infusion pump, and the rate was increased at 15 minute intervals until uterine contractions occurred

approximately every three minutes. The oxytocin infusion was discontinued when a recorded segment of one-half hour was available for analysis. Patients were subsequently observed while still being monitored until uterine activity subsided, and thereafter the test was terminated.

Tests were interpreted as being positive, negative, suspicious, hyperstimulation, or inadequate as follows: (1) positive: repetitive late decelerations with most uterine contractions; (2) negative: no FHR abnormalities with apparently adequate uterine contractions; (3) suspicious: occasional late decelerations; (4) hyperstimulation: FHR deceleration in response to a prolonged uterine contraction, or late decelerations occurring with uterine contractions observed at intervals of two minutes or less, and (5) inadequate: technical difficulties or instances in which the uterus was unresponsive to oxytocin.

Whenever possible, patients scheduled for an OCT underwent a 24 hour urinary estriol determination on a sample collected the day prior to the test.

In most patients the OCT was repeated at weekly intervals. In some instances, however, such as diabetes mellitus, severe hypertension, Rh sensitization, low or falling estriol levels, and suspicious OCT's, or when the intrauterine environment was considered unusually precarious, the test was repeated at more frequent intervals.

Management was determined on the basis of the results of the OCT in conjunction with other laboratory tests and the overall clinical picture. Patients who showed a negative OCT with normal estriols had repeat testing at weekly intervals, and with low or falling estriols were tested more frequently. Patients who demonstrated a positive OCT underwent an L/S ratio determination. If the L/S ratio was mature, delivery was planned either by oxytocin induction of labor when the cervix was favorable, or by cesarean section when the cervix was unfavorable or when the oxytocin induction was judged to be unduly hazardous to the fetus. If in the ensuing induction following a positive OCT late decelerations were not observed, the procedure was discontinued and the test considered false positive. If, however, late decelerations persisted in the ensuing induction, a presumption of a diminished fetal metabolic reserve was entertained, oxytocin discontinued, and a cesarean section undertaken. If the L/S ratio was immature, betamethasone induction of pulmonary surfactant, according to the protocol described by Liggins and Howie,[7] was instituted and delivery was planned 48 hours after the initiation of therapy. In the interim, patients were continuously monitored.

Patients who demonstrated a suspicious test were retested more frequently, and further management determined according to results of the repeated tests. Patients who showed a hyperstimulation or inadequate test were retested at a convenient time in the ensuing days. In spite of the adoption of these seemingly all-inclusive guidelines, it was necessary on occasion to modify the management based on the clinical condition of the individual patient.

Newborn infants were admitted to the neonatal division of the Perinatal Center, and underwent a complete physical and neurologic examination at an appropriate time after birth. Disturbances in growth characteristics were classified into: intrauterine growth retardation (IUGR) and large for gestational age (LGA), based on the criteria set forth by Usher and McLean,[8] and dysmaturity as described by Clifford.[9]

Results

The total number of patients were divided into three groups: Group I consisted of 35 patients who demonstrated at least one positive OCT; Group II consisted of 93 patients who had no positive OCT's, and whose pregnancies were complicated by diabetes mellitus, severe hypertension, severe pre-eclampsia, or low or falling estriols, in addition to those pregnancies which resulted in the birth of a neonate with IUGR, LGA, or

dysmaturity; Group III consisted of the remaining 150 patients who did not show positive OCT's and whose pregnancies and neonatal characteristics did not include those factors mentioned in Group II. Table I shows the number of OCT's and the distribution of the types of tests in each of the three groups described.

Table II summarizes the course of action and outcome in the 35 patients demonstrating at least one positive OCT. Eleven patients underwent cesarean section shortly after a positive OCT without an attempt at oxytocin induction, in nine of these patients because of an unfavorable cervix and in two patients because of multiple suspicious and positive OCT's. In two patients no action was taken and both resulted in fetal deaths seven and ten days, respectively, following the most recent positive OCT. The former patient had viral pneumonia with a tracheostomy and an unstable pulmonary status; at delivery there was a true knot of the umbilical cord. The latter patient had diabetes mellitus, with markedly immature L/S ratios, elevated amniotic fluid alpha fetoprotein levels, and radiologic evidence of fetal malformation; at delivery the stillborn infant was grossly deformed. Five patients underwent oxytocin induction following a positive OCT and no late decelerations were observed in the ensuing induction (false positive); three delivered vaginally after uncomplicated labor, and two delivered by cesarean section for cephalopelvic disproportion. Seventeen patients underwent oxytocin induction following their positive OCT's, and all patients demonstrated persistent late decelerations in the ensuing induction; 15 were delivered by cesarean section and two were delivered vaginally. The two latter patients were delivered of newborn infants who were clinically depressed at birth and both demonstrated scalp pH's of less than 7.15 shortly before delivery; the failure to expedite delivery was considered to be an error in judgment. In subsequent analyses, the group designated as positive OCT will exclude the five patients with false positive OCT's and the nine patients who underwent a prompt cesarean section for an unfavorable cervix since any of the latter could have had false positive OCT's. Of the 35 patients who had positive OCT's, four (11.4%) patients exhibited late decelerations with spontaneous uterine activity and therefore qualify as having had positive contraction stress tests; oxytocin was administered and all four patients continued to show late decelerations. Two were delivered by cesarean section and the remaining two patients (described above) were delivered vaginally.

Table III compares the outcome of patients with positive OCT's and patients who did not show positive OCT's. With the exception of neonates who were LGA and dysmature, all other factors occurred with more frequency in the positive OCT group. Table IV compares the outcome between patients with positive OCT's and patients with no positive OCT's and high-risk factors (Group II). Only the incidences of cesarean section and low Apgar scores were more frequent in the positive OCT group.

Table V compares the outcome in patients with positive OCT's and abnormal estriols to patients with positive OCT's and normal estriols. No significant differences were observed in the characteristics evaluated.

Suspicious OCT's were observed in seven patients with positive OCT's (7/35 = 33.3%), compared to 15 patients in combined Groups II and III (15/243 = 6.2%), and this difference was significant ($p = < .001$). Moreover when patients with suspicious OCT's were collectively compared with the remaining population of patients, both infants with IUGR and those with one-

minute Apgar scores ≤6 were significantly more frequent in patients with suspicious OCT's.

Analysis of the time interval between a negative OCT and either a positive OCT or late decelerations in labor was undertaken. In Group I, of the 21 patients with positive OCT's, two were followed by fetal death, and four patients had only one OCT which was positive. Of the remaining 15 patients, there were eight patients in whom a negative OCT was followed by a positive OCT within three days, two patients within seven days, and five patients more than seven days. One patient had a negative OCT interposed between two positive OCT's that were undertaken three days apart. In Group II there were 73 patients and in Group III there were 117 patients in whom the most recent negative OCT was undertaken within one week of delivery and there were no fetal deaths in either group. In Group II, however, five of the 73 patients (6.8%) showed late decelerations in labor; in one patient immediately after completion of the negative OCT, in two patients one day after the negative OCT, and in two patients four days after the negative OCT. In Group III two of the 117 patients showed late decelerations in labor (1.7%) and in both instances the oxytocin induction was undertaken immediately after completion of the negative OCT.

There were 26 infants with IUGR who had both OCT's and estriol determinations; 10 (38.5%) had positive OCT's, 15 (57.7%) had low or falling estriols, and 8 had neither of the two abnormalities.

Table VI describes the frequency of spontaneous rupture of the membranes and the occurrence of spontaneous labor within 24 hours of OCT's undertaken before 38 weeks and at 38 weeks' gestation or more. In the preterm interval there were two patients who developed spontaneous labor within 24 hours of the OCT at 36 weeks and 37 weeks, respectively, and the outcome in both infants was uncomplicated.

There were four perinatal deaths in the population studies: two fetal deaths in utero described earlier, and two neonatal deaths because of severe congenital malformations incompatible with life. The perinatal mortality rate corrected for severe malformations was, therefore, 3.6 per 1,000 live births.

Comment

The development of the OCT as a method of assessing the functional environment of the fetus without imposing a threat to its existence has undoubtedly been a breakthrough in modern obstetric practice. In the present study, aside from two patients who developed spontaneous premature labor within 24 hours of the test, no maternal or fetal complications could be directly attributed to the procedure.

Table VI. The occurrence of spontaneous rupture of the membranes and spontaneous labor within 24 hours of the OCT

	No.	*Spontaneous labor*	*Spontaneous rupture of membranes*
<38 wk.	158	2(1.3%)	0
≥38 wk.	267	15(5.6%)	7(2.6%)
Total	425	17(4.0%)	7(1.6%)

There were four perinatal deaths and all were considered unpreventable. In one patient with fetal death in utero, no intervention was undertaken because of the critical condition of the mother, and in the remaining three patients fetal and neonatal deaths occurred because of severe malformations. Adherence to the guidelines adopted at the outset of the study is felt to be responsible for this favorable outcome.

The occurrence of late decelerations in response to either spontaneous or oxytocin-induced uterine contractions has been shown to be associated with fetal acidosis,[10] low Apgar scores, and a significantly large percentage of infants with poor outcome.[11] Persistent late decelerations following a positive OCT in all likelihood, therefore, should serve as a valuable indicator of a diminished fetal metabolic reserve and a cesarean section in these instances would be justified as a therapeutic measure to prevent fetal deterioration. Early intervention in these patients may explain the relatively high number of newborn infants with good Apgar scores in spite of persistent late decelerations following their positive OCT. The results of the present study corroborate these observations: in the only two patients in whom delivery was not expedited following a posi-

tive OCT, fetal death occurred shortly thereafter, and in the two patients who continued to show late decelerations in the ensuing induction following a positive OCT, and in whom a cesarean section was not undertaken, resulted in the birth of depressed infants. In addition, high-risk factors such as meconium staining of the amniotic fluid, low or falling estriol levels, IUGR, and low Apgar scores were more frequent in patients with positive OCT's when compared with patients who did not have a positive OCT, and as would be expected, cesarean sections were also undertaken with more frequency in those patients. However, when patients with positive OCT's were compared with patients in Group II who did not have a positive OCT but whose pregnancies were at risk for a compromised metabolic reserve, the only difference observed was lower one- and five-minute Apgar scores and again, as would be expected, a high cesarean section rate. Modanlou and colleagues[12] have shown that a low one-minute Apgar score reflects low fetal scalp pH's and a low five-minute Apgar score reflects on an even more profound depression of fetal scalp pH's. The results of the present study further confirm that even when factors such as meconium, abnormal estriol excretion patterns, and IUGR were equally distributed among a high-risk population of patients, those with positive OCT's were metabolically more compromised and, therefore, more likely to be delivered by cesarean section.

The implication of a false positive OCT is that even though repetitive late decelerations were observed for the duration of the test, the metabolic condition of the fetus is in reality undisturbed. The most plausible explanations have been set forth by Freeman and associates[13] who attribute the phenomenon, among other causes, to the transitory compression of the inferior vena cava while patients are in the recumbent posture. In the present study roughly 23% of patients with positive OCT's had a false positive test. From the standpoint of clinical management, therefore, it would be desirable to consider all patients with positive OCT's collectively as being at risk and institute the appropriate therapeutic guidelines adopted at the outset. If in so doing it becomes apparent that the test was false positive, subsequent management should then be modified to suit the individual patient.

The negative OCT in general was associated with a favorable outcome; however, there were many instances in which negative OCT's were observed in very close proximity to positive OCT's and a few instances in which late decelerations were observed during the ensuing labor following a negative OCT. Moreover, of the 26 growth-retarded infants born during this study, only ten had positive OCT's and the remaining 16 had negative OCT's. Although fetal death within one week of a negative OCT was not observed in the present study, and only very rarely in previous reports,[14, 15] the fact remains that fetal death is a somewhat inappropriate end point for the assessment of fetal health.

Suspicious OCT's were observed with more frequency in patients with positive OCT's than in patients with negative OCT's. In addition, patients with suspicious OCT's were more likely to bear growth-retarded infants. These observations justify more frequent evaluations of the functional environment of the fetus in patients who have demonstrated a suspicious OCT.

The results of this study have also shown that the correlation between abnormal estriol excretion and the results of the OCT and neonatal outcome was somewhat disappointing. Patients with positive OCT's were more likely to have abnormal estriols when compared with patients who did not have positive OCT's. However, of the 21 patients with positive OCT's only eight had abnormal estriols, and of the 26 growth-retarded infants only 15 had abnormal estriols. Moreover, the outcome in patients with abnormal estriols and positive OCT's was not significantly different when compared with the outcome in patients with normal estriols and a positive OCT, indicating that in patients with positive OCT's the finding of abnormal estriol does not necessarily signify a more seriously compromised fetus.

In conclusion, the results of this study have revealed a number of inconsistencies which place some limitations on the information that can be derived from the tests outlined. Both negative OCT's and normal estriols were certainly informative but did not invariably reflect a healthy fetal environment, whereas suspicious OCT's served as a warning for possible impending problems. A positive OCT, however, was invaluable in detecting the seriously compromised fetus and in determining the most opportune time for intervention. The latter conclusion should be weighed against the fact that of the 425 OCT's performed there were only 37 positive tests, a ratio which leaves much to be desired.

We acknowledge the assistance of Sheila Hurley and John E. Connett, Ph.D., for statistical methods.

Antepartum fetal testing

II. The acceleration/constant ratio: A nonstress test

M. ISMAIL BARRADA, M.D.
LAURA E. EDWARDS, M.D.
ERICK Y. HAKANSON, M.D.
St. Paul, Minnesota

For a period of one-half hour of undisturbed fetal monitoring, periodic changes of the FHR in response to spontaneous fetal movements (FM's) were recorded. FM's in patients who subsequently had positive OCT's were less likely to show accelerations ($p = <0.001$) and more likely to show variable decelerations ($p = <0.001$) and no change ($p = <0.001$) in the FHR when compared with patients who did not have a positive OCT. A ratio between the number of FM's associated with accelerations and the sum of FM's associated with no change and decelerations was defined as the acceleration/constant (A/C) ratio. The outcome in patients who exhibited reactive tests (i.e., A/C ratio >1) was more favorable than the outcome in patients with nonreactive tests (i.e., A/C ratio ≤1). Patients with positive OCT's universally showed nonreactive tests, whereas patients with false positive OCT's were more likely to have reactive tests. Evidence is presented to suggest that the A/C ratio is more predictive of the intrauterine environment than the OCT. (AM. J. OBSTET. GYNECOL. 134:538, 1979.)

AT THE outset of electronic monitoring of the fetal heart rate (FHR), efforts were directed toward defining the pathophysiologic basis for periodic decelerations in response to uterine contractions and their relation to neonatal outcome.[1] Accelerations of the FHR were observed but their significance eluded definition until Lee and associates[2] reported that their occurrence was invariably associated with a favorable neonatal outcome. Since then several investigators have corroborated this observation.[3-6]

The finding that late decelerations were associated with fetal asphyxia and metabolic acidosis[7] led to the development of the oxytocin challenge test.[8] Along the same lines, the finding that FHR accelerations were associated with a good outcome resulted in the emergence of the "nonstress test" (NST). The term was chosen on the grounds that the desired end point, FHR accelerations, was not invoked by an external stressful stimulus.

Table I. Distribution of patients with positive OCT's according to management and outcome

No. of patients	*Management-outcome*	*Comments*
4	Prompt cesarean section	2–Unfavorable cervix
1	No intervention—fetal death in utero	Fetal anomaly
3*	Oxytocin induction—no fetal distress	1–Vaginal delivery 2–Cesarean section for cephalopelvic disproportion
7	Oxytocin induction—persistent fetal distress	7–Cesarean section

*False positive OCT 3/10 = 30%.

The standards, however, that have been employed both in the technique and definition of nonstress testing have varied. The present study describes a standardized NST based on the response of the FHR consequent to spontaneous and unprovoked fetal movements (FM's) within a finite period of time; the study also attempts to define the predictive value of this test

in identifying the fetus at risk, by comparing it with the oxytocin challenge test (OCT), estriol excretion, and neonatal outcome.

Materials and methods

Between January, 1976, and July, 1977, consecutive NST's and OCT's were performed on 157 patients who were considered at risk for a compromised fetoplacental unit. For a period of one-half hour of continuous FHR monitoring prior to an OCT, patients were instructed to signal an observer every time a FM was appreciated, and a mark was inserted at the appropriate point on the recording strip.

A periodic change of the FHR in response to each individual and unprovoked FM was clasified as either acceleration, no change, deceleration, or artifact according to the following: (1) acceleration: an acceleration of the FHR to a peak of 15 beats per minute (bpm) or more and lasting 10 seconds; (2) no change: no significant alteration in the constancy and beat-to-beat variability of the FHR; (3) deceleration: a variable type deceleration with a peak of 15 bpm or more and lasting 10 seconds; and (4) artifact: a noninterpretable segment of the FHR. A rapid succession of FM's occurring within a 20 second interval was scored as one movement. Moreover, if a prolonged acceleration was observed, the number of FM's occurring within the time span of the acceleration was collectively counted as one movement.

Immediately upon completion of the NST, an OCT was conducted. Management in each individual patient was undertaken on the basis of the results of the OCT in conjunction with other laboratory tests and the overall clinical picture as outlined in Part I of this study.

Results

The total number of patients who underwent consecutive fetal movement acceleration tests and OCT's was divided according to the outcome of the OCT into two groups: Group I consisted of 15 patients who had shown at least one positive OCT, and Group II consisted of the remaining 142 patients who had no positive OCT's.

The outcome of the 15 patients who demonstrated positive OCT's is shown in Table I. Four underwent prompt cesarean section without an attempt at oxytocin induction, two for an unfavorable cervix and two for an unusually precarious intrauterine environment as evidenced by multiple suspicious and positive OCT's. In one patient no action was taken because of elevated amniotic fluid alpha fetoproteins and radiologic evidence of fetal anomalies; fetal death in utero occurred ten days following the last positive OCT. Three patients underwent an oxytocin induction following the positive OCT and no late decelerations were observed in the ensuing induction (false positive). Seven patients underwent oxytocin inductions after a positive OCT and all were delivered by cesarean section because of persistent late decelerations in the ensuing induction. In subsequent analyses, the group designated as positive OCT will exclude the three patients who had false positive OCT's and the two patients who underwent prompt cesarean section for an unfavorable cervix since either of the latter two could have had a false positive OCT.

Table II shows the results of the NST in the two groups described. Statistical analysis, utilizing two-tailed tests, showed no significant differences in the number of movements, and the number of artifacts. Accelerations, however, were less frequent in Group I, and no change, decelerations, and the sum of no change and deceleration were more frequent in Group I.

Based on these observations, a ratio between the number of FM's that were associated with accelerations of the FHR divided by the sum of FM's associated with no change and those associated with decelerations was constructed. This was defined as the acceleration/ constant (A/C) ratio as follows:

Table III. Characteristics of patients with positive OCT's

†Only 130 of 142 patients with no positive OCT had estriol determinations.

$$\text{A/C ratio} = \frac{\text{Accelerations}}{\text{No change + decelerations}}$$

An NST in which accelerations of the FHR in response to FM were preponderant would show an A/C ratio of more than one; this was defined as a reactive test. An NST in which the majority of FM's were associated with either no change or decelerations of the FHR would show an A/C ratio of less than one; this was defined as a nonreactive test. Of the total 237 tests performed, there were 12 in which the A/C ratio was exactly one: two in Group I (one associated with a positive OCT and one with a false positive OCT) and ten in Group II. A test with an A/C ratio of exactly one was defined as a nonreactive test.

Table III outlines the details of the NST's in relation to the OCT, time before delivery, estriol excretion, and outcome in the ten patients with positive OCT's.

Table IV compares patients with positive OCT's and patients who did not have a positive OCT with respect to the distribution of a number of maternal and neonatal characteristics and to the distribution and variables of the NST.

Next, the total population of patients was divided into two groups: 58 patients who had at least one nonreactive test within one week of delivery and 61 patients who had a reactive test within one week of delivery, and Table V compares outcome between these two groups.

Table VI shows the details of the NST's in relation to the OCT's, time before delivery, estriol excretion, and outcome in the three patients with false positive OCT's.

Table V. Comparison of outcome between patients with nonreactive and with reactive NST's undertaken within one week of delivery

	Nonreactive NST (N = 58)		*Reactive NST (N = 61)*		
	No.	*%*	*No.*	*%*	*p*
Cesarean section	22	37.9	9	14.8	<0.01

Estriol: low or falling*	19	33.3	8	15.1	<0.01
IUGR	11	19.0	3	4.9	<0.02
Dysmature	5	8.6	11	18.0	NS
LGA	6	10.3	5	8.2	NS
Apgar: 1 min. ≤ 6	10	17.2	4	6.6	NS
5 min. ≤ 6	1	1.7	0	0.0	NS
Number of NST's	79		63		
Positive OCT's	13	16.5	2	3.2	<0.01
Suspicious OCT's	8	10.1	2	3.1	NS
Tests with decelerations	31	38.3	4	6.2	<0.001
Tests with <3 accelerations	50	63.3	2	3.2	<0.001

*Only 57 of 58 patients with nonreactive NST's and 53 of 61 patients with reactive NST's had estriol determinations.

There were 16 suspicious OCT's with concomitant NST's of which 13 (81.3%) were nonreactive, 9 (56.3%) showing <3 accelerations, and 6 (37.5%) showing decelerations.

Finally, Table VII describes the frequency of positive OCT's, nonreactive NST's, and abnormalities in estriol excretion in neonates with a disturbance in growth during intrauterine development.

Comment

The results of this study have shown that periodic changes of the FHR consequent to spontaneous and unprovoked FM's show a good correlation with fetal outcome. FM's in patients with positive OCT's were rarely associated with accelerations and frequently associated with variable type decelerations or no change of the FHR. Conversely, FM's in patients who did not show positive OCT's were frequently associated with accelerations and rarely associated with decelerations of the FHR. These observations formed the basis for constructing the A/C ratio in an effort to provide for a quantitative method of assessing the degree of reactivity of the FHR within a finite period of time.

Analysis of the data based on the A/C ratio supported the ratio as a sensitive method for predicting neonatal outcome. Nine of ten patients and 23 of 24 NST's performed on patients with positive OCT's showed nonreactive ratios and the only one reactive

At least one abnormal test	8	33.3	4	57.1	17	89.4

test was observed 32 days before delivery of an infant with IUGR. In contrast, patients who did not show a positive OCT demonstrated a strikingly higher number of reactive ratios. Furthermore, the A/C ratio provides an additional dimension to the assessment of the reactivity of the FHR by incorporating into the final formula FM's associated with no change and decelerations, since the latter two were significantly more frequent in patients with positive OCT's.

Several observations seemed to suggest that the A/C ratio is more sensitive than the OCT as an indicator of fetal compromise: (1) the NST's that were performed on patients who later in the course of their antenatal testing demonstrated a positive OCT were almost universally nonreactive; (2) patients who had false positive OCT's were more likely to have reactive NST's; and (3) newborn infants with IUGR and LGA more often showed nonreactive NST's than positive OCT's.

The hypothesis of this study is predicated on the clinical observation that motion of a healthy fetus results in acceleration of the heart rate, whereas in the case of an unhealthy fetus motion seldom results in accelerations, and often results in decelerations or no change of the heart rate. The regulation of myocardial contractility is under control of the components of the autonomic nervous system, the sympathetic and parasympathetic, which exert contrasting effects upon the different tissues of the heart.[9] Adrenergic impulses in general increase the contractility of the atrial and ventricular muscles, whereas cholinergic impulses exert an opposing effect. Equipped with these two mechanisms, the organism is capable of maintaining a fine adjustment in cardiac rhythm in the face of a constantly changing environment. When the organism is challenged, the sympathetic system is called upon to discharge as a unit, thereby exerting an effect on all tissues innervated by that system including the myocardium, with the resultant increase in the heart rate and blood pressure.

Regulation of the heart rate of the fetus has been shown to be under control of the autonomic nervous system.[10] With a minor challenge such as motion, it is not clear whether acceleration of the heart rate is a result of a discharge of sympathetic activity or a release of parasympathetic inhibition, although evidence suggests that the sympathetic system predominates in the control of cardiac rhythm during fetal life.[10] It is possible that a fetus with diminished metabolic reserve exhibits a general lassitude of the autonomic nervous system and consequently fails to manifest accelerations of the heart rate with motion.[11] In addition, the existence of a weak circulatory system may be responsible for a loss of turgor of the umbilical cord; motion of the fetus in this instance would predispose the vulnerable cord to entanglement and therefore variable-type decelerations.

In the present study, the one-half hour segments considered for analysis were spontaneous and no effort was made to arouse the quiescent or "sleeping" fetus.

In the interest of exactitude, NST's should be conducted in a uniform manner where either all movements that are spontaneous should be considered for analysis or all fetus' should be challenged by a measurable and reproducible stimulus, be it sound,[12] light, or tactile arousal.

The term nonstress test (NST) was used in this study in order to comply with existing nomenclature, although in the opinion of the authors it is somewhat nonspecific. The term encompasses any number of tests in which a stressful challenge was not exerted in order to elicit the desired end point. The term fetal acceleration determination (FAD) test proposed by Lee and Associates[4] is more descriptive but still nonspecific since it can describe any test which determines accelerations of the FHR. The authors propose the term "fetal movement acceleration test" (FMAT) because it describes the two most salient features of this test, namely FM's as well as accelerations of the FHR. In addition, it provides a latitude of flexibility since it can be adjusted to accomodate tests which utilize sound[12] (fetal sound acceleration test), tactile arousal (fetal arousal acceleration test), or other tests along similar lines.

In conclusion, the A/C ratio as a measure of the degree of reactivity of the FHR has been shown to be a sensitive method for the antepartum assessment of fetal well-being. Reactive ratios were associated with a favorable outcome whereas nonreactive ratios were associated with a less favorable outcome. All FMAT's undertaken within a week of positive OCT's were nonreactive. The finding, however, of a number of nonreactive ratios in patients who had a favorable outcome suggests that the test is more suitable as a screening procedure to select candidates for an OCT. Exceptions may be made in view of the findings reported here suggesting that the FMAT may be more sensitive than the OCT. Decisions to terminate pregnancy when the FMAT is nonreactive and the OCT is negative may in selected circumstances be considered appropriate. Examples of such clinical conditions would be patients who manifest a mature L/S ratio in addition to one or more of the following factors: strong clinical evidence for IUGR or LGA, abnormalities in estriol excretion patterns, meconium staining of amniotic fluid, or patients who demonstrate frequent and repeated nonreactive FMAT's.

We acknowledge the assistance of Sheila Hurley and John E. Connett, Ph.D., for statistical methods.

Fetal breathing movements in uncomplicated pregnancies

I. Relationship to gestational age

H. E. FOX, M.S., M.D., F.A.C.O.G.
J. INGLIS, PH.D.
M. STEINBRECHER, B.S.
Rochester, New York

Fetal breathing movements occur in uncomplicated gestations. The relationship of fetal breathing movements recorded in 30 min sessions to gestational age and blood glucose levels is described. A total of 142 recording sessions were obtained from 45 gravid women with uncomplicated pregnancies from 24 to 41 weeks' gestation. There was a significant increase in the proportion of time spent in fetal breathing as gestational age increased. Glucose levels in a normal range (70 to 120 mg/100 ml) at the time of the recording sessions showed no correlation with the proportion of fetal breathing time. (AM. J. OBSTET. GYNECOL. 134:5-4, 1979.)

FETAL BREATHING (FB) movements have been documented in both animal and human gestations. In animal models, FB movements occurred during fetal activity similar to rapid eye movement sleep.[1, 2] Many studies have shown the effects of hypoxia, hypercapnia, and medications on FB movements.[3] In human gestation, it is known that the administration of glucose to the mother is followed by an increase of the time spent in FB.[4, 5]

Noninvasive A-scan, Doppler, and real-time B-scan ultrasound techniques all have been used to record indications of human FB movements. The real-time B-scan imaging system* provides an especially consistent presentation of these movements.[3]

In order to assess the value of FB movement observations in clinical fetal medicine, an understanding of the natural history of their occurrence in uncomplicated gestation is necessary. This report presents data on the relationship between gestational age, maternal blood glucose levels, and the amount of FB observed.

**Advanced Diagnostic Research, Inc., Tempe, Arizona.*

Population

The population consisted of 45 Caucasian gravid women with singleton uncomplicated pregnancies as judged by criteria similar to those of Goodwin and associates.[6] Three breech presentations were included. Maternal age ranged from 19 to 36 years with a mean of 27 ± 3.8 (S.D.) years. Neonatal weights ranged from 2,480 to 4,150 grams with a mean of 3,302 ± 388 (S.D.) grams. There were 20 female and 25 male infants. Gestational age (GA) at delivery ranged from 36 to 42 weeks with a mean of 39.5 ± 1.5 (S.D.) weeks. All 1 min Apgar scores were 5 or greater and all 5 min Apgar scores were 8 or greater. There was one case of intrapartum fetal distress due to apparent occult umbilical cord prolapse. None of the women were in labor during the recording sessions. No patient was delivered within 48 hours of a study session.

Method

Study sessions were approximately 30 min (mean 27 min, median 30 min) at specified times in the morning or afternoon. A linear-array transducer system* (2.25 MHz) was used to produce a longitudinal real-time B-scan image including the fetal thorax and abdomen. Patients were placed in the semi-Fowler position to avoid supine hypotension. No hypotension was noted during the recording sessions and the stabilization period was 10 min. During each recording session, the transducer was moved to maintain consistent orientation of the fetus for visual interpretation of FB

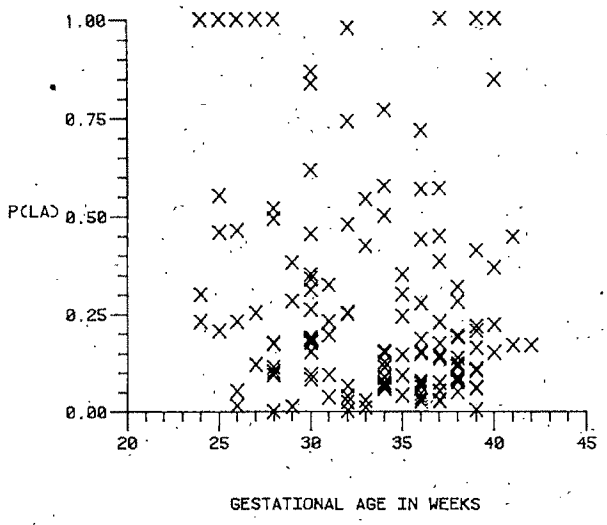

Fig. 1. Proportion of time spent in longest apnea versus gestational age in weeks.

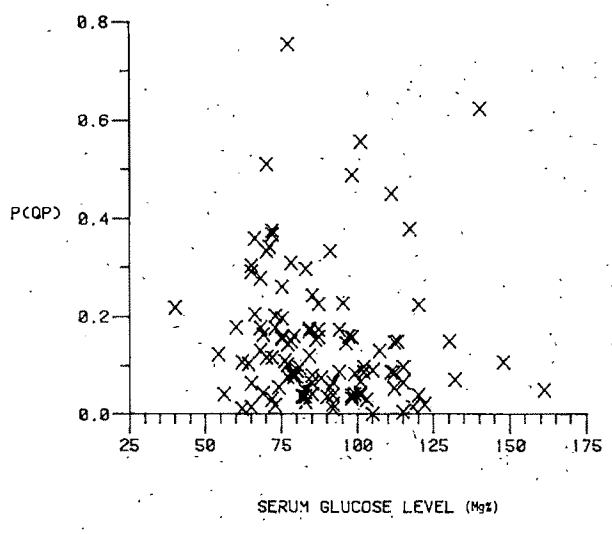

Fig. 2. Proportion of time spent in the longest period of neither breathing nor moving versus blood glucose level.

movements. A blood glucose level was determined by the glucose oxidase method at the beginning of each session. A continuous videotape record of the real-time B-scan image was made of each study session. The videotape was replayed and manually coded onto a polygraph record indicating FB, other fetal movement, and artifact (due to transducer or maternal movement).

The records were analyzed and the following measurements made: total examination time (TT), total FB time, total other fetal movement time (M) (not including FB), longest quiet period (QP), and the longest apnea period (A). Other fetal movement time was defined as documented movement time during which breathing activity could not be determined. A quiet period was defined as a period with no FB or other fetal movement. Apnea was defined as an interval (more than 6 sec) between observed fetal breathing episodes. An apnea interval might include fetal movements other than FB.

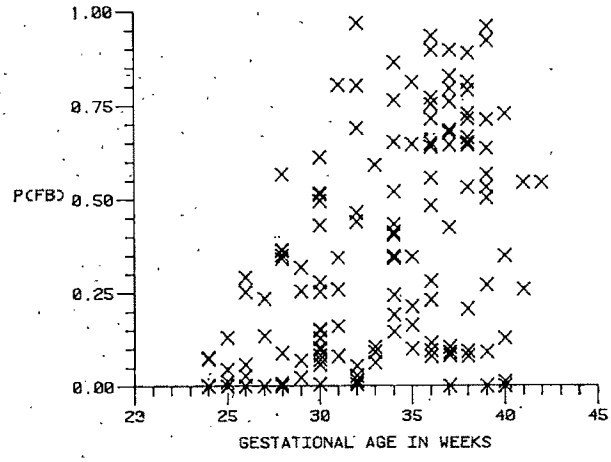

Fig. 3. Proportion of time spent in fetal breathing activity versus GA.

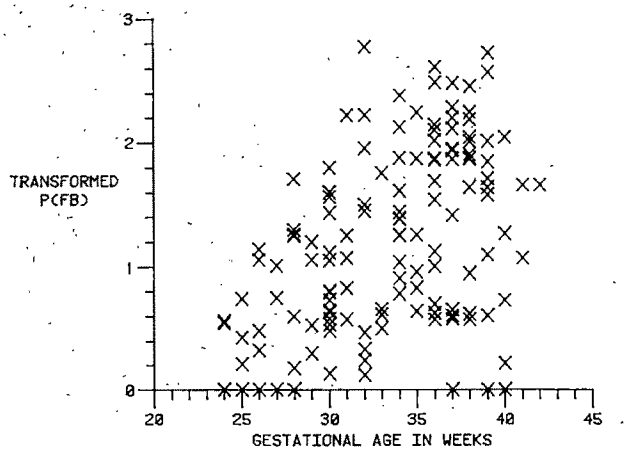

Fig. 4. Transformed proportion of time spent in fetal breathing versus GA.

Observations were made from 24 weeks' gestation to delivery. Gestational age was verified by examination of the neonate after birth.

Results

Data obtained from 142 examinations on the 45 patients were analyzed. Because of variation in total examination time, variables of interest were considered as proportions (P).

The three variables considered were:

1. P(FB) = FB/TT-M—the proportion of the examination time when all fetal activities were discernible that was spent in breathing activity.
2. P(QP) = Q-P/TT-M—the proportion of the examination time when all fetal activities were discernible that was spent in the longest period of neither breathing nor moving.
3. P(LA) = LA/TT—the proportion of the exami-

Table I. Proportion of time spent breathing in various GA categories

GA (wk)	*Examinations (N)*	*P (FB) (mean ± SE)*
24-29	33	0.12 ± 0.03
30-34	46	0.33 ± 0.04
35-39	54	0.51 ± 0.04

nation time in the longest observed period of apnea.

Comparison of morning and afternoon values for all proportions showed no statistical differences. In subsequent analyses, the data were considered as a single group.

Fig. 1 shows P(LA) versus GA. There was no obvious relationship although the rank-order correlation was − 0.21, suggesting a slight inverse relationship. There was a wide variation in P(LA) and in the actual values of LA at all gestational ages. In Nine sessions apnea was present during the entire session. There was an insignificant relationship between P(LA) and blood glucose values (rank-order correlation = − 0.24).

No strong relationship exists between P(QP) and GA (rank-order correlation = − 0.06). Fig. 2 shows P(QP) versus blood glucose levels. There was no clear relationship although the rank-order correlation was −0.22, again suggesting an inverse relationship.

Fig. 3 shows a plot of P(FB) versus GA. There was a clear positive relationship with increasing variability in P(FB) as GA increases. The rank-order correlation was 0.46. Table I shows the average P(FB) as various GA categories.

Because P(FB) is a proportion, the usual regression techniques were not appropriate, so further investigation of the relationship between P(FB) and GA was done with a standard transformation for proportions (2 arc sine $\sqrt{\ }$) and weighted regression.[8] Fig. 4 shows a plot of the transformed P(FB) versus GA. The linear term ($F = 34.9$) was significant ($p < 0.001$) and the nonlinear term ($F = 1.2$) was not, indicating that a simple linear relationship between the transformed P(FB) and GA holds. The addition of the blood glucose levels to the regression equation did not improve the fit.

Comment

A positive correlation exists between the proportion of time spent in FB activity and advancing GA. The relationship is most clear for GAs of less than 32 weeks (refer to Fig. 3). The premature neonate demonstrated developmental changes in breathing patterns as GA advanced.[7] It is reasonable to expect that similar developmental changes are expressed in the intrauterine breathing activity. The relationship between the proportion of time spent in FB and GA may reflect respiratory neuroregulatory control maturation.

An intravenous glucose load administered to the mother increased the occurrence of FB.[4] Also, an oral glucose load has been shown to produce a similar effect.[5] The blood glucose level prior to the recording session was recorded in order to determine any relationship between glucose level and the proportion of time spent in FB with respect to GA. Over a normal glucose range, no significant correlation between blood glucose levels and the proportion of time spent in FB was observed.

Conclusions

There is a significant relationship between the proportion of time spent in FB and GA. This relationship is most obvious at less than 32 weeks' gestation. Maternal blood glucose levels in a normal range at the time of the recording sessions show no significant correlation with the proportion of time spent in breathing activity.

There is an increasing variance in the proportion of time spent in FB as GA increases. It is important to recognize this large degree of variability in the occurrence of FB activity in uncomplicated patients when one considers the study of FB movements as a clinical indicator of fetal condition.

Prenatal diagnosis of Tay-Sachs disease: Studies on the reliability of hexosaminidase levels in amniotic fluid

EUGENE E. GREBNER
LAIRD G. JACKSON
Philadelphia, Pennsylvania

Measurement of hexosaminidase A activity in amniotic fluid was found to be a reliable diagnostic test in the prenatal diagnosis of Tay-Sachs disease. Including normal control specimens, analysis of 39 amniotic fluid samples have correctly predicted the condition of the fetus or, in pregnancies not yet come to term, have been in agreement with results from cultured cell extracts. In each case where both fluid and cultured cell extracts were analyzed, the results were in agreement. Analyses were performed by means of Cellogel, starch gel electrophoresis, polyacrylamide gel electrophoresis, or heat inactivation. (AM. J. OBSTET. GYNECOL. 134:547, 1979.)

THE MEASUREMENT of hexosaminidase A (hex A) activity in amniotic fluid and cultured amniotic fluid cells is the standard procedure for in utero diagnosis of Tay-Sachs disease. Although the hex A deficiency diagnostic of the disease has been demonstrated in both fluid and cultured cell extracts,[1, 2] the reliability of the enzyme levels in fluid has not yet been firmly established and the use of cell extracts is generally advocated.[3, 4]

The results of 27 prenatal diagnoses in our laboratory support those of an earlier report[2] suggesting that amniotic fluid and cultured cell extracts are equally reliable. The presence or absence of hex A in fluid was clearly discernible, and the reliability of this determination seems adequate to warrant use of fluid for early diagnosis while growth of cultured cells for confirmation is awaited. The use of *both* fluid and cell extracts is still strongly indicated because enzymes derived from two different sources provide a valuable cross-check as an added measure of safety.

Methods

Preparation of samples. Approximately 15 ml samples of blood-free amniotic fluid were centrifuged at 300 × g to collect the cells for culturing. The supernatant fluids were tested with urinalysis reagent strips* to verify that the samples were not maternal urine[5] and recentrifuged at 25,000 × g at 4° C for 20 minutes. Five milliliters of the supernatant fluid were concentrated approximately 25-fold in a Minicon B-15 concentrator† at 4° C and used directly for electrophoresis or stored frozen.

Amniotic fluid cells were cultured in Eagle's basal medium (supplemented with 20% fetal calf serum), washed, and suspended in 100 to 200 μl of 0.9% NaCl. Extracts were prepared by freezing and thawing the cell suspension five times. The extract was centrifuged at 1,000 × g for 10 minutes and the cell-free supernatant fluid was used for electrophoresis without further treatment.

Substrate. A 3 mM solution of 4-methylumbelliferyl-N-acetylglucosaminide in 6.1 mM citrate 10 mM phosphate buffer pH 4.4 (C-P buffer) was used as substrate in all experiments.

Electrophoresis. Cellogel strips (5.7 × 14 cm) containing 10 μl of each sample were electrophoresed for 2 hours in 0.04M potassium phosphate buffer, pH 6.5, according to manufacturer's instructions. Strips were dipped in substrate for 15 seconds, incubated in a moist chamber, and viewed under ultraviolet light.

‡See discussion in text.

Starch gel electrophoresis was performed according to the method of Smithies.[6] Gels (14%) were prepared in 5 mM citrate 17.8 mM phosphate buffer pH 6.2. Fifty microliters of each sample were applied to the slots and the gels were electrophoresed for 18 hours at a constant current of 40 mA at 4° C in 0.04M citrate and 0.143M phosphate buffer, pH 6.2. Gels were sliced horizontally and covered with a sheet of filter paper moistened with substrate. After incubation at 37° C for 20 minutes, enzyme bands were visible under ultraviolet light.

Polyacrylamide gels (PAGE) and buffers were prepared according to the method of Friedland and associates.[7] Twenty microliters of sample were mixed with 40 μl of 40% sucrose solution and 20 μl of 0.1M phosphate buffer, pH 7, containing 0.9% NaCl. The mixture was electrophoresed at 2.5 mA per tube for 70 minutes at ambient temperature. Gels were frozen, sliced, and assayed by suspending each slice in 100 μl of C-P buffer to which was added 100 μl of substrate. After incubation for 30 minutes at 37° C, the reaction was stopped with 4.85 ml of 0.17M glycine-carbonate

buffer pH 10, and free 4-methylumbelliferone was measured fluorometrically.

Heat inactivation was performed essentially as described by Kaback.[8] Samples were prepared by diluting 200 μl of unconcentrated amniotic fluid with 1.2 ml of C-P buffer containing 5.75 mg/ml hexosaminidase-free human serum albumin. Inactivation was done under three conditions, 50° C, 2 hours; 52° C, 2 hours; and 60° C, 5 minutes.

Normal and affected control samples were simultaneously run with all samples.

Results

Since 1975, 20 pregnancies at risk for Tay-Sachs disease have been monitored by measuring hex A levels in amniotic fluid and in cultured cell extracts. Samples were analyzed by PAGE, starch gel electrophoresis, Cellogel electrophoresis, or heat inactivation. In every case the results of amniotic fluid and cultured cell extracts were in agreement (Table I, Set A). Seven cases were diagnosed as affected since no trace of hex A was found by any electrophoretic procedure. Thirteen cases showed the unambiguous presence of hex A. Confirmation of all diagnoses was made by measuring hex A levels in cord blood at birth or in tissue extracts of abortuses.

A second set of fluids was tested retrospectively from prenatal diagnoses prior to 1975 when only cultured cell extracts had been used (Table I, Set B). These fluids, which had been stored frozen from 2 to 4 years, still yielded the correct results. Finally, normal (from nonJewish patients) control samples are shown in Table I, Set C. In every case, analysis of the fluid correctly diagnosed the condition of the fetus or, in the two pregnancies not yet come to term (Nos. 19 and 20), have been in agreement with results from cell extracts.

Fig. 1 shows four examples of results obtained with PAGE of amniotic fluid. In all fluids examined by this method, the presence or absence of hex A peak was equally unequivocal. Less clear-cut distinction was obtained from heat inactivation studies on the amniotic fluid samples of set A which at 52° C gave hex A values for affected cases ranging from 3.2 to 7.2 despite the fact that all three electrophoretic procedures showed no trace of hex A for the same samples. We interpret this to mean that the residual hex A activities indicated in the affected fetuses by heat inactivation are spurious values resulting from the usually unavoidable destruction of some hex B or I, which by definition is then designated as hex A. This interpretation is based on our observation that regardless of how conditions of inactivation are varied (pH, temperature, ionic strength, etc.), when adequate destruction of hex A is

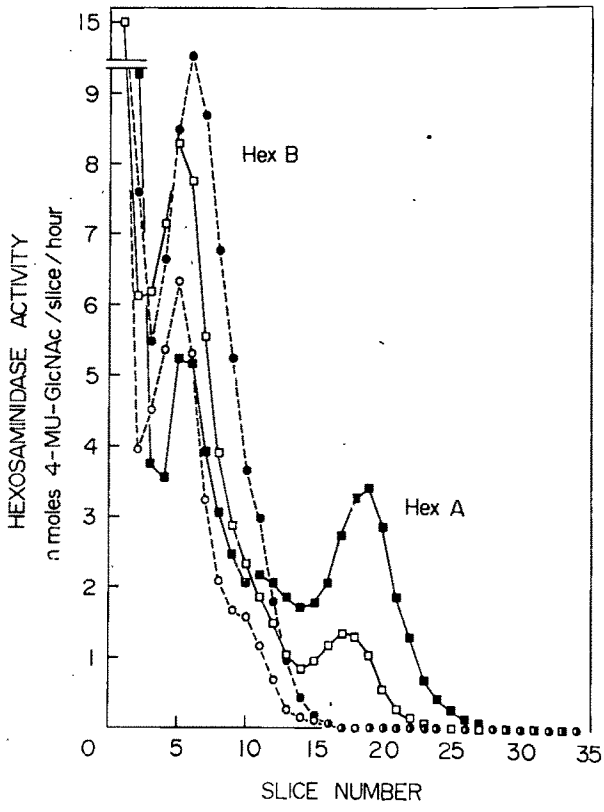

Fig. 1. Polyacrylamide gel electrophoresis showing hexosaminidases in four amniotic fluid samples. Normal enzyme patterns are represented by squares (-□-□-□-□-□-, -■-■-■-■-) and enzyme patterns from affected pregnancies are represented by circles (-o-o-o-o-o-, -●-●-●-●-●-). The peak labeled *HEX B*, consisting of both hex B and I, is prominent in all samples. The more anodic hex A peak is absent in fluid from affected pregnancies.

achieved, some slight inactivation of the heat-stable forms usually also occurs. When samples were inactivated at 50° C all hex A values were lower by an average of 33%, and while some of the affected cases did then show 0% hex A, there was still overlap between some normal and affected subjects and the discrimination was not improved. Heating at 60° C for five minutes gave the poorest discrimination.

Comment

The data show that analysis of amniotic fluid by electrophoretic methods permitted unambiguous determination of the presence or absence of hex A. Affected fetuses had a complete deficiency of hex A activity while those unaffected had clearly demonstrable amounts of hex A albeit much less than those found in fibroblasts and other tissues. Since two thirds of the unaffected fetuses of pregnancies at risk are carriers, the mean hex A values of this group are even lower than those of normal control subjects. The low hex A

activity makes its detection more difficult and requires greater care in technique and choice of methods. Because of this low activity we do not rely on the heat inactivation method which may yield spurious values which at times are difficult to distinguish from real, but low, hex A values of fluid. However, this limitation does not detract from the usefulness of the method for measuring hex A in cell extracts and other tissues which contain high hex A activity.

A particularly stringent test of the reliability of fluid was encountered in Case 2 (Table I) where hex A in both fluid and cell extracts was definitely present but disturbingly low (2.4 and 8%, respectively). The fetus was eventually diagnosed as not affected with classical Tay-Sachs disease (but because of the low hex A levels the possibility of a late onset form was not excluded) and the pregnancy was continued to term. At birth serum hex A values were about one third the mean for nonaffected children of at risk pregnancies, so the unusually low hex A activity in fluid and cells at diagnosis were, in retrospect, an accurate reflection of the low enzyme levels later found at birth. However, at last examination at 23 months the child showed normal development and was free of any symptoms.

In addition to the appropriate analytic techniques and controls, and rigid adherence to proper methodology,[9] other requirements for the successful use of amniotic fluid for prenatal diagnosis are that the sample be free of maternal blood, that it be kept cold or frozen to minimize loss of hex A activity, that the possibility of maternal urine be eliminated, that bacterial contamination be prevented, and that the fluid be sufficiently concentrated.

We wish to express our thanks to Marie Barr, Cheryl Fisher, and Martha Young for providing the cultured amniotic fluid cells, and to Kathleen Grolsko for assistance in preparation of the manuscript.

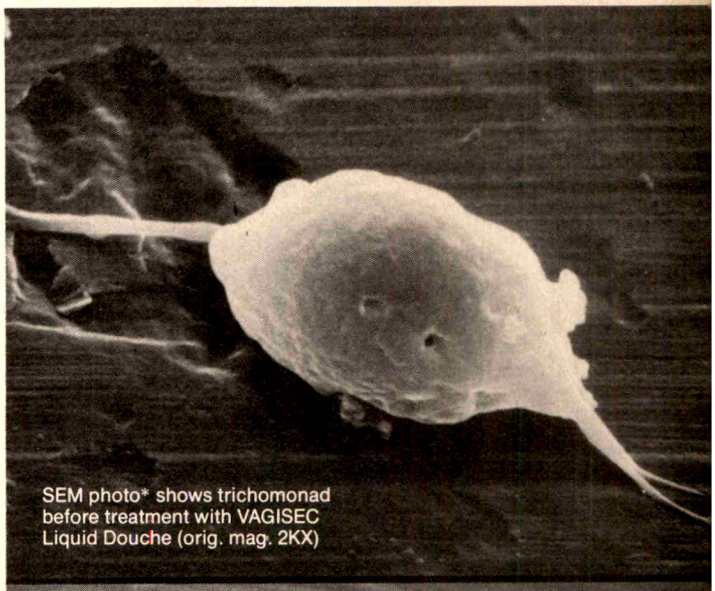
Destroys Trichomonads in 15 seconds

Immediate symptomatic relief

In vitro studies[1,2] show that within 15 seconds of contact, VAGISEC Douche permeates the trichomonad's outer membrane and weakens its cell wall, causing it to swell and die.



VAGISEC Douche/ VAGISEC PLUS Suppositories

regimen for the treatment of trichomoniasis... or mixed vaginal infections

VAGISEC Douche acts on the trichomonads directly—far faster than most systemic medication. It penetrates the vaginal creases and folds; cleanses and dissolves mucinous material; and prevents buildup of microorganisms. Relief from itching, burning, leukorrhea and malodor is almost immediate.

VAGISEC PLUS Suppositories combines the same proved trichomonacide with effective antibacterial action against susceptible strains of staph, strep and coliform organisms,[3] and is particularly useful in mixed infections.

The combination douche/suppositories regimen is recommended in all cases, except during pregnancy, when douching is not recommended. Strict adherence to the treatment program is essential for therapeutic success.

SEM photo* shows trichomonad before treatment with VAGISEC Liquid Douche (orig. mag. 2KX)

15 seconds after treatment, photo shows cell wall destruction and loss of flagella (orig. mag. 5KX)

VAGISEC Liquid Douche/VAGISEC PLUS Suppositories
Contraindications: Douching is not recommended during pregnancy. VAGISEC Liquid Douche and VAGISEC PLUS Suppositories are spermicidal and should not be used on days when the patient is trying to conceive. **Precautions:** *Therapeutic Treatment:* Recurrence of vaginitis often indicates extravaginal foci or infection in cervical, vestibular and urethral glands, etc., or reinfection by the sexual partner. During treatment, patient should refrain from intercourse or the partner should wear a prophylactic. To prevent flare-ups after completion of therapy and for continued vaginal cleanliness, the patient is advised to continue with VAGISEC Liquid as a regular douche, but no more than twice weekly unless otherwise directed by physician. **Side Effects:** No significant side effects reported to date. Any minor irritation is alleviated by discontinuance of douche for a single day. **Administration and Dosage:** *Office Treatment (Adult):* For the treatment of vaginal trichomoniasis and mixed vaginal infections, best results are obtained by scrubbing the vagina with VAGISEC Liquid, diluted 1:100, by the physician in the office; 3 scrubs the first week, 2 the second. A suppository is inserted after each office scrub in the Liquid/Suppository regimen. Patient should be instructed to continue treatment at home. *Home Treatment:* Liquid/Suppository regimen: In all instances, the combination douche and suppositories are recommended for home use. The usual home treatment is VAGISEC Liquid Douche in the morning, followed by a VAGISEC PLUS Suppository inserted deep in the vagina and a second suppository inserted in like manner at bedtime, daily, for a period of 14 days. For those physicians who feel it important to treat the patient through the complete menstrual cycle, the Liquid/Suppository regimen may be continued throughout the month. It is advisable to continue treatment through two menstrual periods. Treatment should be omitted the night and morning preceding an office visit. Patients should be reexamined 3 days after home treatment has been discontinued. The full course of therapy must be completed to eliminate the infecting microorganisms from the vagina. In chronic or stubborn cases, therapy may be repeated with no interval between courses. During treatment, patient should refrain from intercourse, or the partner should wear a prophylactic. No patient should be considered cured until vaginal smears or cultures, taken at monthly intervals for 3 months following treatment, show absence of trichomonads and a return to the normal vaginal flora. **How Supplied:** VAGISEC Liquid—4 oz. plastic bottle. VAGISEC PLUS Suppositories—box of 28 3-gram suppositories, foil-wrapped, with inserter. *Federal law prohibits dispensing VAGISEC PLUS suppositories without prescription. More detailed professional information available on request.*

Vagisec® DOUCHE LIQUID CONCENTRATE

VagisecPlus® SUPPOSITORIES

Each suppository contains
9-aminoacridine HCl 6 mg.
Polyoxyethylene nonyl phenol 5.25 mg.
Sodium edetate .66 mg.
Sodium dioctyl sulfosuccinate 0.07 mg. in a polyethylene glycol base containing glycerin and citric acid

SCHMID PRODUCTS CO.

THE HIGH RISK INFANT - WHO ARE THEY AND WHAT HAPPENS TO THEM?

September 27 & 28, 1979

Sponsored by the
University of Maryland
School of Medicine
Department of Pediatrics
and the
Program of Continuing Education

Designed to acquaint obstetricians, pediatricians and family physicians with factors in the maternal, fetal and newborn histories that relate to long term neurologic, development and behavior outcomes of the child. Practical management of the perinatal and outcome problems will be discussed in both the didactic and frequent small group sessions and share-shops.

Location:

Medical School Teaching Facility
University of Maryland - School of Medicine

PERSONALIZED LIBRARY CASES

Keep your personal copies of AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY in these specially designed library file cases. Designed to keep your journal copies near at hand in your office, library, or home.

Your case is heavy bookbinder's board in a rich red Kivar cover. Files are scuff-resistant and washable.

Lettering is stamped in gold leaf and the cases make a fit companion for the most costly binding.

Files are reasonably priced—only $4.95 each, postpaid (3 for $14., 6 for $24.). Add $1.00 postage per case for orders outside U. S. Satisfaction unconditionally guaranteed or your money back! Use the coupon for prompt shipment.

New! Available for the first time

The ten-year **cumulative author and subject index** to volumes 100-129 (1968-1977) of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY is now available for your journal collection. It is a complete and comprehensive reference guide to over 28,000 pages of authoritative articles published in the Journal during the past ten years.

The world-renowned "Gray Journal" is the oldest specialty journal devoted to obstetrics and gynecology.

Now these influential papers, appearing between 1968-1977, have been cross-referenced to include over 23,100 subject entries. Each entry lists the complete article title, author(s), volume, page, and year of publication.

The author index lists more than 13,850 contributors from this period, along with respective article title, author-to-author referral, volume, page, and publication date.

The 479-page index is handsomely presented in a rust and gold cloth-cover volume. It is a must for every library concerned with obstetrics and gynecology. Send for your copy of this valuable reference today!

479 pages, 8¼" × 11", price $28.75

GYNECOLOGY

Correlation between retinal and pelvic vascular status: A determinant factor in patients undergoing pelvic irradiation for gynecologic malignancy

J. R. VAN NAGELL, JR., M.D.
R. KIELAR, M.D.
E. S. DONALDSON, M.D.
E. C. GAY
D. F. POWELL, M.D.

J. YONEDA, M.D.
Lexington, Kentucky

The degree of arteriolar sclerosis in pelvic vessels has previously been shown to be related to the incidence of radiation-related enteric and genitourinary injury. Retinal vessel changes were compared to pelvic vascular changes in 48 patients, half of whom were either diabetic or hyptertensive. There was an absolute correlation between retinal vessel changes and bowel or cervicovaginal vessel changes in 74% of the cases, and only one patient had a marked (more than one grade) discrepancy between retinal and pelvic vascular status. The findings of this investigation suggest that funduscopic examination of the retina can provide useful information concerning the extent of vascular disease in structures normally present in the field of pelvic irradiation.
(AM. J. OBSTET. GYNECOL. 134:551, 1979.)

ONE OF THE CHALLENGES of pelvic radiation therapy has been to deliver tumoricidal doses to the site of malignancy while minimizing the dose given to adjacent radiosensitive normal tissues.

From the Departments of Obstetrics and Gynecology, Ophthalmology, Pathology, and Radiation Medicine, University of Kentucky Medical Center.

Supported by American Cancer Society Grant ACS 203-65-7H500-T3B52.

Received for publication June 8, 1978.

Accepted July 19, 1978.

Reprint requests: Dr. J. R. van Nagell, Jr., Professor and Director, Gynecologic Oncology Division, Department of Obstetrics and Gynecology, University of Kentucky Medical Center, 800 Rose St., Lexington, Kentucky 40506.

To achieve this goal, sophisticated treatment planning methods have been developed utilizing computerized methods as well as radiologic scanning techniques for localization of tumors and normal pelvic structures. An important factor in the response of normal tissues to radiation has been the vascular status of the patient. Radiation has been shown to cause capillary endothelial proliferation, changes in vascular permeability, and luminal stenosis with consequent decrease in blood flow.[7, 12, 13] When these radiation-related changes are superimposed upon underlying vascular disease, tissue hypoxia and necrosis occur. In previous investigations from this institution,[14, 15] the incidence of major enteric and urinary tract complications following pelvic irradiation for cervical cancer

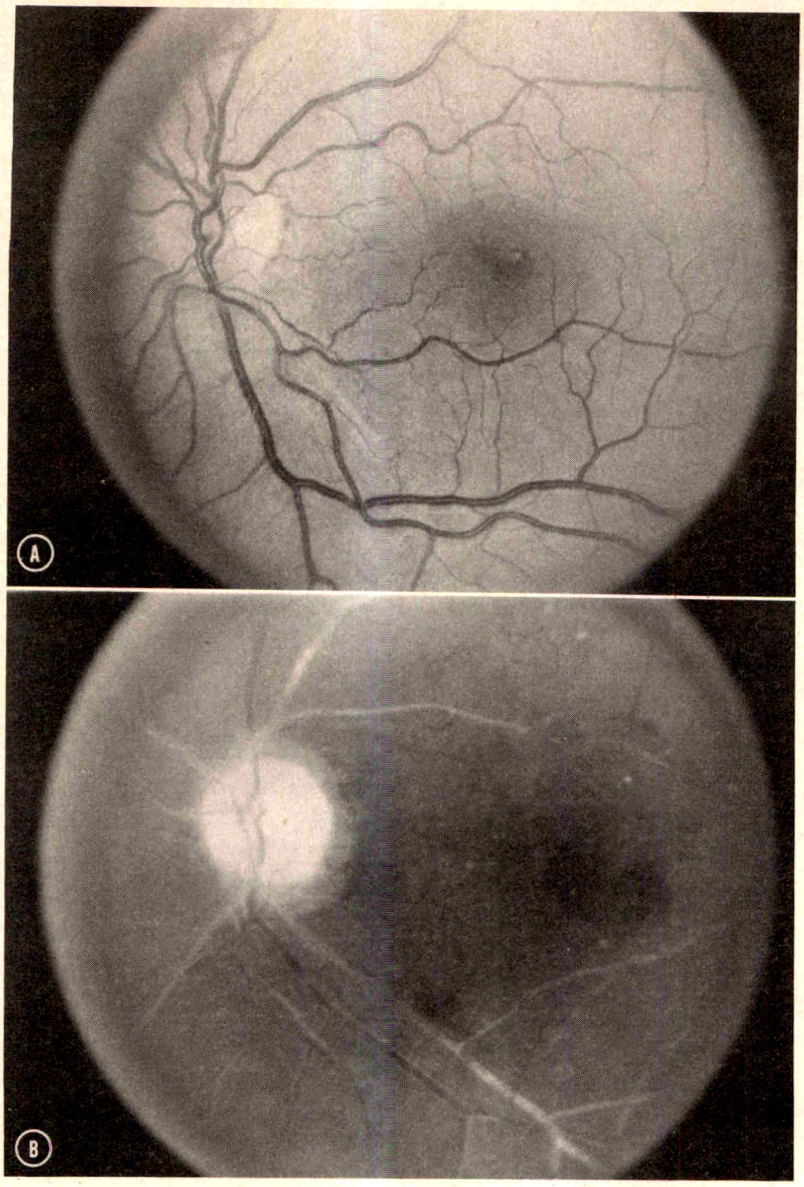

Fig. 1. *A*, Normal (grade 0) retinal vessels with no evidence of arteriolar sclerosis. *B*, Marked retinal arteriolar narrowing (grade 4 changes).

were shown to be significantly increased in patients with hypertension or diabetes mellitus.[14, 15] It was suggested that the underlying angiopathy associated with these diseases when added to radiation-induced arteriolar damage was responsible for the increased incidence of tissue injury and fistula formation.

The present study was undertaken in order to determine the correlation between retinal vessel changes as observed by funduscopic examination and pelvic vascular status. Specifically, changes in the retinal vessels were compared to changes in the small arterioles of organs normally present in the field of pelvic irradiation.

Material and methods

Subjects for this investigation included 48 patients who were admitted to the Gynecology or Gynecologic Oncology Services at the University of Kentucky Medical Center from 1972 to 1977. Hypertension was defined as a systolic pressure of more than 140 mm Hg or a diastolic pressure of over 90 mm Hg. The diagnosis of diabetes mellitus was made if the 2 hour value of the glucose tolerance test was greater than 140 mg per 100 ml. Funduscopic examination and retinal photography were performed on all patients and fluorescein angiography was utilized in selected cases. Retinal vessels were classified according to the system proposed

by Ballantyne and Michaelson[2] (Table I). This classification varied from normal vessels with no evidence of arteriolar sclerosis (Fig. 1, *A*) to extensive arteriolar sclerosis with an arteriolar:venous ratio < 1:4 (Fig. 1, *B*). Within 3 weeks of retinal examination, all patients underwent surgical exploration with removal of bowel, bladder, ovary, uterus, or vagina. No patient had received prior radiation therapy or had a history of previous pelvic inflammatory disease. Small arterioles (<100 μ in diameter) in each of the organs removed were examined histologically without knowledge of the retinal vessel status of the patient and were classified according to the extent of luminal narrowing (Table II). Five to 10 vessels were examined from each specimen and Elastin van Gieson Stains were utilized in selected cases to outline arteriolar dimensions. Arterioles varied from no evidence of sclerosis and a lumen diameter:vessel diameter ratio > 1:2 (Fig. 2, *A*) to marked medial thickening and fibrinoid necrosis with a lumen diameter:vessel diameter ratio < 1:4 (Fig. 2, *B*).

Table I. Classification of retinal vessels

Grade	*Criteria*
0	No evidence of arteriolar sclerosis
1	Increased light reflex (arteriolar:venous ratio = 2:3)
2	Arteriovenous nicking or compression (arteriolar:venous ratio less than 1:2)
3	Copper wire changes (arteriolar:venous ratio less than 1:3)
4	Silver wire changes (arteriolar:venous ratio less than 1:4)

Table II. Classification of pelvic vessels

Grade	*Criteria*
0	No significant changes
1	Slight thickening of the media (lumen diameter:vessel diameter = 1:2)
2	Prominent medial thickening (lumen diameter:vessel diameter = 1:3)
3	Medial thickening with subintimal proliferation (lumen diameter:vessel diameter = <1:3)
4	Medial thickening with fibrinoid necrosis (lumen diameter:vessel diameter = <1:4)

Table III. Retinal vessel–pelvic vessel correlation

Vessel site	*Observations*	*Absolute correlation*	*±1 Grade correlation*
Cervicovaginal	42	32 (76%)	42 (100%)
Bowel	15	11 (73%)	15 (100%)
Other pelvic sites	30	22 (73%)	29 (97%)
Total	87	65 (74%)	86 (99%)

Results

Twenty-four of the 48 patients were either hypertensive or diabetic and there was equal distribution of these patients and normotensive patients in the various organ sites observed. Cervicovaginal vessels were evaluated in 42 cases, large or small bowel vessels in 15 cases, and vessels from various other organs including pelvic muscles, fallopian tube, or ovaries in 30 cases (Table III). There was no evidence of retinal or pelvic vascular abnormality in 92% of normotensive patients. Two of these patients had grade 1 retinal or pelvic vascular changes. Grade 1 to grade 4 vascular changes were noted in the pelvic or retinal vessels of 87% of hypertensive or diabetic patients. The remaining hypertensive patients had no histologic evidence of vascular abnormalities. There was absolute grade correlation between retinal and pelvic vessel changes in 74% of the cases. This correlation was essentially the same whether the patient was known to have vascular disease or was in the control group. There was agreement within ±1 grade in an additional 25% of the cases. There was a marked (>±1 grade) difference between retinal and pelvic vascular findings in only one patient. The statistical correlation between findings in retinal and pelvic vessels was calculated using both the Pearson Product Moment and chi-square systems. There was an overall correlation between retinal vessel and pelvic vessel changes of 0.88 which was significant at a level of $p < 0.001$. The specific correlations between vascular findings in the retina and those in the uterus, and bowel are illustrated in Figs. 3 and 4. The correlation between retinal and cervicovaginal vessel changes was 0.87 and between retinal and bowel vascular findings it was 0.89. Both these correlations were statistically significant ($p < 0.001$). There was also a significant correlation between changes in retinal vessels and in those from other pelvic organs including the ovary and fallopian tube.

Comment

There are much data in both experimental animals and man concerning the effect of gamma radiation on small vessels. Specifically, capillary endothelial proliferation, medial thickening, and increased vascular permeability have been demonstrated within 2 months following radiation.[12] With narrowing of the lumina of arterioles, there is decreased flow in the microcirculation, lowered oxygen tension and oxygen uptake rate, and initiation of anaerobic metabolism.[4] Increased vascular permeability often causes insudation of plasma constituents into the capillary wall with subsequent fibrinoid vascular necrosis and thrombosis.[10] Dutta,[5] using autoradiographic techniques, has demonstrated

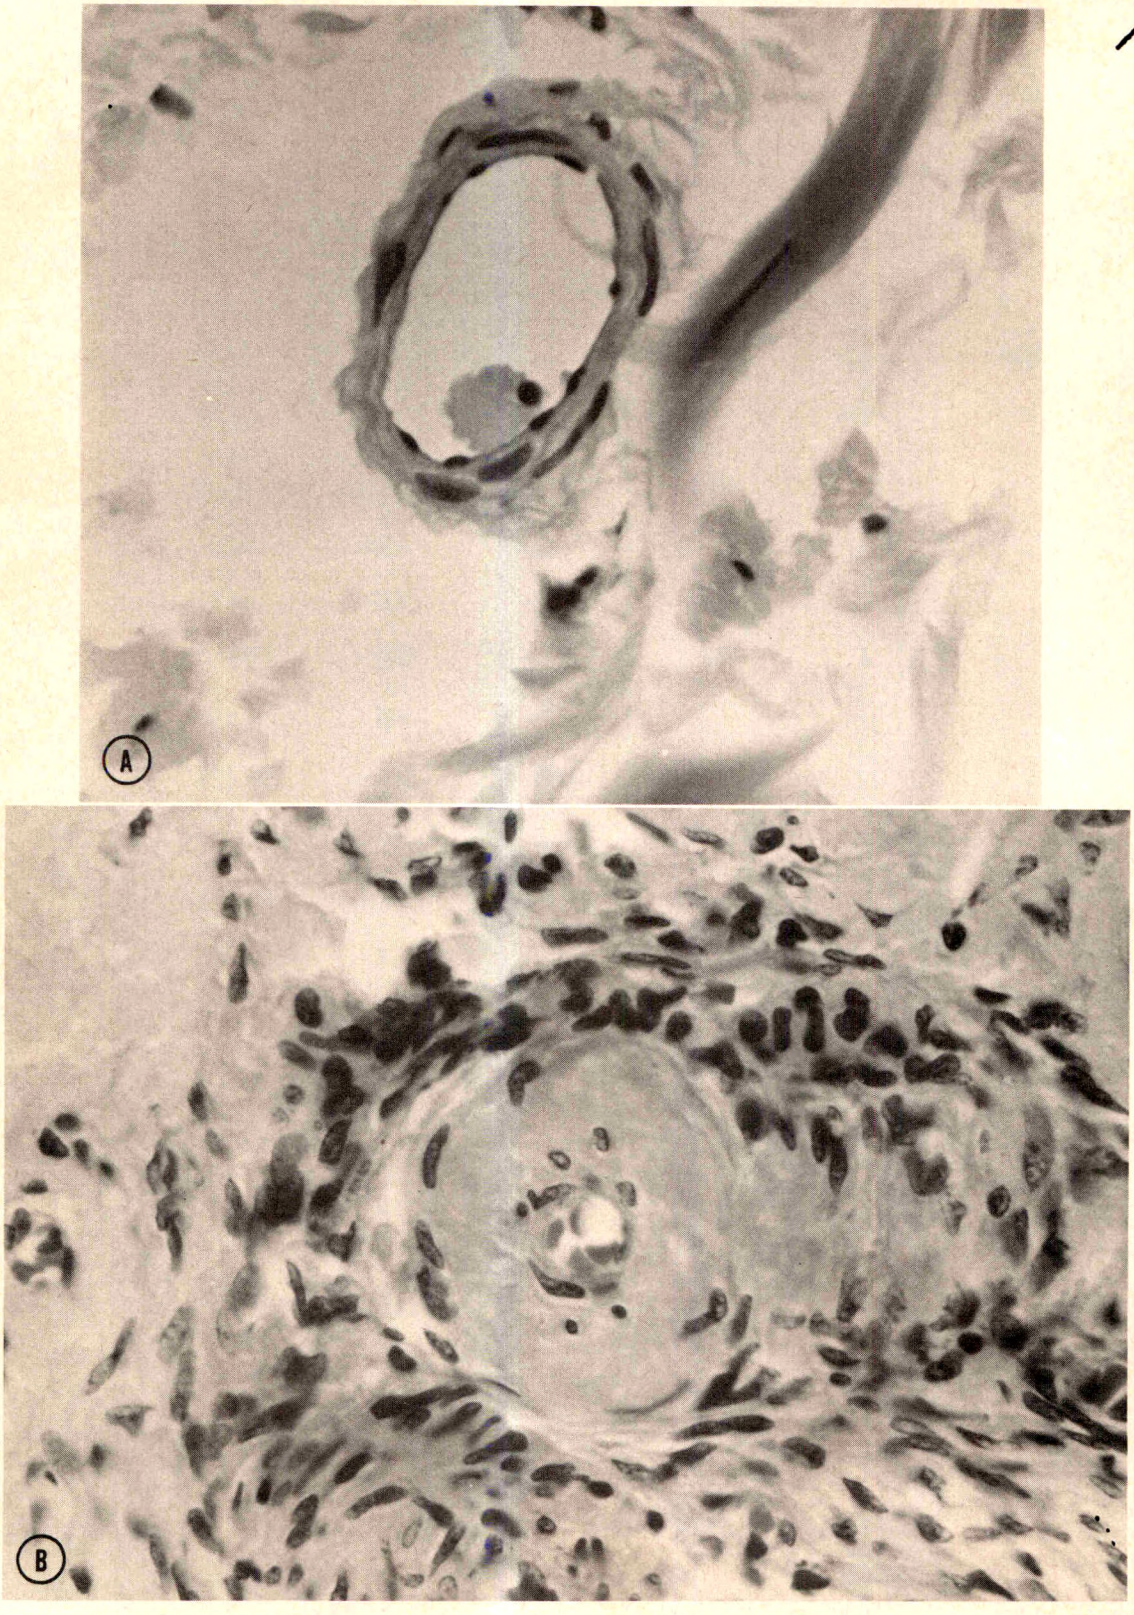

Fig. 2. *A*, Normal pelvic vessel with no evidence of luminal narrowing. (Hematoxylin and eosin. ×400.) Pelvic vessel with marked medial thickening (lumen diameter : vessel diameter = <1 : 4). Absence of fibrinoid necrosis places this vessel in grade 3 category. (Hematoxylin and eosin. ×400.)

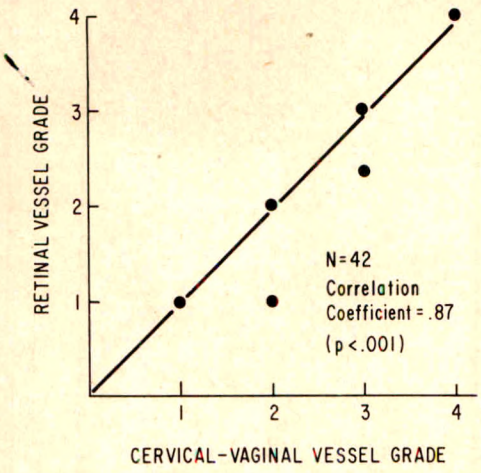

Fig. 3. Correlation between retinal vessel grade and cervicovaginal vessel grade.

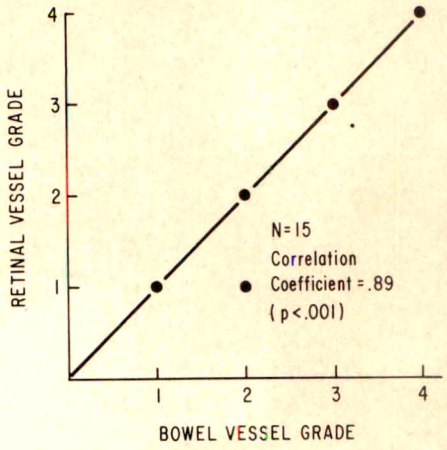

Fig. 4. Correlation between retinal vessel grade and bowel vessel grade.

that radiation causes increased sulfate metabolism in the wall of mesenteric arterioles and that these vessels are then more susceptible to damage by increased intravascular pressure often present in hypertension.

These experimental findings have been confirmed by clinical observations in patients undergoing pelvic irradiation for gynecologic malignancies. van Nagell and co-workers,[14, 15] for example, reported that the incidence of enteric and urinary tract fistula following irradiation for cervical cancer was significantly increased in patients with hypertension or diabetes when compared to patients with no pre-existing vascular disease. Furthermore, arteriolar medial thickening and luminal narrowing in the bladder and rectum was significantly more common in hypertensive or diabetic patients who had not received radiation therapy than in control patients. It was therefore suggested that the underlying microangiopathy present in patients with small vessel disease predisposed these patients to vascular damage following radiation therapy, ultimately leading to tissue necrosis and fistula formation. It was also postulated that patients with pre-existing vascular disease might benefit from greater fractionation of the total dose of pelvic irradiation, thereby allowing for increased normal tissue repair.

It is generally recognized that the extent of arteriolar sclerosis and luminal narrowing is related to both the severity and duration of hypertension or diabetes.[3, 11] When patients requiring radiation therapy for pelvic malignancy are first examined, it is often difficult to determine the extent or length of time they have had vascular disease. Previous investigations[6, 9] have indicated that there is a high degree of correlation between retinal vessel changes and those present in cerebral and peripheral arterioles. The data of the present study confirm these findings and indicate that retinal vessel changes are associated with similar changes in the small arterioles of the bowel and urogenital system. Since the primary goal of any treatment regimen is to achieve tumor control, greater dose fractionation should be considered only for those patients with severe sclerotic vascular changes who are at highest risk to develop radiation-related enteric complications. It is apparent from this and other investigations[1, 8] that funduscopic examination of the retina can provide useful information concerning the extent of vascular disease in structures normally present in the field of pelvic irradiation.

The authors would like to express their thanks to John Haley, Ph.D., of the Department of Behavioral Science, University of Kentucky Medical Center, for statistical evaluation of the data.

Uterine leiomyosarcoma

A review of prognostic clinical and pathologic features

EDWARD V. HANNIGAN, M.D.
LUIS G. GOMEZ, M.D.
Galveston, Texas

A series of uterine leiomyosarcomas was reviewed in an attempt to assign prognostic significance to clinical and pathologic features. Extension of the sarcoma at the time of initial diagnosis was associated with a dismal outcome; no patient with disease beyond the confines of the uterus survived. Histologic grade was a useful prognostic feature, although low-grade sarcoma can be associated with metastases. Mitotic count was also useful in prognosis, although it did not correlate as well with clinical outcome as did histologic grade. There was no number of mitoses below which the diagnosis of leiomyosarcoma was excluded. (AM. J. OBSTET. GYNECOL. 134:557, 1979.)

INTERPRETATION OF LITERATURE describing the clinical behavior of uterine leiomyosarcoma has always been difficult because the reports do not agree on the histologic criteria necessary for diagnosis of the lesion. Indeed, Corscaden and Singh[1] stated that no combination of histologic features is reliable and that only the smooth muscle tumors that metastasize or that recur after excision can be considered as definitely malignant.

Two recent reports in which the clinical and pathologic data were reviewed in series of leiomyosarcoma have emphasized different criteria both for diagnosing the lesion and for estimating the behavior of the tumor. Kempson and Bari[2] stated, after review of the series of Taylor and Norris[3] as well as their own cases, that the sole criterion for malignancy in the absence of obvious vessel invasion or spread to contiguous organs is the mitotic count. Thus, all tumors with less than five mitotic figures (MF) per 10 high-power fields (HPF) are benign; all tumors with greater than 10 MF/10 HPF are malignant. They believe that these criteria are valid regardless of cellular atypia, pleomorphism, or the presence of giant cells. Kempson and Bari also defined an entity they called "smooth muscle tumors of uncertain malignant potential." These are tumors with less than 10 MF/10 HPF and are divided into four categories, consisting of those between 5 and 9 MF/10 HPF (with or without pleomorphism) and those between 1 and 4 MF/10 HPF (with or without pleomorphism). The probability of metastasis or recurrence decreases with decreasing mitotic count and lessening atypia. The total number of such cases in their series is small: seven cases between 5 and 9 MF/10 HPF and 10 cases between 1 and 4 MF/10 HPF.

Silverberg[4] believes that the mitotic count has some prognostic significance but poor diagnostic significance. The features that he believes determine malignancy are nuclear hyperchromatism and nuclear pleomorphism. Those that he considers helpful but not diagnostic are the presence of giant cells and nuclear inclusions. He does not demand any level of mitoses for the diagnosis of sarcoma and believes that even though a relationship may exist between mitotic index and outcome it is fallible and does not correlate as well as histologic grade with outcome. He believes that some insight into the behavior of leiomyosarcomas can be based upon a histologic grading system similar to that suggested by Spiro and Koss.[6] Silverberg's grading system is as follows:

Grade 1. Well-differentiated tumor with typical low-power appearance of benign myoma; bundles of cells are orderly, although there may be foci of hemor-

From the Department of Obstetrics and Gynecology and the Department of Pathology, The University of Texas Medical Branch at Galveston.

Presented at a meeting of the Texas Association of Obstetricians and Gynecologists, Austin, Texas, March 2, 1978.

Received for publication April 28, 1978.

Revised July 24, 1978.

Accepted August 1, 1978.

Reprint requests: Dr. Edward V. Hannigan, Department of Obstetrics and Gynecology, The University of Texas Medical Branch, Galveston, Texas 77550.

0002-9378/79/130557+08$00.80/0 © 1979 The C. V. Mosby Co.

rhage and necrosis; nucleus-to-cytoplasm ratio is increased and the nuclei have mildly atypical cytologic features.

Grade 2. The general architecture of a leiomyoma is still apparent but is both more cellular and more atypical; nuclear hyperchromasia and anisonucleosis are more pronounced. These cells approach the appearance of benign smooth muscle.

Grade 3. The tumors are clearly atypical but are still recognizable as smooth muscle in origin; the spindle shape of cells may be lost, and round or polyhedral shapes may appear; numerous bizarre cell forms are present.

Grade 4. The smooth muscle origin of the tumor is difficult to recognize; pleomorphism is extreme.

Each tumor is graded by its most anaplastic region. Photographs of specimens of each tumor grade may be seen in Silverberg's[4] report.

The purpose of the present study is threefold: (1) to review clinical and pathologic features of all leiomyosarcomas diagnosed at the Hospitals of The University of Texas Medical Branch at Galveston (UTMB) for the past 15 years, (2) to classify this series of tumors by both histologic grade and mitotic count and to attempt to correlate these indices with the clinical outcome, and (3) to combine information on tumors in our experience with data from other reported series that meet Kempson's criteria for "tumors of unknown malignant potential," in an attempt to determine prognostic factors in this subgroup of smooth muscle tumors.

Methods

The patients considered for the study were those recorded by the Tumor Registry at UTMB with the diagnosis of uterine leiomyosarcoma during the 15 year period 1963 to 1977. The clinical records and pathologic material from the patients identified by the Tumor Registry were reviewed. Twenty-seven cases were thought to represent true uterine leiomyosarcoma and were included in the study. Pertinent clinical features were extracted and the follow-up data and survival statistics were brought up to date as recently as possible.

Material for pathologic examination was available for review in 23 cases. The gross appearance of the tumor was abstracted from the data that had been recorded at the initial examination of the surgical specimen. The microscopic slides, identified only by hospital case number, were reviewed independently by each investigator. Special note was made of histologic grade, mitotic count, vascular invasion, type of tumor margin, number of giant cells present, and the evidence of hemorrhage or necrosis.

In 22 cases, only tissue taken from the uterus and primary uterine tumor was evaluated. In a single case, the uterine sample was supplemented with tissue from the metastatic focus.

The histologic grade was determined according to Silverberg's[4] criteria, as given above. Mitotic figures were counted by each observer in at least 30 high-power microscopic fields per slide on two separate occasions. The criteria used to identify a mitotic figure varied between examiners. Results of the microscopic interpretation were compared, and when a discrepancy in pathologic interpretation occurred the material was examined jointly to arrive at a final histologic reading. Mitotic counts were considered to be in agreement, except in those cases in which the discrepancy would result in assignment to different statistical groupings.

Clinical findings. Among the 27 patients evaluated, the median age at the time of diagnosis was 51 years, with a range from 30 to 67. Fifteen women were at or beyond menopause; 10, before menopause; and for two patients, the menstrual stage was not available. Only five patients had had no pregnancies, and 21 had had children, including six who had had eight or more births. Ten patients had had a total of 15 spontaneous abortions.

Nineteen patients have died of leiomyosarcoma, and eight patients either are living and free of residual tumor or have died of nonrelated intercurrent disease. Of the eight surviving patients, six have been observed for more than five years. The remaining two patients are well, without residual disease, after two years. None of the surviving patients have either persistent or metastatic leiomyosarcoma. The two groups do not differ significantly in age, menstrual status, or parity.

Abnormal uterine bleeding, either postmenopausal bleeding or metromenorrhagia, was by far the most common initial symptom (observed in 20 patients). Pelvic pain was reported by seven. A pelvic mass was discovered during physical examination in eight patients before the initial operation, but in only four were any symptoms referable to this mass. Three patients observed a mass, associated with both pain and bleeding abnormalities. One patient complained of an otherwise asymptomatic pelvic swelling. Pelvic relaxation with symptomatic cystocele occurred as an initial symptom in two patients.

In patients with more advanced disease, the most common clinical manifestation of extrauterine spread was a large pelvic mass with progressive involvement and entrapment of adjacent pelvic viscera. A large pelvic mass of this type was observed during the course of the disease in 12 of the 19 patients with extrauterine spread, in eight patients at the time of initial surgical exploration, and in four patients as a central recurrence which developed some time after extirpative pelvic surgery.

Two patients are alive without recurrence at 2 years.

The lung was by far the most common site of distant metastases. Nine patients had lung metastases, four had bone metastases, two had liver metastases, and two had isolated metastases to the small bowel. The duration of symptoms was characteristically short, since symptoms typically were of such a magnitude as to require prompt medical intervention. Menorrhagia so severe as to require blood transfusion before initial diagnostic or therapeutic action occurred in 12 of 24 patients for whom this information is available.

Two patients had been treated for cervical carcinoma in the past with pelvic irradiation. The onset of uterine leiomyosarcoma followed radiotherapy by 29 years in one patient and by just 10 months in the second.

Pathologic observations

Gross appearance. In 15 patients, the tumors were confined to the uterus at the time of initial surgery and descriptions of the pathologic findings on gross examination were available in 12. In six of these patients, the uterus was enlarged and greater than 10 cm in length. In the remaining six patients, the uterus was normal in overall size, with a length from cervix to fundus of 10 cm or less. In all patients, the uterus had visible smooth muscle nodules, many nodules in seven patients and only a single nodule in five. In those patients with the disease confined to the uterus, the largest leiomyosarcoma measured 18 by 13 cm; the smallest, 0.5 by 0.5 cm. (Both occurred in multinodular uteri.) The extremes of tumor size in uninodular uteri were from 3 by 3 cm to 10 by 10 cm.

On cut section, the tumors were described as soft yellow to white nodules, which exhibited a whirling fibrous pattern. Typically, they bulged above the plane of section, and areas of necrosis were visible grossly in eight. All tumors greater than 6 cm in diameter exhibited evidence of hemorrhage and necrosis on gross examination.

Six of the cases of leiomyosarcoma were confined grossly to a single smooth muscle neoplasm or fibroid. The features of these tumors are described below.

Microscopic appearance. No uniform histologic pattern was displayed by these lesions. Even though all tumors were more cellular than the benign myoma, the degree of cellularity varied greatly. In addition, the tumors varied substantially in the degree of pleomorphism, the presence and degree of cellular and nuclear aberration, and the extent to which the individual cells were undifferentiated. As noted earlier, these features, along with individual cell morphology, are the basis for histologic grading (Table I). In seven of the 23 cases examined, the investigators initially were not in agreement about the histologic grade, but in no instance was the disagreement greater than a single grade.

Mitotic activity was evident in all tumors varying from 3 to 34 MF/10 HPF (Table II). The investigators disagreed initially about the mitotic count in eight of

Table V. Leiomyosarcoma confined to the uterus

Case No.	Size (cm)	Grade	MF (No.)	Giant cells	Outcome
Leiomysarcoma "in situ":

12	—	4	30	Abundant	Died (4 yr.)

the 23 cases. In one case, the disagreement was greater than 15 MF/10 HPF, but in the remaining cases the disagreement was never of a magnitude greater than one statistical grouping.

Giant cells of two types were observed. The first was that cell type described as a symplastic cell, which appeared as an aggregate of smooth muscle nuclei, clustered in an irregular fashion, without distinguishing cell boundaries and displaying only minor gradations of nuclear hyperchromatism and pleomorphism. The morphologic relationship of these cells to smooth muscle nuclei is maintained. The second type of giant cell is characterized by densely straining, irregularly shaped masses of nuclear material displaying extreme pleomorphism. These two cell types frequently coexist. The quantitative distribution of giant cells of the type was determined for each group of patients (Table II). The presence of giant cells is closely associated with histologic grade (Table III).

Microscopic evidence of hemorrhage was observed in 11 cases and evidence of necrosis, in eight.

Outcome

The overall survival rate four years after diagnosis was 20% of the group at risk (Table IV). No patient who survived four years after initial diagnosis died of leiomyosarcoma.

As noted earlier, six leiomyosarcomas appeared on gross pathologic examination of the uterus to be a simple myoma or fibroid, and the malignant nature of the neoplasm was discovered only upon microscopic examination. With application of the criteria of Przybora[5] for the diagnosis of "leiomyosarcoma in situ" (that is, an area of sarcomatous tissue inside of a simple myoma without coexistent invasion elsewhere in the uterus), two cases were found in this series. Both tumors occurred as central sarcomatous change of a single myoma in a multinodular uterus. One myoma was intramural and less than 1 cm in diameter; the other was subserous and 6 by 8 cm in size. Both were well-differentiated neoplasms, classified as grade 1, and there was no distinct margin between the sarcomatous areas of the smooth muscle tumor and the surrounding, apparently benign myoma. No giant cells were present in these tumors. The mitotic index was 6 MF/10 HPF in the smaller and 5 MF/10 HPF in the larger. Both patients survived following simple hysterectomy. The histologic features of these two tumors have been compared to those of other leiomyosarcomas confined to the uterus (Table V).

Four additional tumors were noted to be confined to a single smooth muscle neoplasm or fibroid but did not fulfill the criteria for "leiomyosarcoma in situ," either because of microscopic invasion at the tumor margin or because benign leiomyomatous elements were not found surrounding the malignant area. These tumors were larger than the in situ neoplasms, ranging from 3 to 10 cm; two were pedunculated submucous tumors. Unlike the in situ tumors, the entire smooth muscle neoplasms were composed of sarcomatous tissue. Two of the tumors had pushing margins; the others demonstrated infiltration of tissue adjacent to the stalk of the pedunculated tumor. No consistent pattern of histologic grade, mitotic activity, or presence of giant cells was found among these specimens (Table V). One patient with tumor confined to a myoma died of disseminated sarcoma 18 months after hysterectomy.

Six tumors were confined to the uterus but did not present the gross pathologic appearance of a tumor arising in or confined to a single smooth muscle tumor. These tumors either were multifocal or had diffuse spread throughout the myometrium in what has been described as a mural leiomyosarcoma.[8] Mitotic counts tended to be low although one tumor (Case 12) had

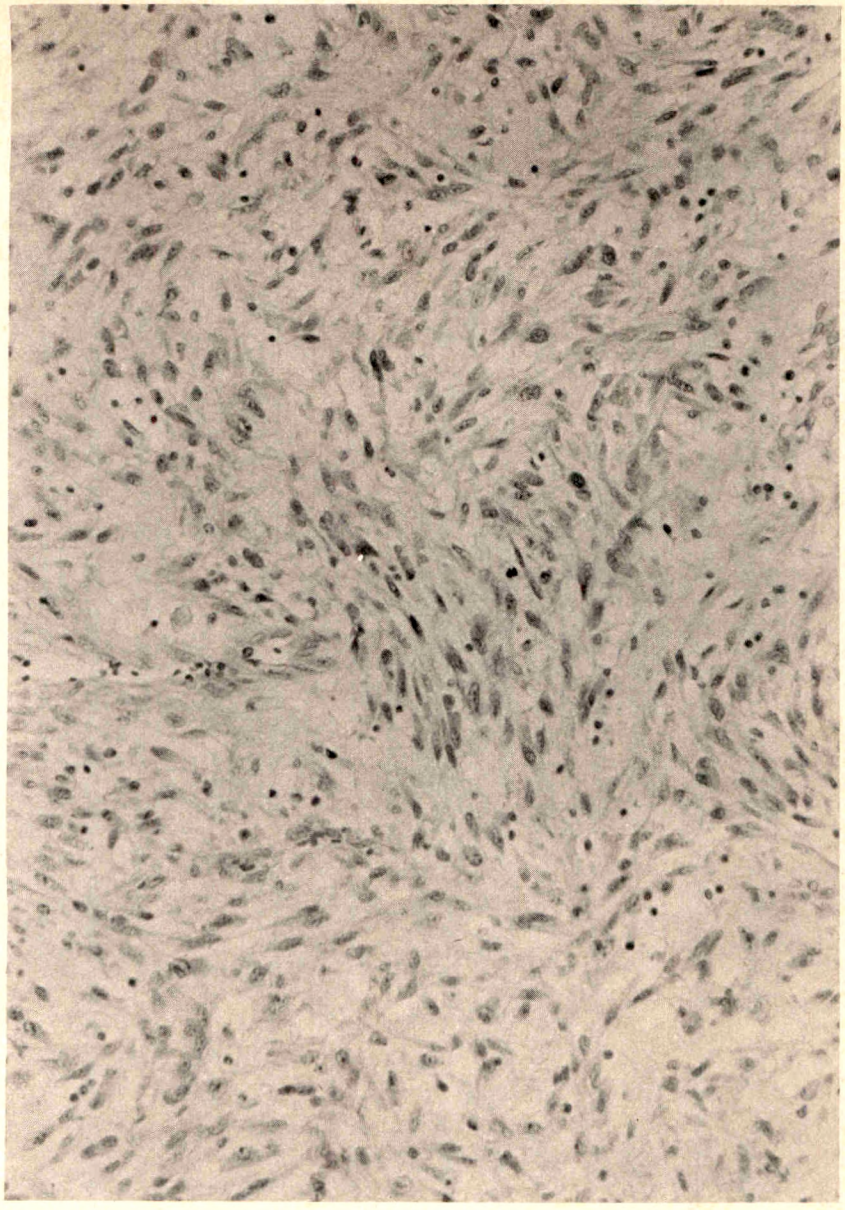

Fig. 1. Case 11. Grade 2 leiomyosarcoma with 3 MF/10 HPF. (Hematoxylin and eosin. ×25.)

pronounced mitotic activity (Table V). Three patients died of recurrent leiomyosarcoma; two of these patients had anaplastic tumors. A third patient (Case 11, Fig. 1), is of special interest in that she had relatively well-differentiated disease with a low mitotic count but died of widely metastatic disease within two years of initial hysterectomy. No spread beyond the uterus was apparent at the time of initial surgery, but she had a large 12 by 8 cm tumor mass penetrating the posterior uterine wall.

No patient with tumor beyond the uterus at the time of initial exploration survived. These patients were treated variously with simple hysterectomy, both alone and with radiotherapy, extended hysterectomy, irradiation alone, and various chemotherapeutic regimens. It is difficult to assign significance to any modality of therapy because of the small, heterogeneous groups involved.

Comment

The strong influence of the extent of the disease at the time of initial extirpative surgery is again obvious in this series of patients (Table VI). The dismal outcome of the 11 patients with sarcoma beyond the uterus is in sharp contrast to the 67% survival rate in the 12 patients with Stage I disease. One possible explanation for this sharp drop in survival is that first suggested by Corscaden and Singh[1] in their review of this phe-

Table VI. Relationship between outcome and stage

nomenon. A large proportion of the 12 patients in this group with Stage I disease may not have had a uterine sarcoma at all, but rather an incorrectly diagnosed cellular leiomyoma or degenerative changes in a benign myoma that appeared anaplastic. There are some data from our series that could be used to support this suggestion.

If the patients are divided into three groups, those with tumor confined to the uterus and surviving, those with tumor confined to the uterus who have died, and those with tumor beyond the confines of the uterus who have died, a cluster of patients with grade 1 tumor occurs in the first group (Table VII). Only a single patient with well-differentiated tumor died of the sarcoma, and no patient with well differentiated disease had extrauterine spread. Grade 1 anaplasia in our hands may be insufficient evidence to warrant a diagnosis of malignancy. The sole patient who died of low-grade sarcoma (Case 6) had pronounced mitotic activity with 21 MF/10 HPF. She developed pelvic and pulmonary recurrences within six months of hysterectomy and surgical removal of a tumor which was presumably confined to a fibroid.

Correlation of mitotic indices with the same three patient groups (Table VII) does suggest a relationship to eventual outcome, even though this relationship is

not as pronounced as that between tumor grade and outcome. Two cases require additional comment. The patient of Case 9 (Fig. 2) had a 7 cm tumor confined to the uterus with only 2 MF/10 HPF and yet she died of the tumor. This tumor, however, displayed pronounced anaplasia with numerous bizarre nuclear forms, and the counting of mitotic figures depended upon the interpretation of the bizarre nuclear patterns. The difficulty in distinguishing mitoses from pyknotic nuclei, polymorphonuclear leukocytes, or small cell fragments folded upon themselves has been commented upon by others.[2, 7] The other patient (Case 11) who had a grade 2 neoplasm with 3 MF/10 HPF, did not display this confusing anaplasia. Special note is made of this case to illustrate that a moderately well-differentiated tumor with low mitotic activity which is confined to the uterus can recur, metastasize, and result in a fatal outcome.

Our data were re-examined and an attempt was made to correlate survival with the greatest number of mitoses observed in any single field (Table VIII). It is obvious that this measure of mitotic activity adds little information about tumors which have spread beyond the uterus at the time of initial diagnosis. Among patients with Stage I disease, there was no clear separation of patients into two groups based on survival and mitoses. There remains a cluster of patients who survived with tumors demonstrating low mitotic activity by this criterion. Attention is again directed toward Case 11 as an example of a tumor with low mitotic activity, which metastasized and resulted in the death of the patient. This tumor displayed a single field with four mitotic figures. As a tumor with a behavior different from that which might be expected, based upon its mitotic index, this tumor was extensively counted. Initially, over 100 consecutive high-power fields failed to demonstrate any area with greater than 2 MF/HPF. A single field with four mitoses was later located during

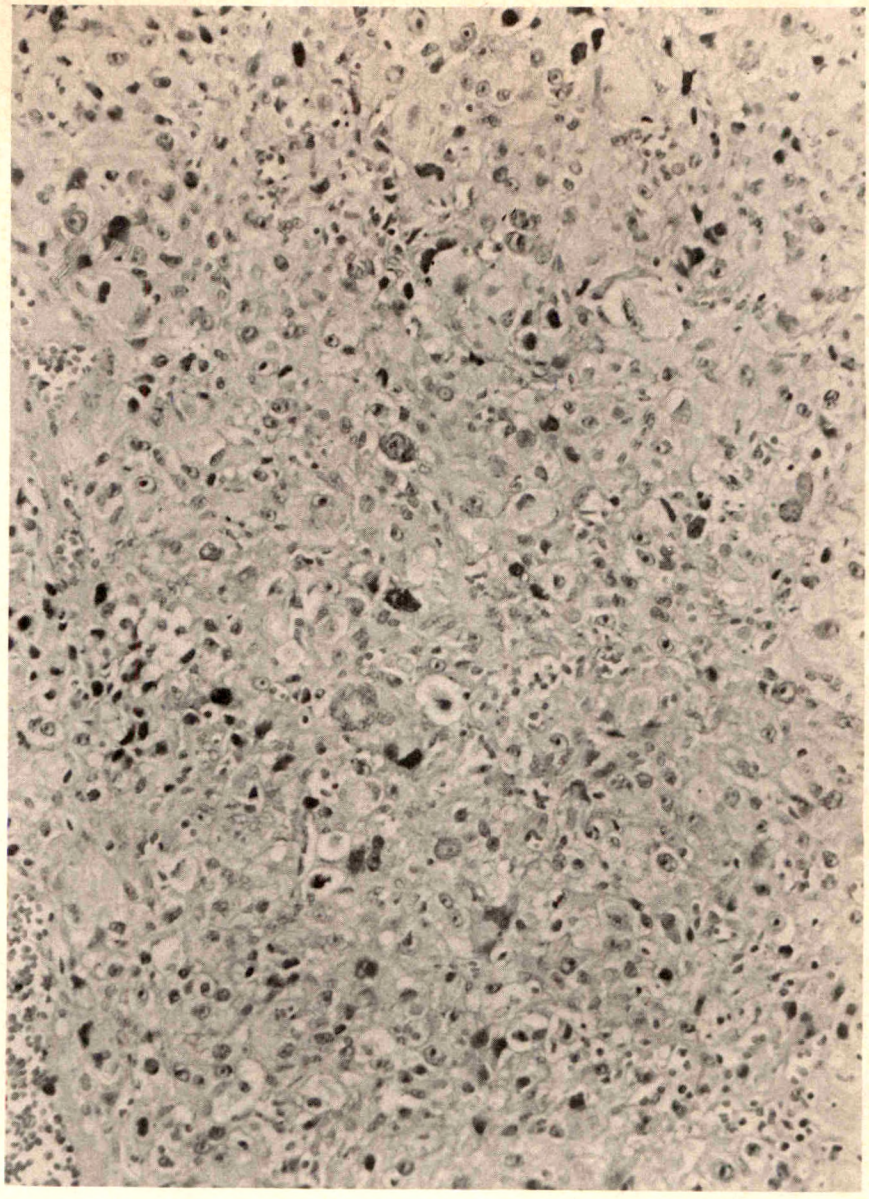

Fig. 2. Case 9. Grade 4 leiomyosarcoma with 2 MF/10 HPF. (Hematoxylin and eosin. ×25.)

one of many reviews of this case. On "step-section" slides made from the same tissue block, no comparable area of mitotic activity could be found in contiguous slides, indicating the extreme focal nature of this activity. Similar study of Case 7 demonstrated several areas with 3 MF/HPF.

As noted earlier, quantitative mitotic activity has been used as the sine qua non of uterine leiomyosarcoma, although the exact number of mitotic figures required to make the diagnosis has varied.[2, 3] Even those who deny that elevated mitotic counts are an absolute prerequisite for diagnosis recognize the strong association between increasing mitotic activity and poor outcome.[4, 8] "Smooth muscle tumors of uncertain malignant potential" is a term that includes tumors which have some characteristics associated with malignancy but an insufficient number of mitoses to justify the diagnosis of sarcoma. No single series contains a large enough number of tumors in this category to justify conclusions regarding their behavior (Table IX).

The data collected from these heterogeneous clinical series are, in many ways, impure (Table IX). For example, among tumors with between 5 and 9 MF/10 HPF, Kempson and Bari's[2] series includes five patients in whom the behavior of the tumor can be evaluated, and four of these patients had extrauterine spread of the disease at the time of diagnosis. All of these patients died. Silverberg's[4] patients likewise all died of leiomyosarcoma, but the stage of the disease is not discernible in this subgroup of his patients. A total of 27 cases has

§One extended beyond uterus.

been collected and eleven of the patients (41%) died of uterine sarcoma. Despite the impurity of the data, the conclusion that the diagnosis of leiomyosarcoma can be made with fewer than 10 MF/10 HPF is justified.

Among 42 collected cases with less than 5 MF/10 HPF, five patients (12%) died, three of whom are included in the patients discussed in this paper (Table IX). As stated earlier, one of these three tumors displayed severe anaplasia, and another was spread beyond the confines of the uterus at the time of initial surgery, but the third is a bona fide case of moderately well-differentiated neoplasm with a low mitotic count, confined to the uterus.

The relatively large number of tumors in this series with low mitotic activity possibly may be explained in several ways. Emphasis was placed on the pathologic features in the primary uterine tumor and a metastatic nodule was evaluated in only one case. This may lower the mitotic index by both selecting against tumors with pronounced mitotic activity and excluding from the mitotic count foci of tumor that possibly contain areas of more active cell division. The arbitrary requirement that the mitotic count be determined by figures observed in 30 HPF on two occasions may be too rigorous. Areas of high activity can be diluted by the inclusion of multiple fields in which no activity is noted. An attempt was made to circumvent this difficulty by considering the group of in situ tumors as a separate entity, including in the count only those areas of sarcomatous change and excluding the surrounding benign-appearing myoma. Even large, homogeneous-appearing sarcomas, however, have extreme variations in mitotic activity between two adjacent foci. A more useful mitotic index may be a figure which reflects the highest level of activity observed in any single microscopic field rather than the average of many fields.

Examination of our cases using this index suggests but does not prove a relationship between aggressiveness and mitotic activity. Moreover, the small difference in mitotic figures per single high-power field obtained in tumors confined to the uterus was found only by laborious retrospective examination of tumors whose biologic behavior was already known.

In summary, the extent of the disease at the time of initial diagnosis is of great prognostic significance. Among those tumors confined to the uterus, both histologic grade and mitotic activity are prominent prognostic factors: Worsening atypia or high mitotic counts are associated with a poor outcome. Although the prognosis improves with decreasing mitotic activity, there is no level of mitotic activity below which the diagnosis of uterine leiomyosarcoma can be excluded.

Further observations on the effect of topical progesterone on vulvar disease

EDWARD A. JASIONOWSKI, M.D.
PATRICIA A. JASIONOWSKI, M.D.
Piscataway, New Jersey

Follow-up studies have confirmed the beneficial effect of topical progesterone in the treatment of vulvar dystrophy, whether of the atrophic, hypertrophic, or mixed variety, in both postmenopausal and premenarchal women. If pruritus is a major symptom, topical corticosteroids should be alternated with the progesterone preparation in order to obtain maximum results. Topical progesterone was also found to be useful in the treatment of labial agglutination in children.
(AM. J. OBSTET. GYNECOL. 134:565, 1979.)

THE FACT that topical progesterone is effective in the treatment of vulvar dystrophy has been previously reported.[1] In four of the original five patients treated, pruritus was not a prominent symptom. These patients responded promptly to topical progesterone, although intravaginal estrogen was necessary to treat a concomitant senile vaginitis in one instance. The fifth patient, a diabetic woman who had pruritus as a chief complaint, was originally considered to represent treatment failure. Topical corticosteroids were added to control this symptom, and good results were then obtained. Maximal improvement, however, did not occur until the diabetes was brought under strict medical control. Subsequently, six additional cases have been treated.

Method of treatment

1. A complete history is taken and physical examination is done when patients are first seen. Special attention is given to the detection of diabetes and vaginitis of both senile and infectious varieties. If present, these conditions are treated prior to institution of therapy. Laboratory tests therefore include a glucose tolerance test and sodium chloride and potassium hydroxide vaginal smears.

2. A provisional diagnosis must be confirmed by histologic specimen.

3. The patients are given a prescription for 200 mg of progesterone in oil to be mixed in 2 ounces of hydrophilic ointment. They are instructed in the local application of a small amount, twice daily. Once a satisfactory response is achieved, this is decreased to a once-a-day application. After one month on this schedule, this is further decreased to every second day and the results are observed.

4. In the presence of pruritus, an additional preparation for a corticosteroid is given (15 gm of 0.1% Valisone ointment*). In these cases, the progesterone is applied in the morning and the corticosteroid in the evening. With an atrophic variety of vulvar dystrophy, the patients are instructed to discontinue the corticosteriod as soon as the itching subsides.

The patients are seen every two weeks for the first three months and then on a monthly basis. Unusual symptoms or reactions are reportable at any time.

Case report

Mrs. A. L., a 71-year-old woman, had been treated by various physicians during the past several years for primary symptoms of vulvar itching and burining. She had received multiple medications for the treatment of these symptoms, including intravaginal sulfa preparations and Mycolog ointment† externally. When first seen, her symptoms were at their maximum (Fig. 1). On observation, the labia were markedly irritated and had a tissue-paper appearance. Vaginal smears were negative for infection. A glucose tolerance test was normal. A presumptive diagnosis of atrophic vulvar dystrophy was made and confirmed by punch biopsy. Treatment consisted of alternate applications of progesterone and corticosteroids.

Two weeks following the initiation of therapy (Fig. 2),

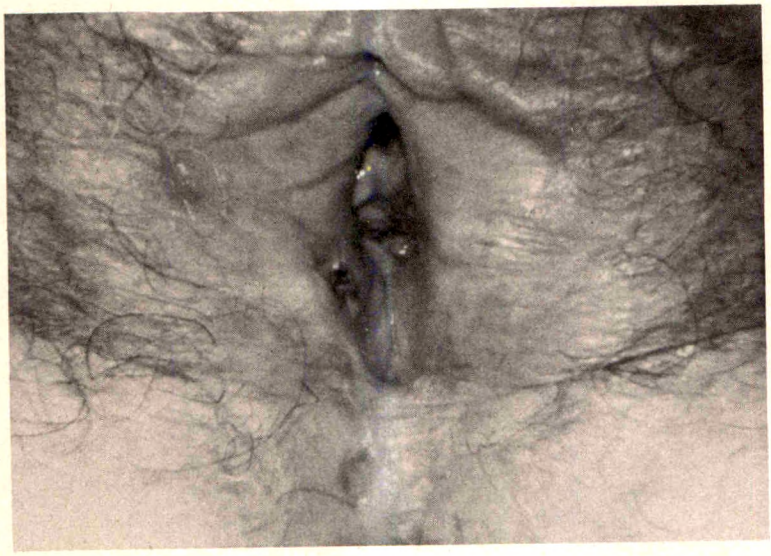

Fig. 2. Two weeks following initiation of therapy. Note biopsy sites at 6 o'clock and 9 o'clock positions. Subjectively the patient is much improved and objectively she is healing.

the patient was much better and was healing. Improvement continued. After 2 months corticosteroids were used only occasionally and after 3 months the progesterone preparation was decreased to every second day.

Results

All six of the new patients responded favorably to therapy. Three of these patients required corticosteriods in addition to progesterone. As noted before, symptoms recurred slowly when treatment was discontinued or tapered off too rapidly. The amount of medication required to maintain remission was found to decrease in proportion to duration of treatment. Interestingly, the first patient treated has been without medication for the past 6 months and subjectively and objectively has had no recurrence. No systemic side effects were noted in any of the patients. One patient noted a localized burning following application of the medication. The vehicle was changed from hydrophilic ointment to oil of petrolatum and was found to be satisfactory. One patient had candida vaginitis which was treated with Monistat cream* prior to initiation of therapy.

*Ortho Pharm. Corp., Raritan, New Jersey.

Treatment of vulvar dystrophy

The question of whether topical progesterone would also be effective in the treatment of vulvar dystrophy in premenarchal patients has also been considered. We have received personal communications from several gynecologists who have successfully treated five cases of the atrophic variety. The response to therapy appears to be slower than in postmenopausal women.

Since topical progesterone appears to have a healing or rejuvenating effect on ectoderm, we decided to use it for the treatment of labial agglutination in children. This condition is usually treated with a combination of manual separation of the labia minora plus application of an estrogenic cream.[3] Some cases takes months for complete separation to occur. Since topical estrogen has no beneficial effect on skin,[2] it is possible that the healing is achieved despite the estrogen content, that is, because of the mechanical separation and the vehicle present in the cream. We used small amounts of the preparation in the treatment of four patients.

Method of treatment. At the time of the first examination, the labia are separated and small amounts of ointment are applied to the area with a cotton swab. The mothers are instructed to repeat this procedure twice a day for 2 weeks and once a day for 2 additional weeks.

A satisfactory response was obtained in all four patients. One of them was an 8-year-old girl who had been resistant to previous therapy, which included estrogen cream. Following 1 month's treatment, labial separation was achieved. No systemic side effects were noted. A slight burning on local application of the ointment was noted in one patient.

Comment

Topical progesterone relieves burning, dryness, and dyspareunia associated with atrophic, hypertrophic, and mixed varieties of vulvar dystrophy. This gives credence to those investigators who claim that these histologic entities are but variants of the same disease process.

Itching, a common symptom, especially of the hypertrophic variety, is not relieved by the topical use of progesterone. A regimen of topical corticosteroids must be alternated with topical progesterone to achieve maximum subjective and objective effect. Previous investigators[2] have shown that topical corticosteroids cause a thinning of tissues which would thereby account for the hastening of the recovery process observed in the hypertrophic variety of vulvar dystrophy. These should be used sparingly in the presence of the atrophic variety.

No systemic side effects were noted in any of our patients. One of the patients complained of localized burning following application of the medication. Oil of petrolatum was substituted for the vehicle and this preparation was found to be satisfactory.

Topical progesterone appears to be effective in the treatment of the atrophic variety of vulvar dystrophy in the premenarche. Topical progesterone also appears to have a healing effect on ectoderm in the vulvar area and is therefore useful in the treatment of labial agglutination.

Comparison of three different models of the Copper T intrauterine contraceptive device

SUBIR ROY, M.D.
JOHN CASAGRANDE, DR.P.H.
DONNA L. COOPER, M.D.
DANIEL R. MISHELL, JR., M.D.
Los Angeles, California

A random sequential comparative study of three models of the Copper T intrauterine contraceptive device (IUD) was undertaken in 1,792 women. For 7 months, the TCu 300 and TCu 220C were randomly inserted, and then the TCu 380A and 220C were randomly inserted for the next 12 months. The log-rank method of life-table analysis of event rates was performed at the end of each of the first 3 years of use of each device. The TCu 380A had the lowest pregnancy rate during each year of use, although the difference was not significant. At the end of each of the first 2 years, the TCu 300 was removed significantly less than the TCu 220C and TCu 380A for bleeding and pain. At the end of three years, the rates of removal for bleeding and pain for the TCu 380A and TCu 300 were similar and lower than that for the TCu 220C, but the overall difference was not significant. There were no differences among the devices for any other relevant use-related reasons. The TCu 380A was removed for other medical reasons significantly more frequently than the other devices at the end of 2 and 3 years. Adjusting for parity did not alter the results. The findings of this study suggest that the copper sleeves along the horizontal arms together with copper wire on the vertical arm in the TCu 380A model provide greater protection against intrauterine pregnancy, whereas the copper sleeves along the vertical arm as in the TCu 220C caused increased removals for bleeding and pain. The TCu 380A should be studied in a larger number of patients for a longer period of time to determine its clinical effectiveness. It may become the IUD of choice for all women irrespective of parity. (AM. J. OBSTET. GYNECOL. 134:568, 1979.)

THE COPPER T 200 (TCu 200) with 200 sq mm copper wire wound around the vertical arm of the plastic T-shaped device has had extensive clinical testing and is now widely used throughout the world.[1–3] It has recently been approved by the Food and Drug Administration for use in the United States. Attempts have been made to improve the effectiveness and longevity of the copper intrauterine contraceptive devices (IUDs) by increasing the amount of copper wire along the vertical arm, as in the TCu 300 model, by placing solid copper sleeves on the horizontal arm in combination with either copper wire on the vertical arm, as in the TCu 380A model, or copper sleeves on both the horizontal and vertical arms, as in the TCu 220C model.

A randomized clinical study comparing the TCu 220C and the TCu 300 indicated that there were no significant differences in use-related termination rates between these two devices.[4] As the TCu 380A has one design characteristic in common with both the TCu 300 and the TCu 220C, it was thought to be of interest to compare the performance of these three Copper T IUDs to determine if there was a difference in event rates that might then be related to design of the device.

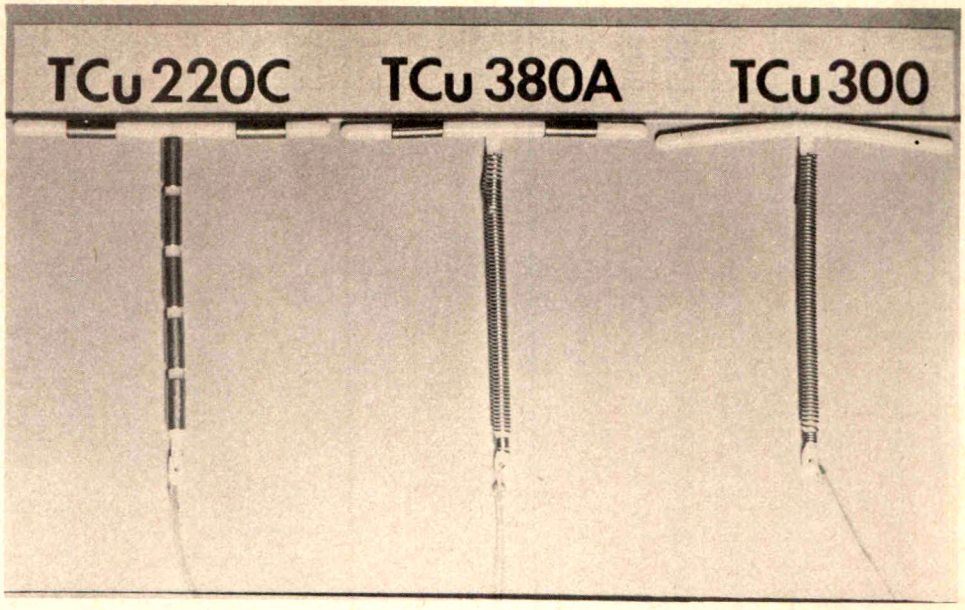

Fig. 1. Configuration and composition of the TCu IUDs used in the study.

follow-up procedures of these three investigational devices, were enrolled in this study.

The enrollment period for this study was from January 2, 1973, to August 13, 1974. A total of 1,792 TCu devices were inserted during this period. The device was chosen according to the last digit of the patient's previously assigned clinic number. All patients with odd numbers had the TCu 220C inserted. From January 2, 1973, to July 31, 1973, all patients with even numbers had the TCu 300 inserted and from August 1, 1973, to August 13, 1974, patients with even numbers had the TCu 380A inserted. Thus, the three devices were not studied in the same time period. The TCu 220C was first compared with the TCu 300 and then with the TCu 380A. A total of 903 women received the TCu 220C while 498 had the TCu 300 and 391 had the TCu 380A inserted. All devices were inserted by Family Planning Clinic staff physicians with the use of a modified loop inserter and push-in technique.[5]

The TCu 300 and the TCu 380A each have 300 sq mm of copper wire wound around the vertical arm. Both the TCu 380A and the TCu 220C have one copper sleeve of approximately 30 sq mm on each horizontal arm. The TCu 220C has five of these sleeves along its vertical arm instead of the copper wire (Fig. 1).

The log-rank method of life-table analysis[6, 7] was employed to generate event rates and to test for differences among the devices at 1, 2, and 3 years of use according to the categories as recommended by Tietze and Lewit[8] with the exception that a subject was considered a loss to follow-up if no contact was made by the time of the scheduled visit. The cut-off date was October 1, 1977, and the analysis was made after December 1, 1977, to ensure that no pregnancies were overlooked.

Results

There were no significant differences in termination rates for the TCu 220C in all use-related and loss–to–follow-up categories in the two groups of women inserted with the TCu 220C in the sequential time periods. They were, therefore, combined for purposes of analysis.

The percentage of nulliparous and parous women having each of the three devices inserted was similar (Table I). The mean age, gravidity, and parity of the parous women were similar for each IUD (Table II). The nulliparous women also had a similar mean age and percent gravidity (Table III).

The cumulative number of termination events in all patients with each type of device after 1, 2, and 3 years of use is shown in Table IV.

The net cumulative probabilities for termination at 1, 2, and 3 years are given in Tables V, VI, and VII, respectively. These tables also contain the χ^2_2 and P value associated with the testing for differences among the devices for each category, as well as woman months at risk.

Pregnancies. The pregnancy rate was lowest for the TCu 380A at each yearly interval after insertion but the differences in pregnancy rates among the devices were not statistically significant.

Of the 33 pregnancies, two were ectopic. Both occurred in the TCu 220C group, 165 and 195 days after

insertion in a parous and nulliparous patient, respectively.

Expulsion. There were no significant differences for rates of expulsion among the devices in the three yearly intervals after insertion.

Bleeding and pain. The rate of removal for bleeding and pain with the TCu 300 1 and 2 years after insertion was significantly less than the rates for the other two devices. At the end of 3 years, however, the rate of removal for bleeding and pain for the TCu 380A was not significantly different from that of the TCu 300. The removal rates for bleeding and pain for these two devices 3 years after insertion, however, were not significantly lower than the rate for the TCu 220C.

Other medical indications. The TCu 380A had a significantly greater frequency of removal for other medical reasons 2 and 3 years after insertion. Vaginal discharge was the most common other medical reason for discontinuation. Removals for salpingitis or endometritis did not occur significantly more frequently for any IUD at any yearly interval. The average annual rate of removal of any IUD for pelvic infection was 0.6%. There was one patient with an infected endometrioma who had a TCu 300. No tuboovarian abscesses were reported.

There were three non–IUD-related deaths: two in the TCu 220C and one in the TCu 380A group. A subject with lupus erythematosus died of acute respiratory failure, while another subject died of acute myocarditis, and the third subject died of leukemia. The IUD was not causally related to any of these deaths.

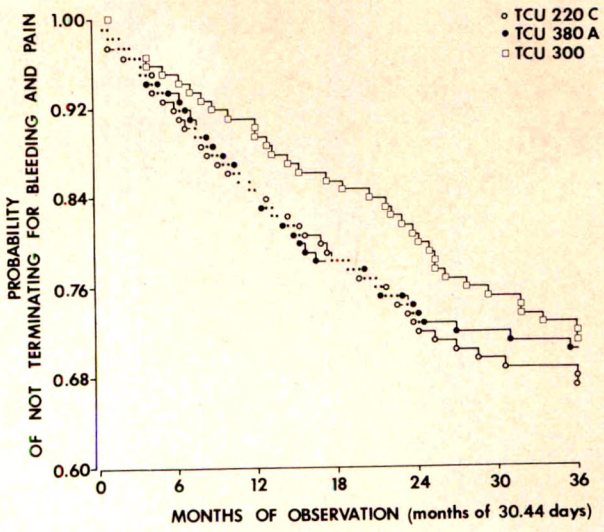

Fig. 2. Probability of not terminating as a result of bleeding and pain as a function of months of observation. Randomly assigned groups of women had the TCu 220C, the TCu 380A, and the TCu 300 inserted. Each vertical drop represents the time at which a patient terminated use of an IUD for bleeding and pain. The dots indicate overlapping of curves.

Planning pregnancy and personal indications. There were no significant differences among the rates of removal in this category among the three IUDs for any yearly time period.

Cumulative relevant terminations: Pregnancy, expulsion, and bleeding and pain. The TCu 300 had the lowest cumulative relevant termination rate at each time interval studied. It was significantly lower than the other devices by 1 and 2 years but not by 3 years after insertion.

Cumulative total terminations. The TCu 300 had the lowest cumulative termination rate for all use-related categories at the first and second yearly time intervals. The differences were not significant at any time intervals.

Loss to follow-up. There were no significant differences in the loss–to–follow-up category at any yearly time intervals.

Parity. Adjusting for parity did not change the results for any of the termination categories.

Comment

The percentage of woman months at risk by device by year was unchanged during the study. The TCu 220C contributed about 50% of the woman months at risk; the TCu 300, about 30%; and the TCu 380A, about 20% in each year of the study. This distribution was expected as a result of the staggered enrollment of

subjects into the study. Despite these differences in observed experience, the advantage of the log-rank method of life-table analysis allows not only for calculations of termination rates but also for hypothesis testing among these devices in a very accurate manner.

This study demonstrated the value of a long-term examination for trends in event rates since not all short-term differences were maintained at a later time.

In this study, the rate of termination for other medical reasons for the TCu 380A was significantly greater than that for the other two devices at both the 2 and 3 year time intervals after insertion. For all other termination categories, a statistically significant earlier difference was not maintained at subsequent yearly time intervals (e.g., bleeding and pain and cumulative relevant terminations). The rates of removal for bleeding and pain were significantly different in each of the first 2 years; however, the difference among these devices changed. The TCu 300 had a lower rate of removal than both the TCu 220C and TCu 380A for bleeding and pain 1 and 2 years after insertion. By 3 years, both the TCu 300 and TCu 380A had a lower rate of removal than the TCu 220C for bleeding and pain as determined by partitioning of the χ^2,[7] but the overall difference among the three devices was not significant.

In graphic form, the probability of not terminating for a termination category is represented by a survival curve.[6] In this study, the survival curves, as a function of time, move apart for other medical indications and closer together for the other termination categories. In the removal for bleeding and pain category, however, the curve for the TCu 380A moves toward the TCu 300 and away from the TCu 220C curve between the second and third year of use (Fig. 2).

The pregnancy rate was not significantly different for any of the devices although there appeared to be a temporal downward trend favoring the TCu 380A. This suggests that if the sample size were larger the lower pregnancy rate associated with the TCu 380A may have been significantly lower than for the other

‡Calculated by dividing woman days at risk by 30.44 (the average number of days per month).

two devices. This corroborates previous reports for various TCu devices studied for shorter intervals of use.[4, 9] Only three pregnancies occurred among women with the TCu 380A. One of these followed on unnoticed expulsion. None of the pregnancies occurred after 2 years of use. Since prevention of pregnancy is the main objective of a contraceptive method, this superior performance of the TCu 380A, although not statistically significant in this study, warrants further long-term large-scale evaluation.

Since only two ectopic pregnancies occurred in this study, no conclusions regarding type of device, duration of use, or parity can be made.

Removals for bleeding and pain accounted for the greatest numbers of removals in the use-related categories similar to previous studies.[10] One year following insertion, a significant difference in the removal rates for bleeding and pain was found in this study, in contrast to the lack of a significant difference previously reported with the same data analyzed by a different method.[4] This difference in significance is attributable to the following two factors related to the log-rank method of life-table analysis. First, in this type of analysis, patients not seen after insertion contributed no woman months of use in the data base. Second, the χ^2 test statistic employed is more sensitive than the overlapping confidence interval approach, which is based on a less exact calculation of standard error. A detailed comparison of log-rank and Tietze methods of life-table analysis has recently been reported.[6]

The greater number of removals for other medical reasons for the TCu 380A was investigated further

The charts of all patients who had the IUD removed for this category were examined to determine whether any bias in the distribution of patients might have contributed to the poorer experience in this category with the TCu 380A in comparison with the TCu 220C and TCu 300. None was found. This difference apparently occurred by chance since removal for other medical reasons is most likely not related to the type of IUD.

Although some studies have suggested that IUD usage increases the risk of developing pelvic inflammatory disease (PID),[11, 12] others have not.[10, 13] None has studied a cohort of women with appropriate control subjects using no method of contraception by life-table analysis. Since the relation of the IUD to development of PID and salpingitis has not been confirmed, the category of other medical removals for salpingitis or endometritis was not considered a relevant use-related risk for termination of IUD usage in this study.

Removals for planning pregnancy or other personal reasons in some instances were the next most common reasons for terminating use of the IUD. Removals for these categories were higher than in other reports.[9, 10] The cumulative total continuation rate, therefore, was lower for similar time periods.[9, 10] The cumulative relevant continuation rate, which reflects the strictly use-related termination categories (pregnancy, expulsion, and bleeding and pain), is a better means to compare different IUDs.

From the point of view of family planning programs, the success of a device is measured in terms of overall continuation rates, which are similar for the three devices described here. However, from the woman's point of view, unplanned pregnancy is far more important than the inconvenience of expulsion or removal for pain, bleeding, or other medical reasons. If a woman conceives with an IUD in place, she is forced into a decision which is based on documented risks. These include the risks of terminating the pregnancy,[14] the chance of inducing a spontaneous abortion if the device is removed,[15] and, if the device is not or cannot be removed, the risk of spontaneous abortion, infection, or premature delivery.[15] The copper sleeves were placed on the horizontal arms in an attempt to provide a copper-bearing surface in the fundal region and thus reduce the chance of an accidental pregnancy in the event of downward displacement. The TCu 380A device had the lowest pregnancy rates at each annual interval studied while the TCu 220C device had rates similar to those of the TCu 300 device. Thus, one device with horizontal sleeves had a reduced pregnancy rate and the other did not. Although the pregnancy rate associated with the TCu 380A did not differ significantly from that of the other devices, the low rate observed with this device suggests that additional study would demonstrate it to be more effective than the other devices. The pregnancy rate with the TCu 380A is comparable to that experienced by oral contraceptive users.[16]

Since the horizontal arms containing copper sleeves are less flexible than those without sleeves, they could produce a downward displacement of the device with uterine contractions. The resulting downward movement of these devices may cause increased bleeding and pain. The TCu 220C had the highest removals for bleeding and pain after three years while the TCu 380A and TCu 300 were not different. The structural difference between the TCu 380A and the TCu 220C device is that the former has wire while the latter has copper sleeves on the vertical arm. Perhaps the vertical copper sleeves of the TCu 220C, because of their rigidity, cause increased pain and the uterus responds with increased contractions which produce a further displacement into the lower uterine segment. This could account for the increased pregnancy rate and rate of removals for bleeding and pain of the TCu 220C.

Therefore, the hybrid design of the TCu 380A, which combines sleeves on the horizontal arms and flexible wire on the vertical arm, would appear to incorporate the best features of both the TCu 220C and the TCu 300 in addition to providing the greatest surface area of copper (380 sq mm). It should be studied in larger numbers of patients for a longer period of time to determine its actual clinical effectiveness. If such studies confirm that the TCu 380A, with a predictable lifespan of about 8 years, has the low pregnancy and removal rates found in this study, it may become the IUD of choice for both nulliparous and parous women.

This study was undertaken as part of the Contraceptive Development Program of the International Committee for Contraceptive Research of the Population Council, New York, New York. The technical assistance of Marie Fielding is acknowledged.

Naproxen sodium in uterine pain following intrauterine contraceptive device insertion

VEASY BUTTRAM, M.D.
ALLEN IZU, M.S.
MILAN R. HENZL, M.D.
Houston, Texas, and Palo Alto, California

In a double-blind parallel trial, repeated doses of naproxen sodium (550 mg initially, followed by 275 mg every 6 hours as needed) and placebo were administered to a group of intrauterine contraceptive device (IUD) users in whom dysmenorrhea and premenstrual uterine pain developed or increased following the insertion of the IUD. Seventeen subjects were treated with naproxen sodium and 16 received placebo. The study covered three episodes of uterine pain and/or cramping. Efficacy of pain relief was judged by: (1) the overall relief which the patients experienced during the treatment and (2) the changes in the pain intensity (measured on a 6 point scale). By both these criteria, naproxen sodium was statistically significantly superior to placebo ($p = 0.02$); consequently, naproxen sodium appears to offer a new treatment modality for pain associated with IUD usage. (AM. J. OBSTET. GYNECOL. 134:575, 1979.)

IN 1974, MASSEY and associates[1] reported that treatment wth a prostaglandin synthetase inhibitor (naproxen*) significantly reduced pain and discomfort following intrauterine contraceptive device (IUD) insertion. We have previously tested the analgesic properties of naproxen sodium,* an analogue of naproxen, in dysmenorrhea[2] and noted beneficial effects of this treatment for a number of women practicing intrauterine contraception. This prompted us to investigate the effects of naproxen sodium in a select population of IUD users in whom uterine cramping developed or increased after they had been fitted with IUDs.

Material and methods

The study was a double-blind, randomized, parallel trial in a group of IUD users. The effects of repeated doses of naproxen sodium were compared with those of placebo during episodes of uterine pain.

Patients. Two groups of women participated in the study, namely, those who after insertion of an IUD started to experience uterine pain and those whose previously experienced menstrual pain increased after IUD insertion. A full medical and menstrual history was obtained; particular attention was paid to the temporal relationship of the uterine pain to the IUD insertion and to the onset of menstrual bleeding. Complete physical and pelvic examinations were conducted, supplemented by peritoneoscopy, if indicated, to exclude obvious pelvic disease (inflammation, myomas, endometriosis, ect.). Women with major cyclic irregularities were excluded from the trial.

Thirty-five patients met the admission criteria and were randomly and sequentially assigned to either naproxen sodium or placebo treatment. The double-blind design of the study was explained to the patients, who were likewise told of possible adverse reactions to the active compound. Signed informed consent forms were obtained from all participants in the study.

Medication schedule. Each patient was given a supply of tablets containing either naproxen sodium (275 mg) or placebo (lactose) and was instructed to take two tablets at the first sign of menstrual distress and to continue to take one tablet every 6 hours as needed during the period of uterine pain. In the event that the test medication was not effective, patients were allowed to take the next dose sooner or to resort to a supplemental conventional analgesic, provided a record was kept of

Severe	1	3	10	9
Moderate	4	8	6	3
Mild	7	2	0	0
None	5	3	0	0
Total	17	16	17	16

*One patient was not included as she took placebo for several days prior to the first menses after IUD insertion and discontinued the placebo on the first day of bleeding because of no relief.

Table II. Number of patients who experienced excellent or good relief during treatment

Good or excellent relief experienced	No. of patients	
	Naproxen sodium	Placebo
In all three dysmenorrheic episodes	7	2
In two dysmenorrheic episodes	3	1
In one dysmenorrheic episode	4	1
In none of the dysmenorrheic episodes	3	12
Total	17	16

p Value = 0.003 (two-sided Mann-Whitney U test for group differences).

the dose concerned and the time it was taken.

Assessment of the drug effect. The patients were instructed to keep detailed records on which they noted the baseline pain intensity (i.e., pain intensity prior to the drug intake), the study drug intake, the relief achieved, and the necessity (if any) to take supplemental analgesic medication. From these entries, the effectiveness of the study drug was assessed by the overall rating of relief and by computing the "daily pain relief scores" (see details in the "Results" section).

Results

Demography. Of the 35 subjects originally enrolled, two left the trial for personal reasons. Data were analyzed for the remaining 33 subjects, 17 treated with naproxen sodium and 16 given placebo. Twenty-seven subjects were treated during three menstrual periods, 15 with naproxen sodium and 12 with placebo. Six subjects were treated for one or two dysmenorrheic episodes only; they either did not experience sufficient relief of symptoms (two of the naproxen sodium group and one of the placebo group) or had no need for further treatment (no dysmenorrhea, two patients; IUD removal, one patient; all three were in the placebo group).

The patients of the two treatment groups were comparable in ethnic background, age (means were 26.4 years, for the naproxen sodium group and 24.7 years for the placebo group), obstetric history, and individual history of dysmenorrhea.

The incidence and degree of dysmenorrhea before and after IUD insertion are given in Table I. The extent to which the pain increased in frequency and intensity after IUD insertion is obvious. All patients, except one, had been using analgesics for uterine pain before entering the study, but only three with noticeable effect.

Baseline pain intensity (i.e., pain experienced before the initiation of treatment) was scored on a 4 point scale: (1) very severe, (2) severe, (3) moderate, and (4) mild. Only patients who completed all three treatment courses were included in this analysis. For each treatment course, the scores obtained on individual days of dysmenorrhea were averaged and summed over the three treatment courses (the lower values represented higher pain intensities; see Fig. 2). It was interesting to observe that, despite the random allocation of patients to the two study medications, less pain was experienced by placebo-treated patients prior to the intake of the study drug (mean value of the sum of the baseline pain intensity scores, 8.57 ± 0.42 [SE]) than by the patients who were treated with naproxen sodium (mean value of the sum of the baseline pain intensity scores, 7.68 ± 0.26 [SE]; p = 0.021).

The overall rating of relief. For this evaluation, all 33 patients participating in the study were taken into account. After each dysmenorrheic episode, the patients assessed the effects of the study drug over the entire treatment course by scoring the experienced relief on a 6 point scale: 6, excellent; 5, good; 4, moderate; 3, fair; 2, poor; and 1, no relief experienced.

The overall relief scores were summed over all three treatment courses, and means were calculated for each treatment group, higher numbers indicating more pronounced relief. This type of evaluation was conducted irrespective of whether or not the patient had recourse to supplemental analgesia and regardless of the baseline pain intensity.

The results are summarized in Fig. 1. For the naproxen sodium group, the mean sum of the overall re-

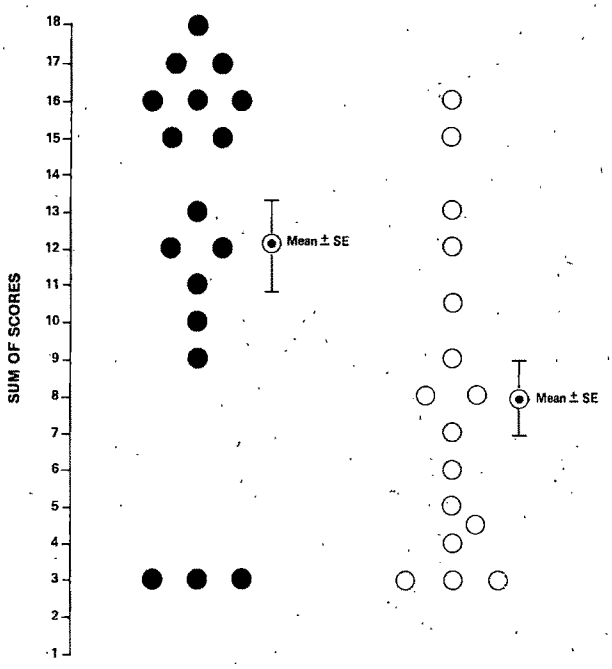

Fig. 1. Overall rating of pain relief. Sum of overall rating scores in three dysmenorrheic episodes for individual patients. • = naproxen sodium; o = placebo. The higher scores indicate a more pronounced effect of the study drug. The highest sum of scores a patient could acquire was 18; the lowest, 3. See details in text. p Value for difference between groups = 0.021.

lief scores was 12 ± 1.2; for the placebo group, 7.9 ± 1.1. The degree of relief afforded by naproxen sodium was statistically significantly higher by comparison with that associated with placebo administration (p = 0.02, two-sided Mann-Whitney U test). Table II shows that more patients experienced "excellent" or "good" relief in the naproxen sodium group than in the placebo group, with high statistical significance (p = 0.003).

Daily pain relief scores. Only patients who had completed all three treatment courses were analyzed (15 of the naproxen sodium treatment group and 12 of the placebo group). The relief achieved daily was graded as: 6, excellent; 5, moderate; 4, mild; 3, no relief; 2, pain worse; and 1, additional analgesia required. The ratings acquired on individual days of dysmenorrheic episodes were summed and average relief scores were calculated. For each patient, the relief scores were totaled over all three treatment courses. The highest sum of scores a patient could acquire was 18; the lowest, 3. For the group treated with naproxen sodium, the mean of all relief scores was 13.9 ± 0.8 (SE); for the placebo group, 10.8 ± 1.2 (SE) (Fig. 2).

In the statistical analysis, the baseline pain intensity was used as a covariable for each patient and the relief

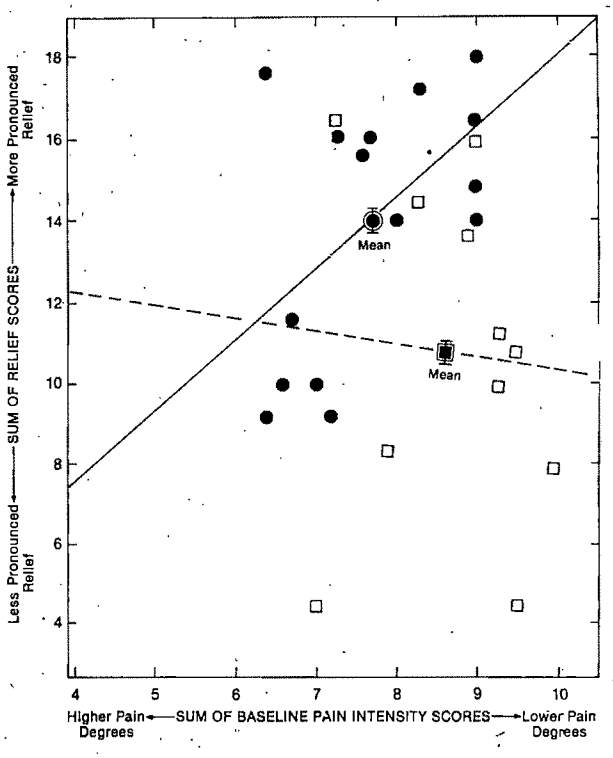

Fig. 2. Baseline pain intensity and pain relief achieved by treatment. Statistical analysis: The "baseline pain intensity score" was used as a covariable; the "relief score" served as the corresponding dependent variable. Baseline pain intensity scores: naproxen sodium group, 7.7 ± 0.26 (mean ± SE); placebo group, 8.6 ± 0.42 (mean ± SE); p = 0.021. Daily relief scores: naproxen sodium group, 13.9 ± 0.82 (mean ± SE); placebo group, 10.8 ± 1.15 (mean ± SE); p = 0.026. The slope of the regression line for the naproxen sodium patients demonstrates the dependence of the pain relief on the baseline pain intensity: Patients with lesser pain degrees at the treatment start experienced more pronounced pain relief. No such correlation is evident in the placebo patients (details in text). • = Naproxen sodium; □ = placebo. —— = Regression line for naproxen sodium patients; ---- = regression line for placebo patients.

scores, as the corresponding dependent variable. A one-way analysis of covariance was computed.[3] The difference in the rating of relief between the two groups was statistically significant in favor of naproxen sodium (p = 0.026).

Fig. 2 displays graphically the relationship between the baseline pain intensity and the relief achieved by the treatment. Each patient's relief score is plotted (on the vertical axis) against the baseline pain intensity (on the horizontal axis). The graph shows that the naproxen sodium–treated patients compared with the placebo patients experienced significantly more pain at the initiation of treatment. Despite that, the relief scores of the naproxen sodium patients were significantly higher than those of the placebo patients.

By fitting regression lines to the points of the two treatment groups, one can observe that the relationship between the baseline pain intensity and the achieved relief is different in the two treatment groups. For the naproxen sodium group, the slope of the regression line indicates that patients with lesser degrees of baseline pain intensity achieved higher pain relief scores than those with higher pain degrees at initiation of the treatment. This corresponds to the clinical impression that patients who started the treatment with the earliest symptoms of dysmenorrhea benefited the most from the treatment. No such correlation could be observed in the placebo patients. The nearly flat regression line demonstrates that the relief (or lack of it) was independent of the baseline pain intensity.

Need for additional medication. Although more patients in the placebo group needed additional analgesics (five during all three treatment courses versus two of the naproxen sodium group), the difference was not statistically significant.

Comment

Naproxen sodium is clearly superior to placebo in alleviating uterine cramping pains caused or aggravated by IUD insertion, and consequently may prove to be a useful drug for this type of condition.

The mechanism of pain relief is probably similar to that through which naproxen sodium is efficacious in primary dysmenorrhea.[2, 5, 6] Hillier and Kasonde[4] demonstrated elevated endometrial prostaglandin E concentrations 1 to 5 months after IUD insertion as compared with values obtained before IUD placement. If this raised prostaglandin concentration indeed contributes to the genesis and augmentation of dysmenorrhea in women practicing intrauterine contraception, then the use of a prostaglandin synthetase inhibitor seems logical as a means of counteracting that pain.

We wish to express our appreciation to Mrs. Carol Janecka, R.N., for coodination of the trial and to Alister Brass, M.D., for editorial assistance.

Vasoactive intestinal polypeptide in tissues of the human female reproductive tract

JOEL E. GOODNOUGH*
THOMAS M. O'DORISIO, M.D.
CHAD I. FRIEDMAN, M.D.
MOON H. KIM, M.D.
Columbus, Ohio

Vasoactive intestinal peptide (VIP) is a known potent hypotensive and vasodilatory agent. Studies were performed to determine the possible role of VIP in the human menstrual cycle in 44 patients in the reproductive age group, some of whom were using oral contraceptives, three pregnant patients, and four postmenopausal patients. No significant relationship between VIP and menstrual cycle phase was found. (AM. J. OBSTET. GYNECOL. 134:579, 1979.)

VASOACTIVE INTESTINAL PEPTIDE (VIP), a known potent hypotensive and vasodilatory agent with an amino acid sequence related to that of secretin, glucagon, and gastric inhibitory peptide (GIP), has been found by immunocytochemical studies in nerves intimately associated with vessels and smooth muscle of the female genitourinary tracts of pigs, cats, rats, and mice.[1] Most of the VIP-containing nerves were shown to occur in the smooth muscle of the genitourinary organs. However, numerous VIP-containing nerves were also found in the endometrium in a tortuous fashion, suggesting innervation of coiled arteries. Thus, evidence is accumulating that VIP may represent a peptide neurotransmitter which may affect smooth muscle contractility and blood flow.[1]

In order to explore the possible role of VIP in the human menstrual cycle, the levels of VIP were determined by radioimmunoassay in endometrial, cervical, and decidual tissues from women of various ages and phases of the menstrual cycle. The study groups consisted of 44 patients in the reproductive age group with or without the use of oral contraceptives, three pregnant patients, and four postmenopausal patients. None of the women were receiving hormonal treatment other than oral contraceptives. Endometrial tissue samples were obtained under direct visualization at the

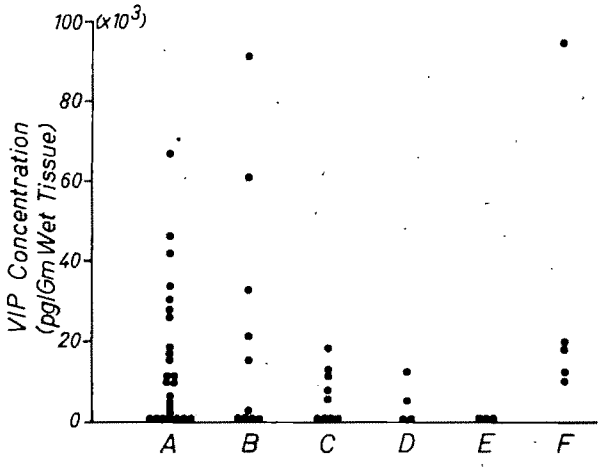

Fig. 1. Distribution of VIP in different tissues and phases of menstrual cycle. *A:* Proliferative endometrium; *B:* secretory endometrium; *C:* endometrium, oral contraceptive users; *D:* endometrium, postmenopausal; *E:* decidua; *F:* cervix.

time of cesarean section for term pregnancy or by dilatation and curettage before hysterectomy or elective sterilization. Cervical tissue was obtained in five patients by punch biopsy. All samples were obtained following general anesthesia and prior to any uterine manipulation. The tissue was frozen immediately on dry ice or in liquid nitrogen and stored at −20° C until the time of analysis. Portions of tissue samples were sent to the Pathology Laboratory for histologic dating of the menstrual phase.

The tissue was weighed to obtain a wet weight before extraction by a modification of the acid-alcohol method previously reported.[2] The tissue was homogenized in 2 to 4 ml of an acid-alcohol solution, refrigerated for 24 hours, and then centrifuged in a cold centrifuge at 2,000 rpm for 30 minutes. The supernatant was decanted, flash evaporated, and reconstituted in 0.05N acetic acid. Aliquots of several dilutions were assayed in duplicate for VIP assay. All determinations were expressed as picograms of VIP per gram wet tissue. The coefficients of variation of intra-assay and interassay reproducibility were 5% and 18%, respectively. The dilution of the human extract paralleled the standard curve for porcine VIP in all assays. Recovery rate of added known amounts of porcine VIP from tissue extract was 80%. A total of 56 tissue samples were assayed. The samples were divided into six different groups based on the source of the tissue, the phase of the menstrual cycle as determined by tissue study, and oral contraceptive usage (Fig. 1).

The present study demonstrated a VIP-like substance to be present in the endometrium and cervix of the woman. The six groups were compared statistically using Student's t test. No significant difference in the VIP levels of endometrial tissues from different phases of the menstrual cycle was found. Measurable amounts of VIP were found in postmenopausal tissues, cervical tissues, and endometrial tissues of those using oral contraceptives. Finally, no measurable levels of VIP were found in decidual tissues of term pregnancies.

In contrast to the known relationship between prostaglandin levels in endometrial tissue and the phases of the menstrual cycle, no such significant relationship could be found for VIP. Large variations of VIP concentration were found in all tissues studied, possibly suggesting a problem in sampling technique or inherent variation among individuals. Furthermore, of the 56 tissue samples, only 14 were from women who were admitted for elective sterilization and who had normal menstrual cycles with no apparent uterine disease. Further evaluation of a large number of women who are menstruating normally may show a direct relationship between the phase of the menstrual cycle and VIP concentrations in endometrial tissue. This may suggest a role for VIP in the regulation of the menstrual cycle.

Thyrotropin-releasing hormone and thyroid hormones in amniotic fluid

J. E. MORLEY
R. A. BASHORE
A. REED
H. E. CARLSON
J. M. HERSHMAN
Los Angeles, California

Immunoassayable TRH (iTRH) was measured in 50 amniotic fluid specimens with a mean concentration of 207 ± 26 (SE) pg/ml. This iTRH demonstrates parallelism with the standard curve for synthetic TRH. With increasing gestational age there is an increase in iTRH levels in amniotic fluid with a decrease in 3,3',5'-triiodothyronine levels (rT_3), while thyroxine levels (T_4) remain unaltered. Preliminary data suggest that iTRH levels in amniotic fluid that are less than 150 pg/ml after 32 weeks of gestation may correlate well with low Apgar scores at birth. There was no correlation of rT_3 or T_4 amniotic fluid levels with the Apgar scores. (AM. J. OBSTET. GYNECOL. 134:581, 1979.)

THYROTROPIN-RELEASING HORMONE (TRH) has been shown not only to be present in the hypothalamus and pituitary but also to be distributed throughout the rest of the brain,[1] retina,[2] gastrointestinal tract,[3] and adrenals.[4] It has been suggested that TRH is a neurotransmitter that has been co-opted by the pituitary to provide a tonic stimulus for TSH release.[1, 3] Recently it has been shown that TRH is present in the placenta and that the placenta is capable of manufacturing TRH from its constituent amino acids in vitro.[5, 16] Thyroxine (T_4) and 3,3',5'-triiodothyronine (rT_3) have been demonstrated in amniotic fluid, whereas triiodothyronine and TSH are not present in detectable amounts.[6] For these reasons we looked for the presence of immunoreactive TRH (iTRH) in human amniotic fluid and have attempted to determine if iTRH can be correlated with Apgar scores at birth.

Methods

Source of specimens. About 10 ml of amniotic fluid was obtained at various stages of pregnancy. Amniocentesis was performed by transabdominal puncture on 50 occasions in 32 women with pregnancies of 25 to 40 weeks for diagnostic purposes. None of the specimens were visibly contaminated with blood or its products. The results of various tests were correlated with the patients' clinical records. For the purposes of this study we have used an Apgar score of less than 7 at 1 minute or 5 minutes as an index of neonatal distress.

Assays. A total of 2.5 ml of amniotic fluid was extracted in 5 ml of methanol and the supernatant was evaporated to dryness in a water bath at 70° C under a stream of air. The dried extracts were taken up in 0.25 ml of phosphate-buffered saline (0.15M sodium chloride and 0.01M sodium phosphate, pH 7.5) and assayed in duplicate for TRH by radioimmunoassay as described by Bassiri and Utiger.[7] Antiserum to TRH was supplied by Dr. Robert D. Utiger, University of Pennyslvania School of Medicine.

For thyroid hormone assays, 1 ml of amniotic fluid was diluted in 2 ml 95% ethanol. The supernatant was removed and evaporated to dryness in a water bath at 37° C under a stream of air and reconstituted in 1 ml of buffer containing 0.25% bovine serum albumin, 0.02% sodium azide, and 0.0075M barbital at pH 8.6. were assayed in duplicate for T_4,[8] and rT_3 was measured with a radioimmunoassay kit from Serono Laboratories, Boston, Massachusetts.[9] The lecithin/sphingomyelin (L/S) ratio was measured as described by Gluck and associates.[10]

Results

We found iTRH in 50 amniotic fluid specimens with a mean concentration of 207 ± 26 (SE) pg/ml. This iTRH demonstrated parallelism with the standard curve of synthetic TRH (Fig. 1). Amniotic fluid, unlike serum, did not degrade synthetic TRH (Fig. 2). Incubation of 0.1 ml amniotic fluid for 2 hours with 0.2 ml human serum resulted in the loss of all immunoassayable TRH. With increasing gestational age (determined from maturity of infant at delivery), iTRH levels in amniotic fluid increase, rT_3 levels decrease, and T_4 levels are unaltered. The amniotic fluid iTRH levels for patients who were subsequently delivered of infants who had 1 minute Apgar scores greater than 7 are given in Fig. 3. Amniotic fluid levels were significantly increased from specimens obtained after 32 weeks (308 ± 5 pg/ml) compared to before 32 weeks (169 ± 31, $p < 0.025$). In amniotic fluid from 23 pregnancies more advanced than 32 weeks, low iTRH levels were more common in those who subsequently had babies with 1 and 5 minute Apgar scores of less than 7 (Table I). Similarly, mean iTRH levels were lower in patients with 1 minute Apgar scores less than 7 ($p < 0.01$) and 5 minute Apgar scores less than 7 ($p < 0.05$). In two normal subjects observed serially during pregnancy there was a rise in amniotic fluid iTRH levels when gestation reached 34 and 35 weeks, respectively. In three subjects with subsequent 1 minute Apgar scores less than 7, there was a rise and then a marked fall in iTRH levels (Fig. 4); these subjects had 5 minute Apgar scores of 7, 8, and 9.

There was no correlation of amniotic fluid iTRH with L/S ratio or T_4 and rT_3 concentrations. T_4 levels in amniotic fluid did not correlate with the L/S ratio or rT_3 levels. There was a significant negative correlation of rT_3 with the L/S ratio ($r = -0.53$, $p < 0.01$). There was no obvious correlation of amniotic fluid rT_3 or T_4 levels with subsequent Apgar scores. In five patients with Rh isoimmune disease, with severely affected fetuses, the rT_3 concentrations were not different from the control values.

Comment

There are many substances of maternal and fetal origin in amniotic fluid. Some of these substances (e.g., cortisol and palmitic acid) vary in concentration with advancing gestational age and most probably reflect the alteration of physiologic conditions leading to delivery.[11, 12] There are, however, no well-documented biochemical criteria either of maturation of the fetal nervous system or of antepartum fetal distress, with the exception of the amniotic fluid bilirubin concentration in cases of isoimmunization. Recently, a preliminary study has suggested that immunoassayable β-endorphin levels in amniotic fluid may be elevated in cases of fetal distress.[13] We have now shown that immunoassayable levels of another neurotransmitter, TRH, are measurable in amniotic fluid and that a fall in

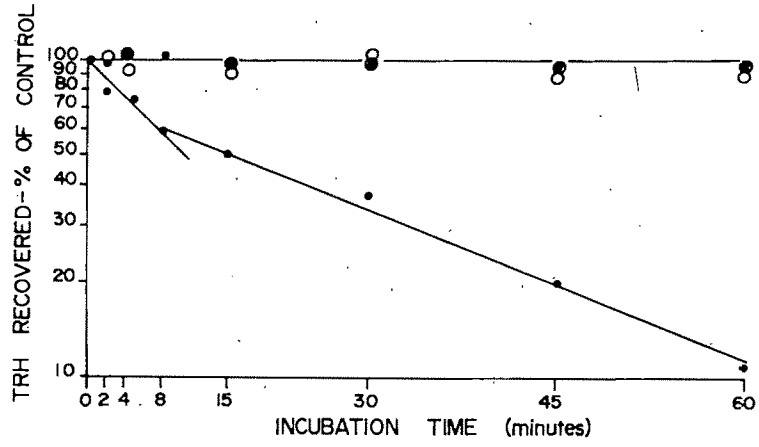

Fig. 2. Failure of amniotic fluid (8——8) to degrade 15 ng/ml synthetic TRH compared to normal degradation of TRH by human serum (●——●).

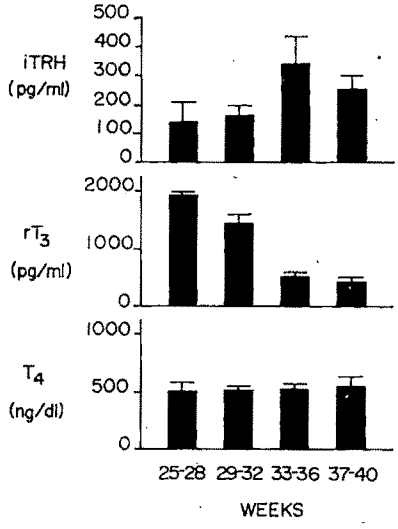

Fig. 3. Amniotic fluid levels of iTRH, rT_3, and T_4.

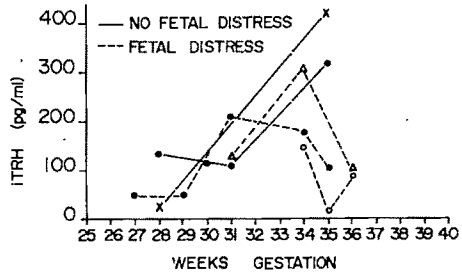

Fig. 4. Effect of advancing gestation on iTRH levels in patients from whom samples were taken on multiple occasions during pregnancy.

these levels during the last 8 weeks of pregnancy may be a marker for fetal or neonatal distress.

We have not shown whether the iTRH we are measuring is of the same size as the synthetic tripeptide or whether it is a larger precursor molecule. However, the degradation of amniotic fluid iTRH by serum is evidence that we are measuring a TRH-like substance as the immunoreactivity of the cross-reacting substances found in human urine is not destroyed by incubation with serum.[14]

We have confirmed earlier work showing that amniotic fluid rT_3 concentrations decrease during pregnancy and that T_4 concentrations are unaltered by advancing gestation.[6] Unlike Osathanondh and associates,[15] we did not find elevated rT_3 levels in patients with erythroblastosis fetalis. There was no correlation of iTRH levels with rT_3 or T_4 levels in amniotic fluid.

In conclusion, we have demonstrated the presence of immunoreactive TRH in amniotic fluid. The iTRH levels increase with increasing gestational age and preliminary evidence suggests that low iTRH levels in amniotic fluid may be a marker for fetal or neonatal distress.

Traumatic intra-uterine adhesions

JOSEPH GUSTAV ASHERMAN
Journal of Obstetrics and Gynaecology of the British Empire, vol. 57, pp. 892-896, 1950

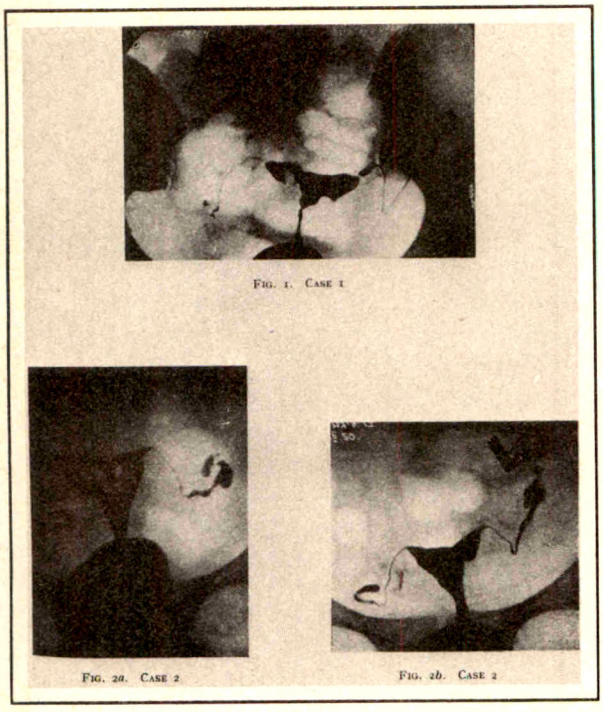

FIG. 1. CASE 1

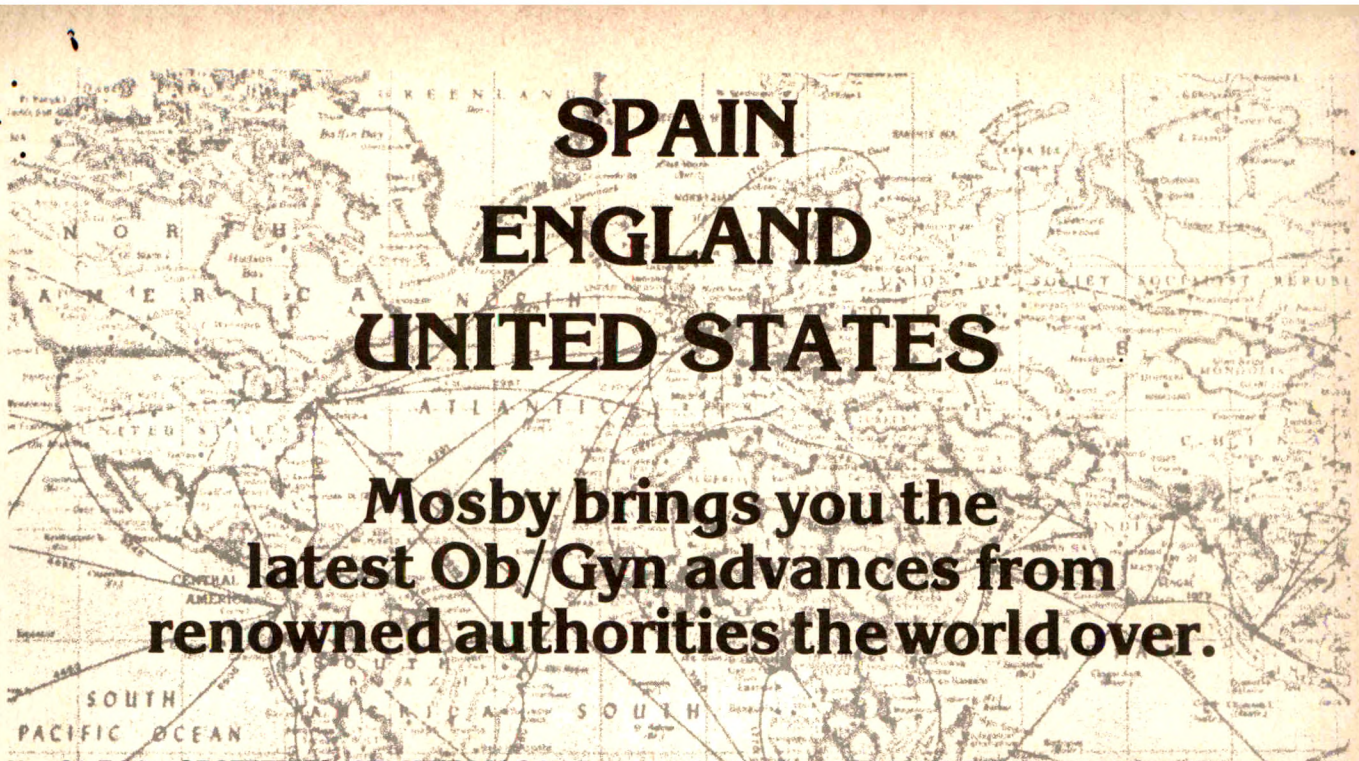

FIG. 2a. CASE 2

FIG. 2b. CASE 2

Adhesions between the anterior and posterior uterine wall as a cause of menstrual irregularities, infertility, and habitual abortion commonly are referred to by the eponym "Asherman's" syndrome. This is somewhat different from the lesion originally described by Asherman of Tel Aviv (Amenorrhoea traumatica [atretica], J. Obstet. Gynaecol. Br. Emp. 55:23, 1948), in which he detailed the findings in eight patients with secondary amenorrhea due to stenosis of the internal cervical os and reported a total of 29 such cases, the majority of which followed curettage for postpartum hemorrhage, incomplete abortion, or missed abortion. In this subsequent report Asherman first described regional obliteration of the uterine cavity due to partial conglutination of the opposing uterine walls. His first case (of eight reported) was of a 34-year-old woman who had experienced five spontaneous abortions during a 6 year period. Hysterography disclosed two filling defects of the uterine cavity (see illustration, *Fig. 1*). Thinking that the uterus contained submucous leiomyomas, Asherman performed a laparotomy and opened the uterus anteriorly. He then excised the unsuspected adhesions, placed a catheter from the endometrial cavity through the cervical os, and closed the incision. Subsequently the patient become pregnant and was delivered of a normal infant. That intrauterine adhesions indeed produced the hysterographic findings was demonstrated in his second case of a 35-year-old woman who had undergone five induced abortions followed by curettage for a missed abortion and infertility. The hysterogram disclosed a fenestrated cavity (see illustration, *Fig. 2a*), which, following hysterotomy with lysis of the adhesions, appeared relatively normal (see illustration, *Fig. 2b*). Asherman noted that he had discovered similar filling defects due to adhesions in 44 of 65 women examined for infertility following two or more curettages. He observed that adhesion formation seemed more frequently to follow curettage of old, organized placental tissue remains than curettage for recent abortion. Although Asherman employed a catheter to prevent readhesion of the uterine wall, he remained unconvinced as to its efficacy. (Later authors have recommended the use of a Foley catheter or intrauterine device for the same purpose.) Apparently, intrauterine adhesions with amenorrhea first were described by Heinrich Fritsch (Ein Fall von Volligem Schwund der Gerbormutterhohle nach Austkratzung, Zentralbl. Gynaekol. 52:337, 1894) in a 24-year-old woman with amenorrhea of 2 years' duration subsequent to a curettage performed 3 weeks after her first delivery. Fritsch was unable to introduce the smallest sound into the uterine cavity. He attempted to fashion a cavity by using a scalpel, dilator, and laminaria tent; however, within 2 weeks the cavity closed and the amenorrhea persisted. About the same time as Asherman's early reports, S. Stemer (Partial and

total atresia of the uterus after excochleation, Acta Obstet. Gynecol. Scand. 26:263, 1946) and Henning Hald (On uterine atresia consequent to curettage, Acta Obstet. Gynecol. Scand. 28:169, 1949) published accounts of a similar nature. (The majority of authors believe that traumatic curettage 1 to 4 weeks post partum or after abortion and, to a lesser extent, infection are involved in the development of the adhesions.) Asherman published several other reports on this condition (Bull. Fed. Soc. Gynecol. Obstet. [Paris] 4:807, 1952 and Int. J. Fertil. 2:49, 1957) as well as on endometriosis and many other topics in gynecology. A native of Czechoslovakia, Asherman emigrated to Palestine in the 1920s and worked as a general practitioner. Following specialty training he ultimately became Chief of the Department of Obstetrics and Gynecology at the Hakyria Maternity Hospital in Tel Aviv. A leader in Israeli medicine, he founded the Israel Society of Obstetrics and Gynecology and was its president for many years.

Mosby brings you the latest Ob/Gyn advances from renowned authorities the world over.

New 6th Edition OBSTETRICS AND GYNECOLOGY. By J. Robert Willson, M.D. and Elsie Reid Carrington, M.D. Through a truly integrated approach, the latest edition of this classic reference emphasizes the treatment of the total woman. Discussions follow the normal life cycle of women — from birth through puberty, maternity, climacteric and senescence. This volume combines the best features of a synopsis and comprehensive reference to provide you with effective methods of diagnosis and treatment. New discussions include important information on amenorrhea, polycystic ovary syndrome and the testicular feminizing syndrome. May, 1979. 680 pages, 609 illustrations. Price, $26.50.

A New Book. GYNECOLOGICAL CYTOPATHOLOGY. Edited by Matias Jimenez Ayala and Francisco Nogales Ortiz; with 16 contributors. Reflecting the work of 16 well-known Spanish cytologists, this atlas amply covers subjects in gynecological cytology and a review of the hormonal, bacteriological, and organic aspects of cytodiagnosis. The book visually shows you technique, normal cytology through various stages of normal, vaginal cytology during inflammation and cytological studies during pregnancy. The excellence of the illustrations clarifies examples of cell differentiation plus a good overview of normal and pathological cytology. November, 1978. 285 pages, 569 illustrations including 304 in color. Price, $36.50.

A New Book. SPERMATOZOA, ANTIBODIES AND INFERTILITY. Edited by Jack Cohen, D.Sc., F.I.Biol. and W.F. Hendry, Ch.M., F.R.C.S. Find out what your British colleagues are learning — and doing — about infertility. This unique volume is composed of thoroughly edited papers from a recent symposium. In it, leaders in the field discuss numerous significant aspects of infertility, including recent advances in the diagnosis and treatment of the problem. Since several of the papers were written from the scientist's point of view, you'll gain insight into the problem's underlying principles. April, 1979. 224 pages, 35 illustrations. Price, $27.50.

New 2nd Edition. HUMAN REPRODUCTIVE PHYSIOLOGY. Edited by Rodney P. Shearman, M.D., F.R.C.O.G. October, 1979. Approx. 600 pages, 90 illustrations. About $58.50.

ESSENTIALS OF FAMILY PLANNING. By Dame Josephine Barnes, M.A., D.M., F.R.C.P., F.R.C.O.G. 1976. 148 pages, 12 illustrations. Price, $5.95.

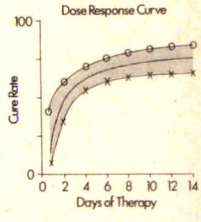
SOUTHERN MEDICAL ASSOCIATION DIAL access

high cure rates in only 7 days

all.

One applicatorful of MONISTAT 7 Vaginal Cream, every night for only 7 nights, produces significantly high cure rates in pregnant† and non-pregnant patients, patients on antibiotics or hormonal therapy, and those treated with other medications. After a single course of therapy, cured patients remained symptom-free with negative cultures throughout the menstrual cycle.

prompt symptomatic relief



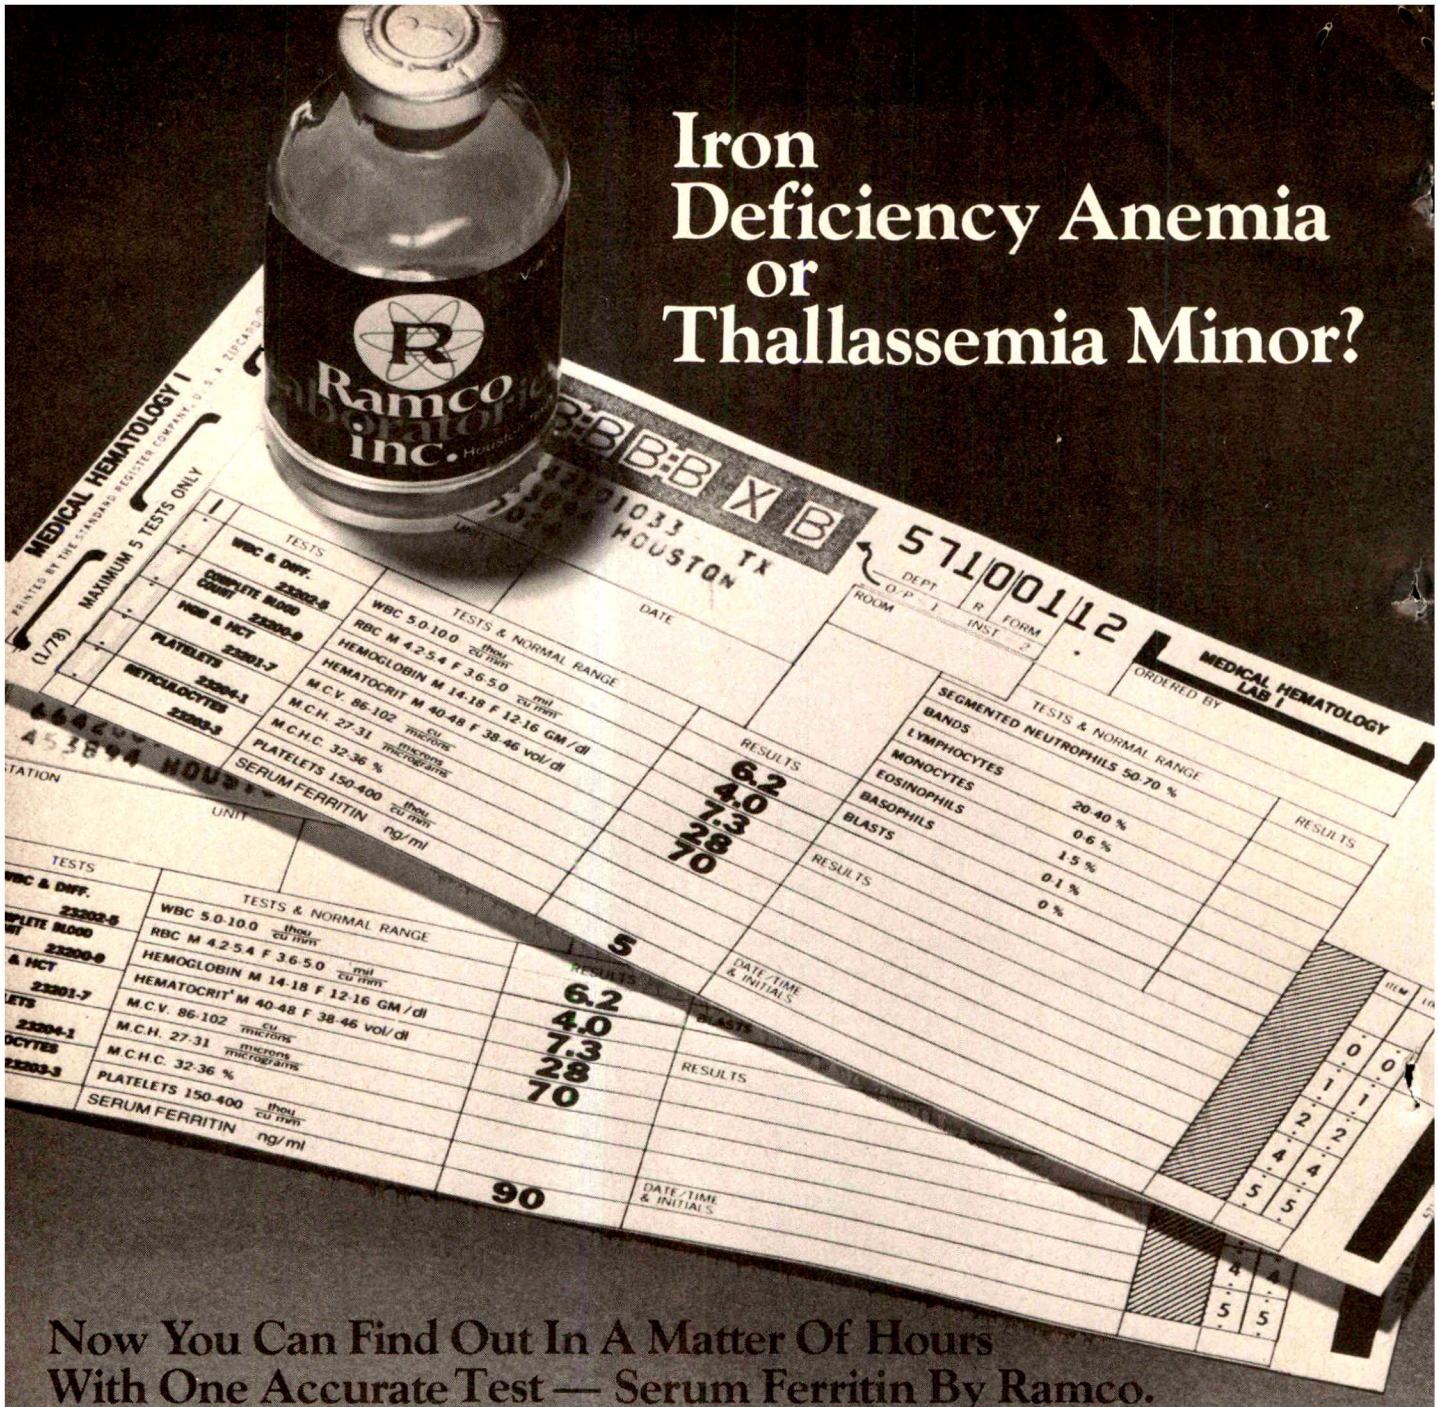
MONISTAT 7 Vaginal Cream contacts rapidly and intimately with infected tissues for prompt relief of symptoms of vulvovaginal candidiasis.

patient acceptance

The shorter, simpler course of therapy is convenient, easy to follow, easy to use, easy to comply with, and well-accepted by many women.

†MONISTAT 7 Vaginal Cream may be used in second and third trimester patients. However, in first trimester patients, it should only be used when the physician considers it essential to the patient's welfare. See Precautions in Prescribing Information.

Description MONISTAT 7 Vaginal Cream (miconazole nitrate 2%) is a water-miscible, white cream containing as the active ingredient, 2% miconazole nitrate, 1-[2, 4-dichloro-β-(2, 4-dichlorobenzyloxy) phenethyl] imidazole nitrate.
Actions MONISTAT 7 Vaginal Cream exhibits fungicidal activity *in vitro* against species of the genus *Candida*. The pharmacologic mode of action is unknown.
Indications MONISTAT 7 Vaginal Cream is indicated for the local treatment of vulvovaginal candidiasis (moniliasis). As MONISTAT 7 Vaginal Cream is effective only for candidal vulvovaginitis, the diagnosis should be confirmed by KOH smears and/or cultures. Other pathogens commonly associated with vulvovaginitis (*Trichomonas* and *Haemophilus vaginalis*) should be ruled out by appropriate laboratory methods.
MONISTAT 7 is effective in both pregnant and non-pregnant women, as well as in women taking oral contraceptives. (See **Precautions**.)
Contraindications Patients known to be hypersensitive to this drug.
Precautions General: Discontinue drug if sensitization or irritation is reported during use. Laboratory Tests: If there is a lack of response to MONISTAT 7, appropriate microbiological studies should be repeated to confirm the diagnosis and rule out other pathogens.
Pregnancy: Since MONISTAT is absorbed in small amounts from the human vagina, it should be used in the first trimester of pregnancy only when the physician considers it essential to the welfare of the patient. Clinical studies, during which MONISTAT was used for 14 days, included 209 pregnant patients. Follow-up reports now available in 117 of these patients reveal no adverse effects or complications attributable to MONISTAT therapy in infants born to these women.
Adverse reactions During clinical studies with MONISTAT for a 14-day regimen, 39 of the 528 patients (7.4%) treated with MONISTAT reported complaints during therapy that were possibly drug-related. Most complaints were reported during the first week of therapy. Vulvovaginal burning, itching or irritation occurred in 6.6%, while other complaints such as vaginal burning, pelvic cramps, hives, skin rash and headache occurred rarely (each less than 0.2% patient incidence). The therapy-related dropout rate was 0.9%.
Clinical Statistical analysis of randomized clinical trials, conducted to determine the shortest effective course of therapy with MONISTAT, demonstrates that a regimen of seven or more days has a cure rate equivalent to the 14-day regimen. The graphic representation of this conclusion plots days of therapy versus cure rates. The solid line represents the mean therapeutic cure rate and the shaded area represents the 95% confidence interval.



Dosage and administration One applicatorful is administered intravaginally once daily at bedtime for seven days. Course of therapy may be repeated after other pathogens have been ruled out by appropriate smears and cultures.
Supplied MONISTAT 7 Vaginal Cream is available in 1.66 oz. (47 g) tubes with ORTHO* Measured-Dose Applicator. MONISTAT Cream (miconazole nitrate 2%) is a development of Ortho Pharmaceutical Corporation and Janssen Pharmaceutica, Belgium.

Iron Deficiency Anemia or Thallassemia Minor?

Now You Can Find Out In A Matter Of Hours With One Accurate Test — Serum Ferritin By Ramco.

Serum ferritin will accurately separate the two — as iron deficient patients have values of less than 30 ng/ml, while patients anemic for other reasons have values in excess of 50 ng/ml.

Patients with both iron deficiency and thallassemia minor may have microcytosis as shown by a low MCV. However, in iron deficiency anemia, iron stores are decreased and in thallassemia minor, iron stores are normal to elevated.

Simple iron deficiency anemia can be identified by the FER-IRON procedure since the ferritin content of the serum is reduced *only as a result of iron depletion*.

ASK your lab about RAMCO's FER-IRON for the determination of serum ferritin. For more detailed information on the clinical applications of serum ferritin:

CURRENT DEVELOPMENTS

Fetal breathing: A review

PETER LEWIS, M.D., PH.D., M.R.C.P.
PETER BOYLAN, M.B., D.C.H.*
London, England

The history, physiology, pharmacology, and clinical application of fetal breathing are reviewed. Early optimism that measurements of fetal breathing would aid in perinatal management decisions has remained unfulfilled. Problems to be overcome include standardization of technique and measurement parameters and allowance for physiologic variations. Recent research developments indicate that the likely role of fetal breathing in perinatal medicine will be in conjunction with other established tests of fetal health. (AM. J. OBSTET. GYNECOL. 134:587, 1979.)

FETAL BREATHING refers to fetal chest wall and diaphragmatic movements which mimic, in utero, the respiratory movements of postnatal life. Gaseous exchange is not part of the process and neither is alveolar expansion.

Although it was suspected at the turn of the century that fetuses made breathing movements in utero, confirmation of this awaited the development in the late 1960s of the chronic fetal lamb preparation by Dawes in Oxford and by Merlet in Paris. The subsequent short history of human fetal breathing research is a history of the development of ultrasound technology.

Indeed, it is arguable that the most significant development in fetal breathing research is about to occur almost unnoticed by the academic research worker. As of late 1978, more than a thousand real-time scanning units have been brought into clinical use in North America. User enthusiasm and mass production will ensure that the number will rapidly increase.[1] In consequence observation of fetal breathing movements is no longer the prerogative of the physiology laboratory or the university clinic; fetal breathing can and will be observed in every obstetrician's office. Even the novice scanner struggling to measure fetal biparietal diameters will scarcely fail to notice whether or not his fetal patient is making breathing movements. What then is the obstetrician to make of this new physical sign? He will wish to know the significance of breathing or not breathing, how this relates to the circumstance of measurement, and whether his observations should alter his management. This paper attempts to review present knowledge of fetal breathing in this practical context.

History

The first graphic records of fetal breathing movements are attributed to Ahlfeldt and Weber at the end of the nineteenth century.[2] In 1888, they observed rhythmic fetal movements through the maternal abdomen and attributed them to attempts by the fetus to breathe. Ballantyne,[3] in a text published in 1902, gave an eloquent description of the physiologic nature of fetal breathing movements and stated that several other workers had observed and obtained graphic records of breathing in utero. He noted the movements to be of two types; the first, a series of sharp elevations

0002-9378/79/130587+12$01.20/0 © 1979 The C. V. Mosby Co.

and depressions, were attributed to hiccups, while the second, a series of undulations, were attributed to regular interuterine respiratory movements. Windle,[4] in 1940, observed fetal respiratory efforts in a variety of animal species at cesarean section but concluded that these movements were a reaction to abnormal stimuli. Barcroft,[5] in 1946, arrived at similar conclusions following observations of sheep fetuses. In fetuses observed through the transparent amniotic sac and delivered into a warm saline bath, breathing movements could be elicited from day 35 to day 60 by tactile stimuli. Term gestation in the sheep is 147 days. After 50 days of age spontaneous fetal body movements initiated breathing movements, but from 60 days on fetal breathing movements could be provoked only by asphyxia. Barcroft concluded that the development of fetal breathing was related to the functional development of the nervous system and that once the ability to perform regular breathing movements was attained the fetus rested until delivery. These early experimenters had no method of performing long-term observations on fetal sheep.

In the late 1960's, Dawes and his group[6] in Oxford repeated Barcroft's observations using recently developed experimental techniques. Fetal lambs were delivered into a warm saline bath under maternal epidural anesthesia, or catheters and electrodes were inserted and the fetus was replaced in the uterus. Using these techniques the Oxford group undertook many basic measurements on the arterial pressure of the fetus, the movements of fluid in the trachea and esophagus, the amniotic pressure, and the electrocortical and transorbital potentials. A similar approach was being adopted at this time by Merlet and colleagues[7] in Paris. Observations made during the course of these experiments form the basis of present-day knowledge of fetal breathing. The existence of breathing movements in the sheep fetus was confirmed and these were seen to be a spontaneous physiologic phenomenon even in late pregnancy.

In 1971, Boddy and Robinson[8] described the application of A-scan ultrasound to the observation and measurement of fetal breathing in the human. By 1975, the A-scan technique had been used to observe breathing movements of 200 fetuses in labor and more than 500 antenatally.[9] Breathing movements were detected as early as 11 weeks' gestation and after 36 weeks a regular pattern was detected, similar to that seen in postnatal life. The movements were present from 55% to 90% of the time, until the approach of labor when the incidence fell. A diurnal rhythm was described, which resembled that seen in the fetal sheep.

Fasting reduced the incidence of fetal breathing while intravenous glucose given to fasting women stimulated breathing movements. Altered patterns of fetal breathing, both antenatally and during labor, initially held great promise as a method of detecting fetal compromise and, therefore, preventing perinatal hypoxia. However, these preliminary results were, in the words of the authors, "almost too good to be true" and they advocated independent verification of their tentative conclusions.

The A-scan technique for the detection of fetal breathing movements is tedious, relying as it does on the fetus' remaining in one position. Various other fetal and maternal movements produce records similar to those produced by breathing. The limitations of the technique are well outlined in the paper of Farman and associates[10] who recommended further technical sophistication before the method could be said to provide reliable information. Various attempts were used to improve A-scan methods, including the use of a double-beam scan,[11] but none of these was totally successful in eliminating artifact.

The development of real-time, gray-scale B-scan machines was a major advance. These systems consist of a multiple array of ultrasonic transducers which allow video reconstruction of a cross section of the uterine contents in real time. Therefore, a moving, rather than static, image is available for observation. The application of the method to the study of fetal breathing movements was first demonstrated by Gennser in Oxford and by Fox and Hohler[12] in the United States, around the end of 1975. Despite the fact that current machines have a spatial resolution limited to 0.5 mm, similar to the smallest chest wall movement of the fetus, the resolution is in practice sufficient to detect very small chest wall movements. This is because with every breath a characteristic visual cue is given not only by the chest wall of the fetus but also by structures moving within it. In the last three years many observations of human fetal breathing have been made using real-time ultrasound and the subject has undergone re-evaluation. Many of the earlier hopes that the study of fetal breathing movement would give a good indication of fetal health are having to be reassessed.

Fig. 1 illustrates the chest wall movements seen using this technique. The chest wall movements are of small amplitude and very difficult to detect when viewed as still photographs. When the chest is viewed in real time, however, the associated cues of changing lung density make their movements readily identifiable. The figure shows the chest and head of a 26 week fetus.

One other ingenious method has been used to investigate human fetal breathing. This is based on the observation that when the fetus makes breathing move-

ments high-velocity Doppler shift signals are generated within the fetal chest and upper abdomen.[13] These signals are generated either by jetting of venous blood in the inferior vena cava across the diaphragmatic hiatus or from blood flow changes in the umbilical vessels coincident with breathing movements.[14] It transpires that many clinicians have heard fetal breathing movements while using ultrasound echocardiography and dismissed the signals as artifacts. However, despite the simplicity of the method, observing fetal breathing by Doppler ultrasound has not gained a following as wide as that of those methods employing direct visualization of the fetal chest wall by real-time ultrasound.

Physiology of fetal breathing

Animal studies. Dawes and associates[6, 15, 16] published their findings in the now classic papers of the early 1970s. They concluded that fetal breathing movements were normally, but intermittently, present in the fetal lamb over the greater part of gestation.

Fetal lambs delivered into a warm saline bath exhibited brief outbursts of spontaneous, irregular respiratory activity, from 40 days' gestation onward. In the chronic fetal sheep preparation tracheal pressure changes were observed which were independent of amniotic pressure changes; the most likely explanation was fetal breathing. A continuous record of fetal diaphragmatic activity confirmed that contractions of the diaphragm were responsible for the changes in tracheal pressure.[17] Tactile stimuli to the face also elicited what appeared to be a primitive rooting reflex, previously described by Barcroft,[5] and an expiratory effort. With advancing gestational age the depth and frequency of the movements increased.

Two types of movement were described, single inspiratory efforts, or gasps, and bursts of rapid irregular activity. Gasps were present for approximately 5% of the observed time and occurred in episodes lasting a few minutes. They had a frequency of 1 to 4/minute and an amplitude of 20 mm Hg and more. Asphyxial gasps were regular, more prolonged, and deeper than those described above. Episodes of rapid irregular breathing were of much higher frequency and lasted from a few seconds to an hour; inspiratory efforts were irregular in both rate and depth.

The characteristic circadian rhythm was noted. The peak incidence of fetal breathing was in the late evening while fewest movements were made toward dawn. This diurnal variation was noted to be present from 85 days' gestation onward. Simultaneous electroencephalographic recording showed that rapid fetal breathing movements were always associated with low-voltage, rapid-frequency electroencephalographic activity.

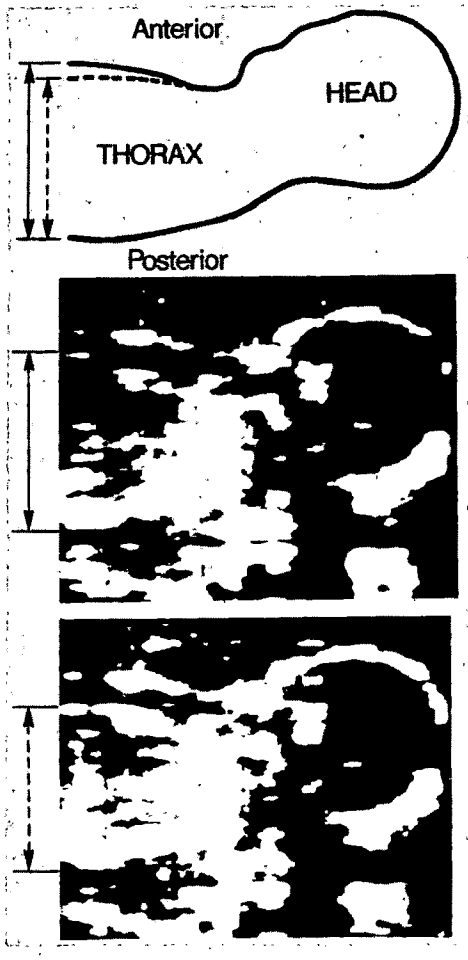

Fig. 1. Fetal breathing movements in a 26 week human fetus as observed by two still photographs from a real-time scanning sequence showing maximal inspiration *(I)* and expiration *(E)*.

There was no such association with gasping. Electrodes designed to detect eye movements revealed that rapid eye movement (REM) sleep was associated with the same electroencephalographic activity. The electrocortical characteristics of REM sleep are well developed only after 125 to 130 days' gestation in the sheep; therefore, it was apparent that rapid, irregular fetal breathing occurred in the absence of such electrocortical activity in the early stages of pregnancy.

Blood gas concentrations over the range of spontaneous variations encountered did not influence fetal breathing in any way. In addition cervical vagosympathetic trunk section or blockade with a local anesthetic drug had no effect on the movements. Dawes concluded that, under physiologic conditions, neither pulmonary stretch receptors nor central or peripheral chemoreceptors played any part in regulation of fetal breathing activity.

The effects of hypoxia and hypercapnia were then studied. Reducing fetal arterial Po_2 from its mean

normal of 25 to 16 mm Hg abolished rapid irregular fetal breathing. When there was also a fall in arterial pH the recovery period was much prolonged. The electroencephalogram during hypoxia showed a slow, large-voltage pattern characteristic of quiet sleep.

Increasing fetal arterial Po_2 up to 35 mm Hg had no effect on the character or incidence of breathing movements. Therefore, oxygen supply was not felt to be a limiting factor.

Hypercapnia caused a sustained increase in fetal breathing. Raising the fetal arterial Pco_2 by 8 to 10 mm Hg doubled tracheal fluid flow and the proportion of time during which fetal breathing movements were present.

During rapid, irregular fetal breathing tracheal fluid movement was minimal, fluid displacement amounting to no more than 0.5 ml per breath compared with approximately 80 ml of air after birth. This finding was consistent with the relatively high density and viscosity of the fluid. Between episodes of breathing there occurred, once or twice an hour, an outward flow of approximately 2 ml associated with a brief rise in tracheal pressure. Net tracheal flow was in an outward direction and near term could amount to 100 ml/kg/day.

Breathing movements were associated with cardiovascular changes. Rapid, irregular breathing was accompanied by tachycardia, a rise in carotid pressure, and an increase in aortic flow. Expiratory efforts were accompanied by a fall in heart rate and carotid pressure and a decrease in aortic flow. Dalton and colleagues[18] more recently have found an increase in heart rate variability during episodes of fetal breathing; they concluded, however, that it is not possible to identify episodes of breathing from characteristic fetal heart rate changes.

Fetal hypoglycemia, <10 mg glucose/100 ml, inhibited breathing activity. In sheep studies there was insufficient diurnal variation in blood glucose levels to account for the circadian rhythm of fetal breathing activity. Handling and light general anesthesia also inhibited fetal breathing.

Three of the ewes studied went into spontaneous labor during the course of the experiments; none showed a significant change in rapid, irregular breathing before the onset of labor. In one lamb fetus the record during labor was of sufficiently good quality to allow analysis and in this fetus breathing movements were significantly reduced during labor.

Fetal breathing movements under physiologic conditions have been measured directly in several other species, including the goat[19] and the monkey.[20] In all species studied the movements have been periodic rather than continuous, with bursts of breathing interspersed with periods of apnea. The incidence of breathing at term varies among species, ranging from 40% in the lamb to 80% in the monkey.

Breathing patterns before death in a group of 16 lambs have been described by Patrick and associates.[21] Three patterns were noted. In all there was a prolonged apneic interval between cessation of normal fetal breathing and onset of antemortem patterns.

In six of the fetuses there was a continuous "picket fence" pattern of rapid, regular breathing which continued until a few minutes before death in all but one fetus; all those with the "picket fence" pattern had hypercapnia. In eight there were episodes of gasping with a background of apnea; as death approached the frequency and amplitude of the gasps increased. In the third pattern, noted in two lambs, there were episodes of rapid breathing accompanied by gasping, again with a background of apnea. A similar response, apnea followed by isolated gasps, was also noted by Tchobroutsky and colleagues,[22] who asphyxiated fetal lambs with an inflatable cuff around the umbilical cord. Manning and co-workers[23] observed terminal gasping in a series of seven rhesus monkey fetuses that died. However, in these monkeys the "picket fence" pattern was absent and they feel that this may be because panting is not a characteristic breathing pattern in nonungulate species. Panting has been observed in exteriorized lambs by raising the bath temperature 1° C from 39.5° C.[16] Boddy[24] reported that Robinson observed similar episodes in the human associated with a rise in maternal temperature.

Chapman and associates[25] have recently reported on patterns before death in six lamb fetuses which subsequently died before labor. In all six a period of apnea preceded the abnormal patterns before death. One fetus had isolated gasps with a background of apnea. In three fetuses the apneic interval was followed by episodes of regular, rapid breathing with interspersed gasps; these episodes merged into a uniform continuous pattern. In the remaining two fetuses there were episodes of gasping which progressively lengthened and eventually merged into the uniform continuous pattern described above. The various patterns are represented graphically in Fig. 2

In all animal species so far described the prognostic significance of a period of apnea followed by either gasping or rapid continuous breathing is apparent. Dawes has emphasized, however, that such patterns do not inevitably terminate in death and that recovery is possible.

In conclusion, therefore, fetal breathing movements in the nonhuman occur intermittently from an early stage of gestation and become more organized as term

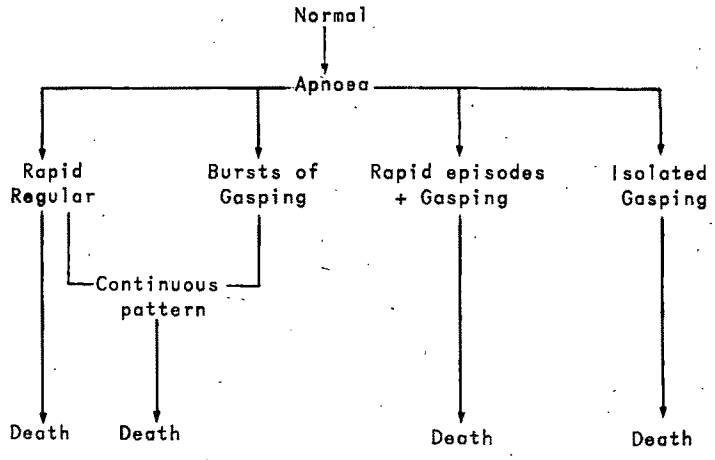

Fig. 2. Changes in fetal breathing behavior in lambs prior to intrauterine death as observed by recording tracheal pressure (Modified from Chapman and associates.[25])

approaches. They are not influenced by changes in blood gas concentrations over the physiologic range but are markedly inhibited by anoxia and stimulated by hypercapnia. Hyperoxia has no effect. Handling, light general anesthesia, and hypoglycemia inhibit fetal breathing. Tracheal fluid oscillations are minimal during normal fetal breathing but with gasping, amniotic fluid, with or without meconium, is inhaled as far as the matured bronchial structure allows. Normally there is a net outward flow of tracheal fluid which increases toward term and is reflected in the increasing amounts of surfactant found in the amniotic fluid.

Fetal death is associated with particular patterns, the most characteristic preceding feature being prolonged apnea. Labor appears to be associated with inhibition of fetal breathing but in the very small series reported the movements do not appear to decrease with the approach of labor. It must be borne in mind, however, that almost all the above conclusions have been derived from work on the fetal lamb and other species have been much less studied.

Human pregnancy. Boddy and Robinson were the first to describe the characteristic features of human fetal breathing; all their observations were performed using the A-scan technique. They observed breathing movements from 11 weeks' gestation; by 36 weeks the pattern was regular, similar to breathing movements in postnatal life. Breathing movements were present during 30% to 90% of any recording period. A circadian rhythm similar to that reported in the fetal sheep was present with a minimum amount of breathing movements in the early morning. Hypoglycemia was associated with a decrease in breathing and intravenous glucose given to fasting mothers stimulated fetal breathing within 10 minutes.

Antenatally the presence of normal breathing movements for less than 50% of the time, accompanied by some gasping, was felt to predict the probable development of fetal distress in labor. Patterns leading up to fetal death were described in 11 fetuses; in 10 there were gasping movements only; in one fetus of a diabetic mother there were short bursts of unusually rapid breathing in the 2 days prior to death.

In labor normal fetal breathing movements were noted for 60% to 90% of the time if the maternal P_{CO_2} was normal or raised and if there was no hypoxia; if the P_{CO_2} fell because of hyperventilation then movements were reduced in incidence but there was no gasping. Asphyxia was accompanied by the cessation of normal breathing and onset of gasping.

Real-time ultrasound. Certain of the above characteristics of human fetal breathing have not been confirmed using real-time ultrasound. Dawes has suggested that the A-scan results need to be re-evaluated critically using real-time scanning. Since the first reports by Gennser in 1975 several papers have been published which do not corroborate the original A-scan findings. The advantages of real-time ultrasound were described by Fox and Hohler,[12] who noted the easier orientation, more precise definition of the timing of events, and elimination of movement artifacts; they compared A-scan and real-time results and found that real time gave a satisfactory record 95% of the time after 20 weeks' gestation whereas the A scan resulted in reliable images 28% of the time before 28 weeks and 66% of the time after 28 weeks. Longitudinal midline alignment gave the most satisfactory orientation for accurate scoring of fetal breathing although some workers prefer a transverse scan through the fetal thorax.

Fetal breathing in normal pregnancy. A very wide range in incidence of fetal breathing in normal pregnancies has been observed by several workers. The incidence

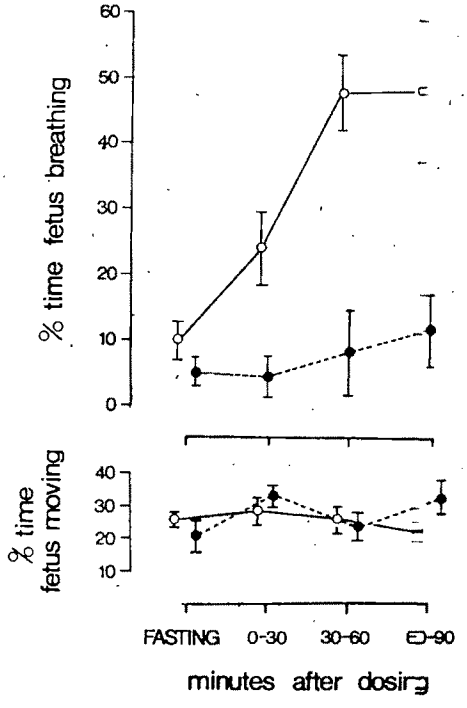

Fig. 3. Fetal breathing and fetal whole body movements following maternal ingestion of 50 gm oral glucose and water in equivalent volume. Six patients in each group, 36 weeks' gestation.

may range from 90% to none in the observation period, generally 30 minutes. In contrast to the A-scan findings, prolonged periods of apnea are compatible with a satisfactory perinatal outcome.

Patrick and associates[26] studied a group of 10 normal fetuses between 09.00 and 17.00 hours at 34 to 35 weeks' gestation. The mean hourly incidence of breathing activity increased during the day from 16% before noon to 35% in the 5 hours after noon. Periods of apnea lasted up to 20 minutes. Fetal hiccups were seen at least once in every fetus during the 8 hours of observation time.

Fox and Hohler[12] examined 24 normal patients and found a mean incidence of 30%, with a range of 98% to complete apnea. As gestation advanced the incidence of fetal breathing movements appeared to increase; Angel and associates[27] noted an increase from 5% at 25 weeks to 43% at term.

Because of the known inhibitory effect of hypoglycemia on fetal breathing, Trudinger and associates[28] standardized the observation period by giving a 50 gm glucose drink to the mothers 30 minutes prior to observing the fetus for a period of 30 minutes. In 12 normal fetuses breathing movements were present for 40% to 70% of the observed time. In fetuses of fasting mothers breathing activity was present for no more than 10% of the time. Fig. 3 illustrates the responses of a group of normal 36 week fetuses to maternal ingestion of 50 gm of glucose. While ingestion of water had no effect on either breathing or fetal movements, glucose quadrupled breathing and had no effect on other fetal movements. Natale and associates[29] have recently obtained similar results in a group of 22 healthy patients in late pregnancy.

Fox and Hohler[12] looked at the influence of an oral glucose load given to fasting and nonfasting mothers. They studied 18 nondiabetic patients; nine were fasting and the incidence of fetal breathing increased from less than 30% to more than 60% following the glucose. In the nine patients who were not fasting there was no difference before and after the oral glucose, although the initial amount of breathing was greater in the fetuses whose mothers were not fasting.

Patrick and associates[26] noted that the percentage of time spent in breathing increased from 18% to 43% following an 800 calorie meal; maternal blood sugar levels were not estimated during this study. In the same paper they described some observations on diabetic pregnancies; breathing movements were present more than 80% of the time with maternal glucose concentrations greater than 180 mg% while the same fetuses breathed less than 5% of the time with maternal glucose concentrations of 40% to 50 mg%.

Roberts and associates[30] examined 16 normal patients throughout the 24 hour period; scanning was done for 1 hour every 3 hours. The incidence of fetal breathing ranged from 11% to 61% (mean 30%). A marked diurnal variation was noted with a peak in the early afternoon and trough in late evening and early morning. Fetal breathing increased in rate, depth, and amount following meals; a significant correlation was found between the incidence of fetal breathing and plasma glucose levels and between rises and falls in the plasma glucose level.

However, Angel and associates[27] found no correlation between blood glucose and the incidence of fetal breathing in a series of 21 patients observed through pregnancy from 18 weeks' gestation to term. Similarly, in diabetic patients, McCune[31] found no correlation between breathing and maternal blood glucose concentration. Table I summarizes published work on normal subjects.

From the reported studies on the influence of glucose on fetal breathing movements it appears that maternal fasting and hypoglycemia inhibit fetal breathing movements, and a rapid increase in maternal, and, therefore, presumably fetal, blood glucose concentration stimulates breathing movements. In the nonfasting mother there does not appear to be a correlation as direct as that with maternal blood glucose status. The

physiologic mechanisms involved in this interaction between swings in blood glucose concentration and fetal breathing are not understood. Human fetal breathing activity may be a reflection of neurological maturity, with an immature respiratory center being overly sensitive to hypoglycemia. In this context it is interesting to note that in the neonate hypoglycemia may be responsible for apneic attacks.[32] Studies on the fetus of the diabetic mother might help to explain this relationship.

Blood gas alterations. Hypercapnia and hypoxia have profound influences on breathing in the fetal sheep. Ritchie[33] has studied the influence of hypercapnia in the human; maternal hypercapnia, induced by breathing 5% carbon dioxide in air, increased the incidence of fetal breathing threefold in 52 of 54 normal fetuses. Maternal hyperoxia had no effects on the incidence of breathing in a group of 32 normal fetuses. Van Weering and associates[34] obtained similar results in a group of 25 normal patients.

Fetal hiccups. Fetal hiccups, or singultus fetalis movements as Bots and associates[35] call them, which are often noticeable by the mother, have been described by Lewis and Trudinger,[36] by Lemay and associates,[37] and by Patrick and associates.[26] They are apparently a normal phenomenon although Bots and associates have recently pointed out that they were present in greater frequency in a group of low–birth weight infants; the difference was not statistically significant and they advocated further examination of the phenomenon. Dunn[38] pointed out that a similar type of movement had been described in 1902 by Ballantyne.[3]

Fetal presentation. Marsal and associates[39] using A scan, formed the impression that fetal presentation influenced the incidence of breathing movements. They found a reduced incidence in the leading twin in a cephalic presentation but not in a breech presentation. They also found less breathing in singleton pregnancies where the presentation was cephalic compared with breech and concluded that pelvic side wall pressure on the fetal head exerted an inhibitory effect on fetal breathing activity. However, Angel and associates,[27] using the real-time system, more recently found no such differences. This is a further example of discordance between results from the A scan and those from real-time scanning.

Amniocentesis. Manning and associates[40] noted a significant decrease in fetal breathing activity for up to 2 days following amniocentesis in a group of 24 high-risk pregnancies.

Fetal breathing in labor. The initial reports from the Oxford group of workers concerning fetal breathing in labor, measured with the A scan, have not been substantiated with the real-time system.

Table I. Fetal breathing in normal subjects

Study	*No.*	*Weeks' gestation*	*Time fetus spent breathing (%)*
Patrick et al.[26]	10	34-35	32
Fox and Hohler[12]	24	20-41	31
Roberts et al.[30]	16	30-39	30
Angel et al.[27]	21	25	5
		30	20
		37	35
		Term	43
Trudinger et al.[28]	12	34-48	10 (Fasting)
			55 (After glucose)
Fox and Hohler[12]	8		60 (After glucose)

Wittman and associates[41] reported on a group of 25 patients studied in labor between 8 AM and 4 PM. Nine of the labors were spontaneous and 16 were induced. The patients fasted for at least 16 hours although the mean blood glucose level was 91 mg%; 20 of the patients were receiving a 5% dextrose infusion. Breathing was observed in 13 of the 25 fetuses and tended to occur in episodes shorter (up to 30 seconds) than those of movements observed antenatally. They found a significant correlation between a decrease in the amount of fetal breathing and an abnormal fetal heart rate tracing (an abnormal fetal heart tracing was defined as having poor variability, late or severe variable decelerations, or bradycardia). Fetal hiccups were observed in three of the 25 subjects.

We have also studied women in labor. Of 10 patients in induced labor only three exhibited regular fetal breathing. Two of these patients were receiving a dextrose infusion. Blood glucose concentrations were 284 and 85 mg% respectively. A period of hiccupping was seen in one further patient. In the remaining six patients in whom no fetal breathing movements were seen the mean maternal blood glucose level was 71 mg%. All the patients were delivered of healthy infants of appropriate weight for gestational age and none developed any perinatal problems. These results indicate that absence or paucity of fetal breathing in induced labor is compatible with a satisfactory perinatal outcome. In addition they point to a possible etiologic role of maternal blood glucose in the control of fetal breathing in labor. It is worth noting that labor was induced with intravaginal prostaglandin E_2.

Pharmacology of fetal breathing

Animal pharmacology. All quantitative work on the animal pharmacology of fetal breathing has been carried out in sheep, usually in chronic preparations in which the fetal trachea was catheterized. Boddy and associates,[42] in 1976, carried out a careful study of the effect of small doses of pentobarbital (4 mg/kg intrave-

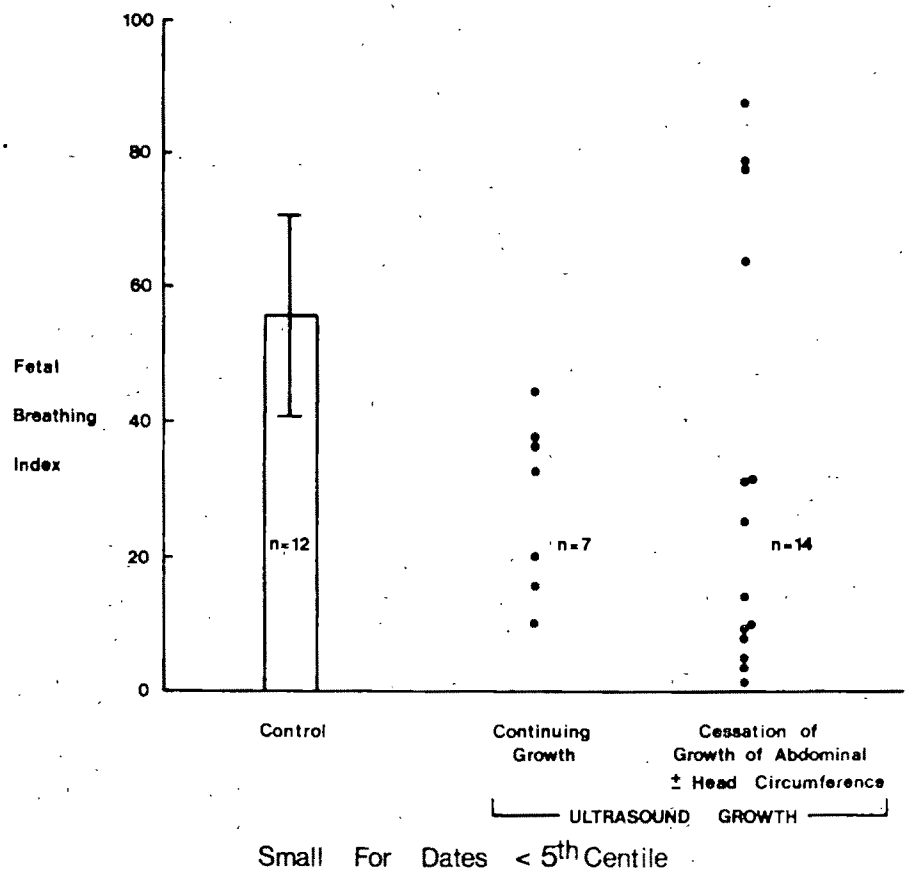

Fig. 4. Proportion of a 30 minute observation period which fetuses spent breathing, 30 minutes following maternal ingestion of 50 gm oral glucose. All fetuses were subsequently born small for dates (less than the fifth percentile, apart from the control group). (From Trudinger et al, 1978.[28])

nously) given to sheep in the last third of pregnancy. This small dose of barbiturate had little apparent effect on the ewe but markedly diminished fetal breathing movements. The effect of a single dose lasted approximately 2 hours and coincided with a change to a high-voltage pattern in the fetal electrocorticogram. The time to arrest of fetal breathing following administration of pentobarbital varied with gestational age. It is interesting that in similar experiments doses of meperidine (1 to 3 mg/kg) had no consistent effect on fetal breathing movements. However, when fetal breathing had been augmented by inducing maternal hypercapnia subsequent dosing with meperidine reduced breathing by the fetus.

Condorelli and Scarpelli[43] in similar experiments also reported that various barbiturates injected into the fetus and into the ewes stopped respiratory movements by sheep fetuses in late gestation.

Piercy and associates[44] studied the effects of diazepam. Maternal intravenous infusion of diazepam in a dose of 0.18 to 0.22 mg/kg reduced the incidence of fetal breathing movements. The time course of this reduction was reproducible and breathing returned to preinjection levels about 60 minutes after dosing. These authors also studied the effects of caffeine and doxapram. Both of these drugs stimulated fetal breathing. When caffeine (1.5 to 5 mg/kg) was administered directly to the fetus, breathing was transiently stimulated for 3 to 5 minutes. Doxapram also initiated fetal breathing when given directly to the fetus in a dose of 1 to 2 mg/kg. Hogg and co-workers[45] also reported that maternal infusion of doxapram stimulated fetal breathing movements in the sheep.

Pilocarpine in small doses stimulates fetal breathing movements in the sheep. Brown and colleagues[46] feel that the effect is mediated through sensitization of carotid sinus chemoreceptors. Atropine and carotid sinus nerve ligation abolish the response.

Human pharmacology. Most pharmacologic studies carried out in human pregnancy have been done in patients actually being treated with the substance under investigation and were in the nature of incidental observations. With the exception of the study of Marsal and associates[47] on betamethasone, these

human studies have not included control or placebo experiments. Since fetal breathing is not a stable activity it is possible that some of these drug effects might have been due to the lapse of time or the psychological effect of the mother's being alarmed or reassured by the treatment she was receiving. However, most of the results in human pregnancy accord well with the concept developed in sheep, namely, that central nervous system depressants decrease fetal breathing while respiratory stimulants increase it.

Adrenocortical steroids.

BETAMETHASONE. Marsal and co-workers[47] investigated 29 pregnant women between the twenty-ninth and thirty-fifth weeks of pregnancy who were at risk of preterm delivery. Nineteen of these women were treated with 12 mg betamethasone daily while 10 served as controls. The incidence of fetal breathing movements was similar in both control and treated groups, implying that the steroid had no effect on fetal breathing activity and that its effect, if any, on surfactant production is mediated by other mechanisms.

Narcotic analgesics.

MEPERIDINE. Gennser and colleagues[48] reported the results of meperidine, 1 mg/kg, administered to a group of five women before the onset of labor. There was a decrease of about 50% in fetal breathing movements. Lewis and Oliver[49] performed a double-blind investigation on six normal nonsmoking primigravid patients between 34 and 35 weeks' gestation. Following an overnight fast the women were given a 25 gm glucose drink; after 30 minutes' control scanning the women received, in a double-blind manner, either intravenous meperidine or intravenous saline. The results showed that 5 mg intravenous meperidine had no discernible effect on fetal breathing movements, and there was no effect of placebo.

Benzodiazepines.

DIAZEPAM. Boddy[50] examined the effect of 20 mg diazepam given intramuscularly and found that it caused a marked reduction in fetal breathing.

Lewis and Oliver,[49] using the same protocol they used with meperidine, found that 2 mg diazepam given intravenously had no discernible effect on fetal breathing. Again there was no effect from injecting the saline placebo. Gennser and associates[48] showed that intravenous and intramuscular injection of diazepam had little effect on fetal breathing.

Barbiturates.

AMYLOBARBITAL. Boddy[50] reported that amylobarbital had little effect on fetal breathing.

Selective β_2-receptor stimulants.

SALBUTAMOL. Lewis and Oliver[49] have studied oral salbutamol in doses of 4 and 8 mg. Normal, primiparous, nonsmoking patients were studied between 34 and 38 weeks. The patients were fasting and no glucose was given to them during the course of the experiment. Placebos were not included since the previous work with diazepam and meperidine had shown no placebo effect. Six patients were studied for each dose of salbutamol for half-hour periods from 30 to 60 and 90 to 120 minutes after drug administration. Salbutamol was chosen for investigation because work by Gennser and colleagues[48] suggested that terbutaline had a stimulatory effect on fetal breathing, because stimulation of β_1-receptors in the adult increases respiratory rate and because salbutamol is a mildly hyperglycemic agent.

The results show that salbutamol, either 4 or 8 mg, had no effect on fetal breathing activity. Salbutamol also had no effect on fetal movements. This was unexpected since it has been reported that when women are given large oral doses of salbutamol they often complain of excessive fetal movement. This may be another illustration of the difference between the activity of normal and compromised fetuses.

TERBUTALINE. Gennser and colleagues[48] reported that in one case of terbutaline infusion to a woman in labor fetal breathing movements were stimulated.

Antihypertensive agents. Boddy has reported that methyldopa diminished fetal breathing in some patients to whom it was given but this was not a consistent effect. Methyldopa is known to regularly produce sedation in laboratory animals and man. However, it has also been reported to increase REM sleep in man.[51]

Smoking. Manning and co-workers[52] studied 19 women with uncomplicated pregnancies between the thirty-second and thirty-eighth weeks. They showed that smoking two cigarettes caused a marked fall in the proportion of time that fetal breathing movements were observed. The effect lasted up to two hours.

Manning and Feyerabend[53] showed that the fall in fetal breathing movements was significantly related to the rise in maternal plasma nicotine after smoking but not to the rise in carboxyhemoglobin. The nicotine effect was thought to be placental rather than fetal since nicotine given to fetal lambs stimulated rather than depressed breathing.

Gennser and associates[48] presented results to show that cigarette smoking and chewing nicotine containing gum decreased fetal breathing activity.

Caffeine. Finally, Lewis and Oliver[49] studied the effect of 50 mg of caffeine given orally in a study using six patients. Caffeine had no effect on fetal breathing or body movements.

Conclusions. The first conclusions from these studies on human fetal breathing and the effect of drugs are that the human fetus is not as exquisitely sensitive to

Table II. Correlation of fetal breathing movements with outcome of pregnancy

Study	*Type of test*	*No.*	*Correlation with outcome*
Fox and Hohler[12]	FBM in pts with positive OCT.	7	Good

Roberts et al.[30]	FBM alone—24 hour study	5	Good

FBM: Fetal breathing movements. CTG: Cardiotocography.

central nervous system depressant drugs as has often been thought. Some of the less well-controlled data on depressants in human pregnancy are questionable. In the normal fetus it seems that fetal breathing is a stable activity much more influenced by maternal plasma glucose than by sedative or stimulant drugs.

Fetal breathing in abnormal pregnancy. There have been several studies performed on abnormal pregnancies but, again, none has provided conclusive confirmation of the earlier A-scan results of Boddy and Robinson. The range of incidence of fetal breathing in both normal and abnormal pregnancies is such that prediction of outcome in the individual fetus is almost impossible, using fetal breathing measurements as the sole index of fetal health. Fox and Hohler[12] and Manning and associates[54] have recently presented data combining fetal breathing measurements with some other test of fetal health, with results more promising than those with fetal breathing movements alone.

In obstetrics the term "high-risk" encompasses a multitude; previous obstetric history and events in the present pregnancy combine to place patients in this category. The term is usually meant to refer to fetal risk of death in utero or perinatal hypoxia with all its attendant long-term problems. Maternal hypertension of pregnancy, with a diastolic pressure not greater than 100 mm Hg and no proteinuria, has been shown not to be injurious to fetal health.[55] Nevertheless many series of high-risk pregnancies include just such patients. Similarly, retrospective analysis of fetal heart rate tracings in labor and classification as "abnormal" are meaningless in the absence of accompanying data on scalp pH.[56] Perhaps the results of antenatal screening might be better if only those fetuses truly "at risk" of dying or developing perinatal hypoxia were included in the abnormal group.

Fox and Hohler[12] presented their findings in seven patients with positive oxytocin stress tests (OCT). Two of these fetuses had no fetal heart rate acceleration with fetal movement; one had prolonged apnea, while the other exhibited gasping movements; both had poor perinatal outcomes. The other five fetuses had fetal heart rate accelerations with movement; two had breathing movements for more than 20% of the observed time and both had satisfactory perinatal outcomes; the other three had poor perinatal outcomes and had either prolonged apnea or fetal breathing for less than 10% of the observed time. Therefore, the combination of a positive OCT with a reduced incidence of fetal breathing gave a poor prognosis while in this small group of patients fetal breathing for more than 20% of the time indicated a healthy fetus despite a positive OCT.

Manning and colleagues[54] similarly combined nonstress antenatal cardiotocography with fetal breathing to assess predictive accuracy. They found that if both cardiotocography and fetal breathing were abnormal then 45% of fetuses had low Apgar scores at birth. McCune[31] failed to find any correlation between patterns of fetal breathing, heart rate, and perinatal outcome. Marsal has postulated that looking at some other quality of fetal breathing rather than the incidence may be of more value.

Van Weering and associates,[34] in a series of small-for-dates fetuses, found that the absence of an increase in fetal breathing with maternal hypercapnia followed by a positive reaction to maternal hyperoxia was a poor prognostic sign. In normal pregnancy they found, in common with Ritchie and Lakhani,[33] that maternal hyperoxia does not influence fetal breathing.

In two studies using fetal breathing alone as the index of fetal health, Manning[57] and Trudinger and associates[28] found a wide range of incidence of fetal breathing in the abnormal pregnancies. Prolonged apnea or a grossly reduced incidence, however, did seem to be of poor prognostic significance. In Manning's study three of four fetuses with prolonged apnea required intubation at birth while in the study of Trudinger and associates three fetuses with an incidence of less than 10% died in the perinatal period. Trudinger and associates had standardized the procedure by giving a 50 gm glucose load to the mothers 30 minutes before screening.

As can be seen from Fig. 4, two patterns of fetal breathing emerge in the small-for-dates group; breathing for a greater or lesser percentage of time than expected. However, there is a considerable degree of overlap and in the individual case the prognostic sig-

nificance of a particular pattern is difficult to assess when fetal breathing is used as the sole parameter of fetal health.

Roberts and associates[30] in their study of the incidence of fetal breathing throughout the day found a low incidence in three asymmetrically growth-retarded fetuses but no such reduction in two symmetrically growth-retarded fetuses. The inference is that a fetus with a reduced hepatic glycogen store is unable to tolerate physical exercise for prolonged periods of time; in other words, the starved fetus is not as physically fit as his well-nourished brother. Table II summarizes published data on the correlation of antenatal fetal breathing with perinatal outcome.

Comment

The pattern that emerges from a review of results so far presented indicates that measurement of fetal breathing may be of value antenatally but the initial hopes that this would provide the answer to difficult perinatal therapeutic problems have not been borne out.

Most benefit would appear to be gained from combining fetal breathing results with some more established method of assessing fetal health such as cardiotocography. The very wide range of normal in the incidence of fetal breathing, which appears to be governed to a certain extent by time of day and maternal blood glucose fluctuation, suggests that standardization of the circumstance of measurement would allow more direct comparison of results.

The study of fetal breathing in labor is in its infancy and basic physiologic research needs to be done before any clinical application can be hoped for. In common with many procedures in obstetrics fetal breathing investigation is undergoing a period of re-evaluation. While the place of fetal breathing in the investigation of fetal physiology and pharmacology is unrivalled, clinical application in the management of patients needs to await further confirmation of its value.

The "purpose" of fetal breathing remains obscure although it has been suggested that movement is necessary for adequate development of the lung. It might also be speculated that, as in the adult, rhythmic movement increases the production of prostacyclin in the pulmonary vasculature. This recently discovered prostaglandin is thought to play an important role as a circulating anti–platelet-aggregatory hormone in the arterial circulation.[58, 59] However, the last word should perhaps be left to Ballantyne[3] who, in 1902, considered fetal breathing to be "thoracic gymnastics in preparation for the great extra-uterine function of atmospheric respiration."

COMMUNICATIONS IN BRIEF

This section is suitable for reporting results of therapeutic trials, descriptions of new procedures or instruments, and case reports which illustrate a principle. Reports should be limited to seven hundred words and two references. Use of an illustration or table requires a proportionate reduction in total words.

Induction of ovulation and pregnancy in a woman with sex chromosomal mosaicism 45,X/46,XX/47,XXX

CARL GEMZELL, M.D.
GEORGE I. SOLISH, M.D., PH.D.

Department of Obstetrics and Gynecology, Downstate Medical Center, State University of New York, Brooklyn, New York

A WOMAN WITH secondary amenorrhea, polycystic ovary disease (POD), and sex chromosomal mosaicism 45,X/46,XX/47,XXX was treated once with human menopausal gonadotropin (hMG) and human chorionic gonadotropin (hCG). She conceived and, in week 30 of gestation, spontaneously gave birth to normal twins, a 46,XY male and a 46,XX female.

B. T., a 32-year-old white woman, para 0000, was first seen in 1965 with a history of incomplete development of secondary sexual characteristics and failure of cyclic menses to occur by age 21. A pelvic examination showed a well-estrogenized vagina, a normal-size uterus, and ovaries estimated to be approximately 2 by 2 cm in size. She was 177 cm in height with an arm span of 181 cm. Buccal and vaginal smears were both positive for nuclear sex chromatin. Eighty-four metaphases from peripheral blood were 46,XX and 14 cells had 45,X karyotype. A repeat karyotpye done 5 years later showed 46,XX in 86 cells, 45,X in 8 cells and 47,XXX in 6 cells.

When treated with Provera orally, in doses of 10 mg/day for 10 days, vaginal bleeding followed in each of three cycles. She was given a course of 100 mg of clomiphene citrate for 8 days without response. Laparoscopy revealed the ovaries to be 2 by 2 cm in size and both fallopian tubes were found to be patent. Biopsies of both ovaries revealed "fibrous tissue" and a minute area of ovarian stroma in which no follicles were identified.

0002-9378/79/130599+02$00.20/0 © 1979 The C. V. Mosby Co.

Her history further revealed that she has seven siblings, two of whom are identical twin girls. Two sisters are dizygotic twins and two brothers are fraternal twins. One sister is married and has produced a healthy child.

The patient married in 1975 and 2 years later wanted to become pregnant. Despite the 45,X/46,XX/47,XXX karyotype and failure to demonstrate oocytes on ovarian biopsy, but based on the low plasma follicle-stimulating hormone (FSH) and withdrawal bleeding following progesterone, it was felt that oocytes were present and induction of ovulation was possible.

The low plasma levels of FSH and slightly elevated levels of lutenizing hormone (LH) and E_2 indicated a polycystic ovary syndrome and clomiphene citrate would be the first choice for induction of ovulation. However, clomiphene citrate had already been tried twice without response. It was therefore decided to induce ovulation with hMG (Pergonal).

The treatment with Pergonal lasted 12 days and the patient was monitored with daily E_2 determinations in plasma. The final dose of Pergonal was 4 ampules/day. Following hCG administration, she ovulated and conceived. On day 69, the uterus was enlarged to the size of an 8 to 10 week pregnancy; 3 days later ultrasound examination revealed the presence of twins.

Except for an episode of vaginal spotting from weeks 14 to 17 of gestation, the prenatal course continued normally until the early part of week 30 when, without difficulty, she was delivered vaginally of twins. Due to the spotting during gestation, she refused amniotic fluid examination.

Twin A, a 46,XY male, weighed 1,350 grams and Twin B, a 46,XX female, weighed 1,560 grams. Both infants appeared phenotypically normal and are doing well postnatally (12 months).

Clinical features in women with sex chromosome mosaicism involving a 45,X cell line are more variable than in those women with a single 45,X cell line. Somatic defects may be absent or milder, or may be indistinguishable from those of a typical Turner's phenotype. Gonadal development seen in sex chromosomal mosaicism may range from nonfunctioning streak ovaries to normal ovaries capable of producing regular menses

and spontaneous ovulation. The variation may be explained by the proportion of primordial germ cells which bear a 45,X karyotype to those with a 46,XX or 47,XXX constitution.

Our patient had a positive buccal smear and high proportion of primordial germ cells of 46,X karyotype compared to those with 45,X and demonstrated very few minor somatic features of Turner's syndrome. She represents a select group of women who may seek evaluation of infertility. Ordinarily, a woman with secondary amenorrhea and almost complete secondary sex development might not be examined for sex chromosomal abnormality.

Reyes, Koh, and Faiman[1] reviewed the literature up to 1976 regarding fertile women with a 45,X mosaicism. They reported on 25 women who had been pregnant 58 times. Eight of these women had cell lines similar to that of the patient reported in this study. Their history included eight abortions, two malformed stillborn infants, and 12 live births with one set of twins.

The 45,X line is generally conceded to be a postfertilization phenomenon arising by nondysjunction at or after the first cleavage. The etiologic agent responsible for nondysjunction in these situations is unknown, but twinning among siblings has been noted to be associated. Thus, Nance and Uchida[2] reported seven sets of monozygotic twins in 34 siblings in whom the proband was apparently 45,X.

We thank Drs. Charles A. Strott and Griff T. Ross for allowing us to use the clinical and laboratory data from National Institutes of Health.

Benign blue nevus of the uterine cervix

BHAGIRATH MAJMUDAR, M.D.
ROBERT JEOFFREY ROSS, M.D.
LEO GORELKIN, M.D.

Departments of Pathology and Laboratory Medicine and Gynecology and Obstetrics, Emory University School of Medicine, Atlanta, Georgia

Recently we encountered a case of blue nevus of the uterine cervix. Review of the literature revealed only 17 previously reported cases. Clinically, the lesion has sometimes been mistaken for malignant melanoma. Clinicians should therefore be aware of this lesion.

Reprint requests: Dr. B. Majmudar, Department of Pathology, Grady Memorial Hospital, 80 Butler St., S. E., Atlanta, Georgia 30303.

A 72-year-old black woman was admitted to Grady Memorial Hospital for subtrochanteric fracture of the right femur. Pathologic examination of the bone showed the structure of an anaplastic carcinoma. Since the patient had a pelvic mass and a pathologic fracture, she was referred to the Gynecologic Tumor Service, although she had no gynecologic symptoms. Physical examination showed a midline pelvic mass extending above the umbilicus but not related to the uterine cervix or adnexa. The parametrium was uninvolved. The cervix demonstrated a smooth mucosal surface on which a spherical blue lesion, 0.4 cm in diameter, was seen at the 11 o'clock position. The lesion was biopsied and at the same time biopsies of the cervix, endocervix, and endometrium were obtained. Pathologic examination of the endometrium showed the structure of a mixed mesodermal tumor. The blue lesion of the cervix was composed of subepithelial deposition of heavily pigmented spindle-shaped cells demonstrating long, thin, bipolar cytoplasmic processes. The pigment displayed the characteristic histochemical reaction of melanin and did not stain with Prussian blue stain for iron. No pigment was present in the overlying cervical epithelium. The histological findings were diagnostic of a blue nevus (Fig. 1). The patient's lesion was diagnosed as Stage IVB mixed mesodermal tumor of the uterine corpus. She died very soon after the diagnosis was made.

There have been 17 previously reported cases of the blue nevus arising in the uterine cervix, and two cases arising in the vagina.[1, 2] The majority of them are small and detected as an incidental finding on clinical or pathologic examination. Occasionally a blue nevus can be very large. Tobon and Murphy[1] described a blue nevus located at the apex of the anterior vaginal wall of a 73-year-old woman. The nevus measured 1.0 cm in diameter and was clinically diagnosed as melanoma. Rodriguez and Ackerman[2] described the case of a 19-year-old woman with a large, cellular blue nevus involving the cervix, vagina, and hymenal ring. The lesion was discovered during the routine prenatal care in the fifth month of pregnancy. The tumor in the vagina was hard and nodular. The pelvic examination was unremarkable. No lymphadenopathy was detected. The patient was lost to follow-up after 45 months. In a series of 45 cases of cellular blue nevi reported by these authors,[2] three cases were clinically diagnosed as malignant melanoma. An erroneous clinical and pathologic diagnosis of malignant melanoma in one patient resulted in unwarranted radical surgery. It is very important therefore that both clinicians and pathologists should be familiar with the gross and microscopic appearance of a cellular blue nevus. Although instances of malignant blue nevi or blue nevi metastasizing in the regional lymph nodes are reported in the literature, all the 17 cases of cervical blue nevi had a benign course. Adequate local exicision is, therefore, the treatment of choice. Incomplete excision can result in recurrence.

0002-9378/79/130600+02$00.20/0 © 1979 The C. V. Mosby Co.

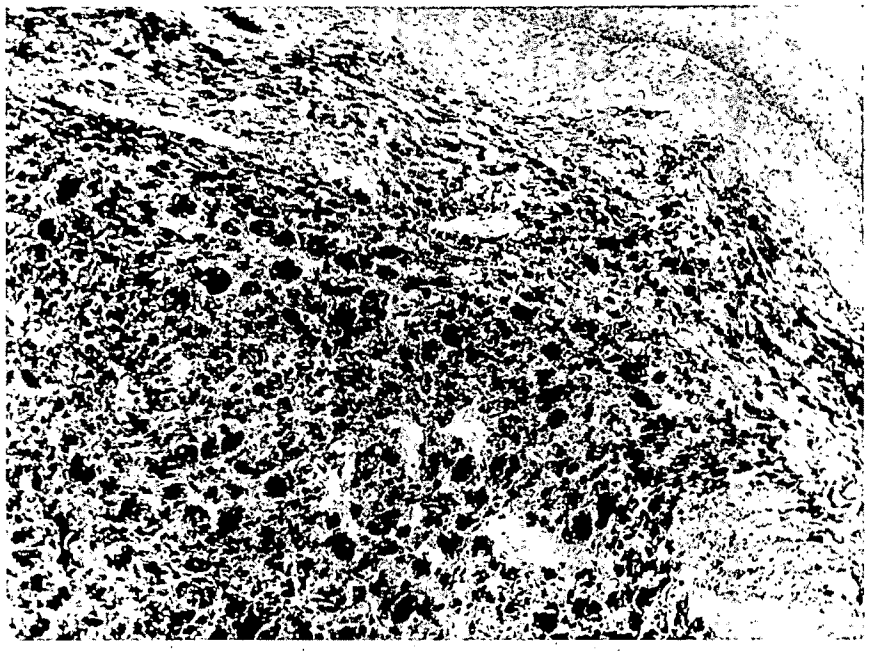

Fig. 1. Section of the cervix showing subepithelial deposition of heavily pigmented bundles of melanocytic cells. Note clear space between blue nevus and normal cervical mucosa. (Hematoxylin and ecsin; ×78.)

Besides blue nevi, one occasionally encounters melanosis or melanoma primarily involving the vagina or the uterine cervix. This phenomenon is histogenetically interesting. It is a generally held opinion that Schwann cells transforming into melanocytes are responsible for such a pigment disorder. This view is disputed by others and the precise mechanism is not known.

Correction of postpartum uterine inversion by the application of intravaginal hydrostatic pressure

G. SHER, F.A.C.O.G., M.R.C.O.G.

Department of Obstetrics and Gynecology, North Carolina Memorial Hospital, Chapel Hill, North Carolina

ACUTE INVERSION of the postpartum uterus is fortunately rare, occurring in approximately 1 out of 20,000 pregnancies. Few obstetric emergencies are more demanding of immediate intervention than this condition. Most methods described for the management of acute postpartum uterine inversion require digital replacement. In 1945, O'Sullivan[1] reported on a simple and effective method of dealing with this condition. His technique involved the occlusion of the vaginal introitus with the forearm, while a warm antiseptic solution was introduced, under pressure, into the vagina from a douche can held about 3 feet above the level of the patient's perineum. The purpose of this manuscript is to report on the satisfactory application of a modified O'Sullivan technique in two cases of acute postpartum uterine inversion.

The inverted uterine fundus is gently replaced into the vagina and a douche nozzle is directed into the posterior fornix. An antiseptic solution is liberally applied to the surgeon's cleansed forearm, which is then forcefully applied to the vaginal introitus longitudinally, while an assistant presses the labia to the surgeon's forearm so as to completely occlude the vaginal orifice. A second assistant forces 2 to 3 L of a warm, sterile saline solution through the douche nozzle under pressure into the vagina. The pressure is maintained for approximately 5 minutes, whereupon the surgeon removes his forearm and the saline is allowed to gush from the vagina. A vaginal examination is then performed in order to evaluate the effect of management. The procedure can be repeated if necessary.

M. V., an obese 29-year-old woman, had an uneventful prenatal course followed by a spontaneous vaginal delivery at

Reprint requests: Dr. Geoffrey Sher, Reno Women's Clinic, 429 W. Sixth St., Reno, Nevada 89503.

term. An attempt to deliver her placenta by guided cord traction (the Brandt-Andrews method[2]) resulted in complete inversion of the uterus. An intravenous line was introduced and blood was immediately cross-matched. Thereupon, the placenta was detached without difficulty and the uterus was gently reduced into the vagina. The modified O'Sullivan technique as described above was employed and the uterus reverted to its normal anatomic position within 5 minutes of initiating the procedure. Shock did not ensue and the total estimated volume of blood loss was 450 ml. The patient tolerated the procedure well and prophylactic antibiotics were prescribed. She made an uneventful recovery.

B. G., a slender 27-year-old non-Caucasian multiparous patient, had a benign prenatal course followed by a spontaneous delivery at term. It became evident after 45 minutes in the third stage of labor that despite the infusion of oxytocics, the placenta by the Credé method. This was followed by incomplete uterine inversion, with the fundus of the uterus protruding through the cervix, but not through the vaginal introitus. The placenta was easily detached from the uterine fundus, whereupon the modified O'Sullivan method was used to correct the inversion. This was achieved within 5 minutes of initiating the procedure. The patient did not become shocked and made an uneventful recovery.

The conventional method for managing acute postpartum uterine inversion is digital replacement; where this fails, a laparotomy is performed and surgical correction achieved. Profound vasovagal and hemorrhagic shock often accompanies this condition. Digital manipulation of the inverted uterine body is likely to aggravate both the vasovagal and hemorrhagic components of shock.

It is important to bare in mind that postpartum uterine inversion is often associated with a firmly attached placenta (i.e., accreta, increta, and percreta). An attempt to detach such a placenta piecemeal will result in uncontrollable hemorrhage. Accordingly, it is advisable to correct the inversion without prior removal of the placenta in such cases. Once this has been achieved, manual removal of the placenta can be attempted under general anesthesia, and in full preparation for hysterectomy should bleeding become uncontrollable.

The O'Sullivan technique as described above has several advantages: (1) it can be performed without general anesthesia; (2) the fluid, introduced under pressure into the vagina, exerts hydraulic pressure on the inverted uterus in a manner which allows the most efficient reduction of the inverted organ; (3) the method precludes the requirement for digital manipulation of the inverted uterus and thereby reduces the risk of aggravating the shock; (4) the method is both simple and reliable.

Methergine-induced uterine tetany treated with epinephrine: Case report

RICHARD WONG,
LIEUTENANT COMMANDER (MC) USNR
RICHARD H. PAUL, M.D. F.A.C.O.G.

United States Naval Hospital, Lemoore, California, and the Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, University of Southern California School of Medicine and Women's Hospital, Los Angeles County–University of Southern California Medical Center, Los Angeles, California

UNCONTROLLABLE uterine tetany leading to fetal damage can result from the inappropriate use of oxytocic agents. Fig. 1 shows the direct fetal monitor tracing of a patient who inadvertently received intramuscular methergine while in labor. The effects of methergine and the subsequent therapy with epinephrine are documented.

An 18-year-old white woman, gravida 1 para 0, was seen regularly for prenatal care. The patient was admitted for induction of labor at 43 weeks, following an abnormal nonstress test. AROM was performed at 0930 hours with application of a scalp electrode and intrauterine catheter. The patient entered labor without oxytocic stimulation. At 1650, the patient was inadvertently given 0.2 mg of methergine intramuscularly, ordered for another patient who had recently been delivered. At 1700, the cervix was 80% effaced and 2 to 3 cm dilated. At 1710, the strip chart showed contractions of increasing frequency and hypertonus. The fetal heart rate (FHR) had decreased to 80 to 90 bpm with increased variability. Then ½ cc of 1:1000 epinephrine was given rapidly intravenously. There was a rapid decline in the excessive uterine activity. Concomitantly, a fall in the FHR to 40 to 50 bpm with a flat baseline occurred, with a subsequent slow return to baseline. Hypertonus gradually recurred and another injection of epinephrine (⅙ cc of 1:1000) was given intravenously. A similar FHR-UC response was seen, but was of shorter duration. Uterine activity gradually resumed a normal labor pattern and the patient was delivered of a 6 lb ¼ oz male infant, with Apgar scores of 5/7, by low forceps 6 hours later. Moderately severe variable decelerations occurred during the second stage and may have contributed to the depressed 1 minute Apgar score. The baby did well and was discharged to his home with the mother on the third postpartum day. Subsequent infant examinations over 9 months have been normal.

The dramatic effects of oxytocic agents on both uterine activity and FHR are illustrated by this case. Methergine is an ergot derivative that causes an irregular polysystole which can progress to tetany.[1] It was widely studied as a labor-inducing agent in the 1940's but, due to difficulty in regulating dosage and occurrence of hypertonus, its use was discontinued.

The opinions or assertions contained herein are those of the authors and are not to be construed as official or reflecting the views of the Department of the Navy or the Department of Defense.

Reprint requests: Richard H. Paul, M.D., Women's Hospital 5K-22, 1240 N. Mission Rd., Los Angeles, California 90033.

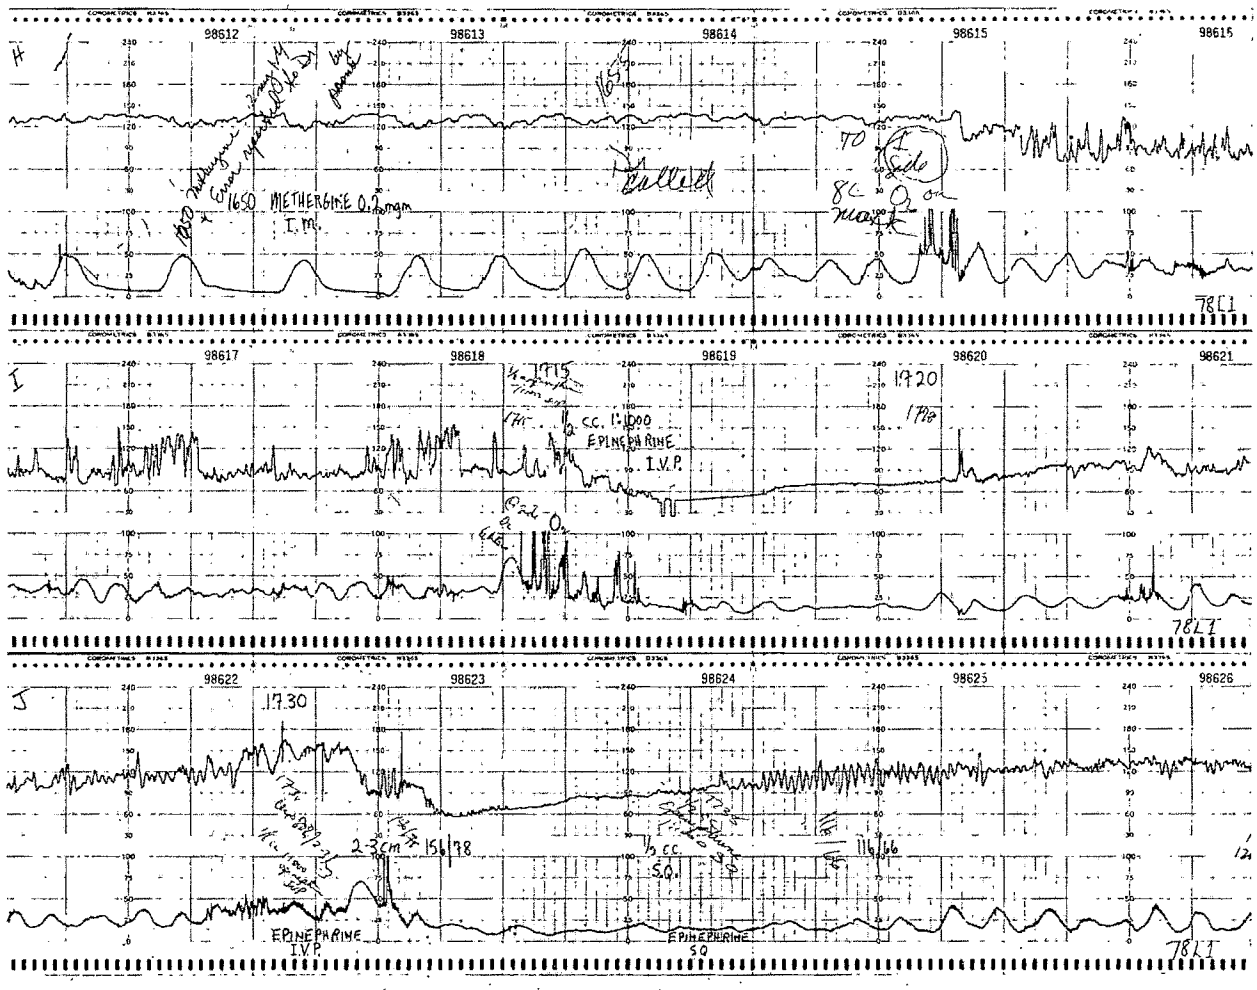

Fig. 1. The FHR-UC characteristics with the use of direct methods for monitoring are shown. The dramatic response associated with epinephrine administration is evident.

Epinephrine is known to produce uterine relaxation, but of such short duration that it is generally not considered useful when prolonged relaxation is required.[1] It has also been found to cause bradycardias in the human fetus, although true distress from its administration has not been documented.[2]

In situations of uterine tetany secondary to an oxytocic infusion, therapy is simply to discontinue the offending drug.

The therapy of iatrogenic tetany secondary to drugs given in an unregulated manner is unclear. In the face of such a crisis situation, the decision in this case was made to utilize epinephrine, which is known to have tocolytic action. Examination of the tracing reveals the two effects. The prompt uterine relaxation represents the β-sympathomimetic effect of the drug. The profound, fetal bradycardia is probably due to an α-adrenergic effect on the uterine vasculature with resultant decreased uterine blood flow. A direct effect on the fetal circulation and myocardium cannot be ruled out, but seems unlikely in the face of uterine hypertonus.[2]

The use of epinephrine in this patient may have been beneficial to the fetus. Epinephrine clearly reduced uterine activity following both episodes of intravenous administration. Even though the second dose was reduced by two thirds, an equivalent tocolytic effect occurred. The FHR response suggests a stress factor which likely was related to vasoconstriction. The FHR response following the second dose was less dramatic, suggesting a dose-related response.

In cases of excessive uterine activity, it would be desirable to achieve tocolysis without an adverse effect on uterine blood flow. β-Sympathomimetic drugs possess such activity but are unavailable in this country. Epinephrine in low dosage might achieve a primary beta effect, but titration would be difficult.

In view of this case, it would appear that another alternative agent, such as magnesium sulfate, should be considered.

International Conference of Biological Engineering Society: Foetal and Neonatal Physiological Measurements

The International Conference of the Biological Engineering Society, "Foetal and Neonatal Physiological Measurements," will be held September 3-5, 1979, in Oxford, England.

Offers of papers should be made now and submitted with an abstract on one side of A4 paper to the Programme Chairman: Dr. P. Rolfe, Bioengineering Unit, Department of Paediatrics, John Radcliffe Hospital, University of Oxford, Headington, England 0X3 9DU.

All other enquiries and requests for further information should be directed to: Keith Copeland, Honorary Secretary, Biological Engineering Society, c/o Royal College of Surgeons of England, 35/43 Lincoln's Inn Fields, London, England WC2A 3PN.

Professor K. de Snoo Memorial Congress

The Professor K. de Snoo Memorial Congress, in cooperation with the Eleventh Meeting of the Organisation Gestosis, will be held at The Hague, The Netherlands, September 18-21, 1979.

For information write: The Secretariat, P. O. Box 175, 2770 AD Boskoop, The Netherlands.

Second Trimester Abortion: Perspectives After a Decade of Experience

"Second Trimester Abortion: Perspectives After a Decade of Experience" sponsored by the Department of Obstetrics and Gynecology, University of North Carolina at Chapel Hill, and The Charles A. Fields Foundation, Ltd., Madison Wisconsin, will be presented in Chapel Hill, North Carolina, at the Carolina Inn, September 27-28, 1979.

For information write: The University of North Carolina, c/o Office of Continuing Education, University NC School of Medicine, 236 MacNider Bldg. 202H, Chapel Hill, North Carolina 27514.

Nutrition and the Killer Diseases

The Institute of Human Nutrition at Columbia University is sponsoring a 2 day symposium, "Nutrition and the Killer Diseases," at the Sheraton Centre (formerly Americana Hotel), 52nd St. and Seventh Ave., New York, New York, November 29-30, 1979.

For further information write: Director, Institute of Human Nutrition, Columbia University, 701 W. 168th St., New York, New York 10032.

Interdisciplinary Aspects in Diseases of the Female Breast

An International Congress on Seniology: Interdisciplinary Aspects in Diseases of the Female Breast, organized by the Senologic International Society, will be held in Hamburg, Germany, May 27-31, 1980.

Direct inquiries to: Prof. Dr. H.-J. Frischbier, Universitäts Frauenklinik, Martinistrasse 52, 2000 Hamburg 20, Germany.

Annual autumn seminar of the Department of Obstetrics and Gynecology, University of Minnesota Medical School

The Department of Obstetrics and Gynecology of the University of Minnesota Medical School will present its annual autumn seminar, October 24-26, 1979, at the IDS Center Conference Theatre in Minneapolis, Minnesota.

For further information contact: Office of Continuing Medical Education, Box 293 Mayo Memorial Bldg., 420 Delaware St. S.E., Minneapolis, Minnesota 55455.

Office Ultrasound

The University of Tennessee Center for the Health Sciences, Knoxville, Tennessee, will present "Office Ultrasound," October 25, 26, 27, 1979, at the Sheraton Inn, Gatlinburg, Tennessee.

For further information contact: Department of Continuing Medical Education, U.T.C.H.S./K.U., Drawer 116, 1924 Alcoa Highway, Knoxville, Tennessee 37920. Phone: (615)971-3345.

International Congress on Ageing and Gonadal Function: Biological and Clinical Aspects in Male and Female

An International Congress on Ageing and Gonadal Function: Biological and Clinical Aspects in Male and Female, sponsored by the Italian Society of Obstetrics and Gynecology, Italian Society of Andrology and Fondazione Giovanni Lorenzini, will be held in Rome on November 28-30, 1979.

A limited number of communications (in the form of posters and talks) will be considered by the Scientific Committee.

For further information please contact the Organizing Secretariat: Fondazione Giovanni Lorenzini, via Monte Napoleone, 23-20121 Milan, Italy. Telephone: (02) 783.868 or 702.267. Cable: LORENZFOUND.

EDITORS! REVIEWERS! AUTHORS!

For you . . . a new book that contains virtually everything you want to know about

THE SCIENTIFIC JOURNAL: EDITORIAL POLICIES AND PRACTICES

Guidelines for Editors, Reviewers, and Authors

In 1665 the first scholarly journal was published in France. Since that time, there has been no one source of editorial guidelines for journal editors. This new book now provides you with such a source.

YOU DECIDE YOUR OWN APPROACH!

Presenting the advantages and disadvantages of each specific decision, eminent editors offer you various recommendations, discussions, and opinions concerning the problems you may encounter:

"Because we are aware that there is no 'right' policy on most editorial matters, we have tried not to prescribe rules, but have, instead, explored various facets of the problems that confront the editor in his daily work."

The book is divided into two general sections: editorial policies, which usually require major decisions; and editorial practices, which involve minor decisions, often about format or mechanical style. You'll find essays exploring: the manuscript reviewing system; special types of manuscripts (abstracts, transactions, solicited manuscripts, book reviews). You'll value chapters which cover: information for authors; copyright; errata; references cited; copy-editing; journal cover; etc.

From "the purpose of scientific journals" to "binding practices," this new book contains virtually everything you want to know as editor, reviewer, or author. See for yourself!

By Lois DeBakey, Ph.D. In collaboration with: Paul F. Cranefield, M.D., Ph.D.; Ayodhya P. Gupta, M.D.; Franz J. Ingelfinger, M.D.; Robert J. Levine, M.D.; Robert H. Moser, M.D.; J. Roger Porter, Ph.D.; and F. Peter Woodford, Ph.D. August, 1976. 128 pages, 6″ × 9″. Price, $12.50.

BELLERGAL-S™ TABLETS

Composition: Each Bellergal-S Tablet contains: phenobarbital, USP, central sedative (Warning: May be habit forming), 40.0 mg; Gynergen (ergotamine tartrate, USP) sympathetic inhibitor, 0.6 mg; Bellafoline (levorotatory alkaloids of belladonna, as malates) parasympathetic inhibitor, 0.2 mg.

Properties and Therapeutics: Based on the concept that functional disorders frequently involve hyperactivity of both the sympathetic and parasympathetic nervous systems, the ingredients in Bellergal are combined to provide a balanced preparation designed to correct imbalance of the autonomic nervous system. The integrated action of Bellergal is effected through the combined administration of ergotamine and the levorotatory alkaloids of belladonna, specific inhibitors of the sympathetic and parasympathetic respectively, reinforced by the synergistic action of phenobarbital in dampening the cortical centers.

Indications: Bellergal is employed in the management of disorders characterized by nervous tension and exaggerated autonomic response:

Menopausal disorders with hot flashes, sweats, restlessness and insomnia.

Cardiovascular disorders with palpitation, tachycardia, chest oppression and vasomotor disturbances.

Gastrointestinal disorders with hypermotility, hypersecretion, "nervous stomach," and alternately diarrhea and constipation.

Genitourinary – uterine cramps, etc.

Premenstrual tension

Interval treatment of *recurrent, throbbing headache*.

Contraindications: Peripheral vascular disease, coronary heart disease, hypertension, impaired hepatic or renal function, sepsis, third trimester of pregnancy and glaucoma. Hypersensitivity to any of the components.

Precautions: Even though the ergotamine tartrate content of this product is extremely low and untoward effects have been rare and insignificant, caution should be exercised if large or prolonged dosage is contemplated, and physicians should be alert to possible peripheral vascular complications in patients highly sensitive to ergot. Due to presence of a barbiturate, may be habit forming.

Side Effects: Blurred vision, dry mouth, flushing, drowsiness occur rarely.

Dosage: Bellergal-S Tablets: One in the morning and one in the evening.

How Supplied: Bellergal-S Tablets (compressed, scored tablets of tricolored pattern: dark green, orange and light lemon yellow) in bottles of 100.

NONHORMONAL therapy for menopausal vasomotor instability is receiving renewed attention.

BELLERGAL-S™

TABLETS

Each Bellergal-S Tablet contains: phenobarbital, USP central sedative (Warning: May be habit forming), 40.0 mg; Gynergen® (ergotamine tartrate, USP) sympathetic inhibitor, 0.6 mg; Bellafoline® (levorotatory alkaloids of belladonna, as malates) parasympathetic inhibitor, 0.2 mg.

Long clinical experience has established the effectiveness of Bellergal-S Tablets in managing menopausal disorders characterized by exaggerated autonomic response—hot flashes, sweats, restlessness, and insomnia.

Because Bellergal-S reduces autonomic nervous system activity, symptoms of vasomotor instability are eliminated or significantly reduced. *Bellergal-S does not contain estrogen in any form.* That's one reason why it is receiving renewed attention from physicians who wish to avoid the potential complications of estrogen therapy in vasomotor instability.

So when estrogen therapy is undesirable... prescribe Bellergal-S Tablets.

Please see prescribing information on an adjoining page.

Why the choice is Cu-7®

intrauterine copper contraceptive

1. She wants nonhormonal contraception.
2. She wants to space her family.
3. She smokes.
4. She has passed the "Pill" years.

Freedom—intrauterine contraception is the most convenient of all contraceptive methods.

Comfort—smallest inserter diameter of all IUDs. This means minimal discomfort during insertion.

Cu-7	Lippes Loop® D	Saf-T-Coil® (Nullip)	Saf-T-Coil® (Standard)
3.07 mm.	5.33 mm.	3.76 mm.	4.50 mm.

Security—high efficacy and relatively low incidence of expulsion and medical removal.

(Rates—based on labeling claims—expressed as events per 100 women through 12 months of use for parous women)*	Cu-7[1]	Lippes Loop® D[2]	Saf-T-Coil[2]
Pregnancy	1.9	2.7	2.4
Expulsion	5.7	12.7	18.3
Medical Removal	10.9	15.2	15.6

*These rates are derived from separate studies conducted by different investigators in several population groups. Different rates have been reported from other clinical trials.

Intrauterine contraception is not appropriate for all women. Please see complete product information prior to use. A brief summary of product information appears on the next page.

Description: The plastic component of the Cu-7 is composed of pharmaceutical grade polypropylene homopolymer with barium sulfate added to render it radiopaque. Its shape approximates the number 7. It is substantially smaller than previously available intrauterine devices; the vertical dimension measures 36 mm. and the horizontal, 26 mm.

Coiled around the vertical limb is a pure, virgin electrolytic copper wire providing approximately 200mm² of exposed copper surface area. A retrieval thread is fastened to the free end of the vertical limb of the Cu-7.

The Cu-7 is supplied with a simple tubular polypropylene inserter. All components are sterile.

Mode of Action: Available data indicate that the contraceptive effectiveness of the Cu-7 is enhanced by a minute quantity of copper released continuously from the coiled copper into the uterine cavity.

The exact mechanism by which metallic copper enhances the contraceptive effect of an IUD has not been conclusively demonstrated. Various hypotheses have been advanced, the most common being that copper placed in the uterus interferes with enzymatic or other processes that regulate blastocyst implantation.

Animal studies suggest that copper may play an additional role by reduction of sperm transport within the uterine environment.

Indication and Usage: The Cu-7 is indicated for contraception.

Contraindications: The Cu-7 should not be inserted when any of the following conditions exist: pregnancy or suspicion of pregnancy; abnormalities of the uterus resulting in distortion of the uterine cavity; acute pelvic inflammatory disease or a history of repeated pelvic inflammatory disease; postpartum endometritis or infected abortion in the past three months; known or suspected uterine or cervical disease such as hyperplasia or carcinoma including unresolved, abnormal "Pap" smear; vaginal bleeding of unknown etiology; untreated acute cervicitis until infection is controlled; diagnosed Wilson's disease; known or suspected allergy to copper; previous ectopic pregnancy, and significant anemia.

Warnings

1. Pregnancy: (a) Long-term effects. The long-term effects on the offspring of the presence of copper in the uterus when pregnancy occurs with the Cu-7 are unknown.

(b) Septic abortion. Reports have indicated an increased incidence of septic abortion associated in some instances with septicemia, septic shock and death in patients becoming pregnant with an IUD in place. Most of these reports have been associated with the mid-trimester of pregnancy. In some cases, the initial symptoms have been insidious and not easily recognized. If pregnancy should occur with a Cu-7 in situ, the Cu-7 should be removed if the thread is visible or, if removal proves to be or would be difficult, interruption of the pregnancy should be considered and offered to the patient as an option, bearing in mind that the risks associated with an elective abortion increase with gestational age.

(c) Continuation of pregnancy. If the patient chooses to continue the pregnancy and the Cu-7 remains in situ, she must be warned of the increased risk of spontaneous abortion and the increased risk of sepsis, including death. The patient must be closely observed and she must be advised to report immediately all abnormal symptoms, such as flu-like syndrome, fever, abdominal cramping and pain, bleeding, or vaginal discharge, because generalized symptoms of septicemia may be insidious.

2. Ectopic pregnancy: (a) A pregnancy which occurs with an IUD in situ is more likely to be ectopic than a pregnancy occurring without an IUD. Therefore, patients who become pregnant while using a Cu-7 should be carefully evaluated for the possibility of an ectopic pregnancy.

(b) Special attention should be directed to patients with delayed menses, slight metrorrhagia and/or unilateral pelvic pain, and to those patients who wish to interrupt a pregnancy occurring in the presence of a Cu-7, to determine whether ectopic pregnancy has occurred.

3. Pelvic infection. An increased risk of pelvic inflammatory disease associated with the use of IUDs has been reported. While unconfirmed, this risk appears to be greatest for young women who are nulliparous and/or who have a multiplicity of sexual partners. Salpingitis can result in tubal damage and occlusion, thereby threatening future fertility. Therefore, it is recommended that patients be taught to look for symptoms of pelvic inflammatory disease. The decision to use an IUD in a particular case must be made by the physician and patient with the consideration of a possible deleterious effect on future fertility.

Pelvic infection may occur with a Cu-7 in situ and at times result in the development of tubo-ovarian abscesses or general peritonitis. The symptoms of pelvic infection include: new development of menstrual disorders (prolonged or heavy bleeding), abnormal vaginal discharge, abdominal or pelvic pain, dyspareunia, fever. The symptoms are especially significant if they occur following the first two or three cycles after insertion. Appropriate aerobic and anaerobic bacteriologic studies should be done and antibiotic therapy initiated promptly. If the infection does not show marked clinical improvement within 24 to 48 hours, the Cu-7 should be removed and the continuing treatment reassessed on the basis of the results of culture and sensitivity tests.

4. Embedment: Partial penetration or lodging of the Cu-7 in the endometrium or myometrium can result in a difficult removal. This may occur more frequently in smaller uteri. (See removal instructions.)

5. Perforation. Partial or total perforation of the uterine wall or cervix may occur with the use of the Cu-7, usually during insertions into patients sooner than two months after abortion or delivery or in uterine cavities too small for the Cu-7. The possibility of perforation must be kept in mind during insertion and at the time of any subsequent examination. If perforation occurs, laparotomy or laparoscopy should be performed as soon as medically feasible and the Cu-7 removed. Abdominal adhesions, intestinal penetration, intestinal obstruction, and local inflammatory reaction with abscess formation and erosion of adjacent viscera may result if the Cu-7 is left in the peritoneal cavity.

6. Medical diathermy: The use of medical diathermy (short-wave and microwave) in a patient with a metal-containing IUD may cause heat injury to the surrounding tissue. Therefore, medical diathermy to the abdominal and sacral areas should not be used on patients using a Cu-7.

7. Effects of copper. Additional amounts of copper available to the body from the Cu-7 may precipitate symptoms in women with undiagnosed Wilson's disease. The incidence of Wilson's disease is 1 in 200,000.

Precautions

1. Patient counseling. Prior to the insertion the physician, nurse, or other trained health professional must provide the patient with the Patient Brochure. The patient should be given the opportunity to read the brochure and discuss fully any questions she may have concerning the Cu-7 as well as other methods of contraception.

2. Patient evaluation and clinical considerations. a) A complete medical history should be obtained to determine conditions that might influence the selection of an IUD. A physical examination should include a pelvic examination, "Pap" smear, gonorrhea culture and, if indicated, appropriate tests for other forms of venereal disease. The physician should determine that the patient is not pregnant.

(b) The uterus should be carefully sounded prior to the insertion to determine the degree of patency of the endocervical canal and the internal os, and the direction and depth of the uterine cavity. Exercise care to avoid perforation with the sound. DO NOT USE THE Cu-7 INSERTION INSTRUMENT AS A SOUND. In occasional cases, severe cervical stenosis may be encountered. Do not use excessive force to overcome this resistance.

(c) The uterus usually sounds to a depth of 6 to 8 cm. Insertion of a Cu-7 into a uterine cavity measuring less than 6.5 cm. by sounding may increase the incidence of pain, bleeding, partial or complete expulsion, perforation, and possibly pregnancy.

(d) To reduce the possibility of insertion in the presence of an existing undetermined pregnancy, the optimal time for insertion is the latter part of the menstrual flow or one or two days thereafter. The Cu-7 should not be inserted post partum or post abortion until involution of the uterus is complete. The incidence of perforation and expulsion is greater if involution is not complete.

It is, however, necessary to place the Cu-7 as high as possible within the uterine cavity to help avoid partial or complete expulsion that could result in pregnancy.

Since the Cu-7 represents a different design in intrauterine contraception, physicians are cautioned that it is imperative for them to become thoroughly familiar with the instructions for use before attempting placement of the Cu-7.

(e) IUDs should be used with caution in those patients who have an anemia or a history of menorrhagia or hypermenorrhea. Patients experiencing menorrhagia and/or metrorrhagia following IUD insertion may be at risk for the development of hypochromic microcytic anemia. Also, IUDs should be used with caution in patients receiving anticoagulants or having a coagulopathy.

(f) Syncope, bradycardia or other neurovascular episodes may occur during insertion or removal of IUDs, especially in patients with a previous disposition to these conditions.

(g) Patients with valvular or congenital heart disease are more prone to develop subacute bacterial endocarditis than patients who do not have valvular or congenital heart disease. Use of an IUD in these patients may represent a potential source of septic emboli.

(h) Use of an IUD in those patients with acute cervicitis should be postponed until proper treatment has cleared up the infection.

(i) Since the Cu-7 may be partially or completely expelled, patients should be reexamined and evaluated shortly after the first postinsertion menses, but definitely within three months after insertion. Thereafter annual examination with appropriate medical and laboratory evaluation should be carried out. The Cu-7 should be replaced every three years.

(j) The patient should be told that some bleeding or cramps may occur during the first few weeks after insertion, but if these symptoms continue or are severe she should report them to her physician. She should be instructed on how to check after each menstrual period to make certain that the thread still protrudes from the cervix and cautioned that there is no contraceptive protection if the Cu-7 has been expelled. She should also be cautioned not to dislodge the Cu-7 by pulling on the thread. If a partial expulsion occurs, removal is indicated and a new Cu-7 may be inserted. The patient should be told to return within three years for removal of the Cu-7 and for replacement if desired.

(k) A copper-induced urticarial allergic skin reaction may develop in women using a copper-containing IUD. If symptoms of such an allergic response occur, the patient should be instructed to tell the consulting physician that a copper-containing device is being used.

(l) The Cu-7 should be removed for the following medical reasons: menorrhagia and/or metrorrhagia producing significant anemia; uncontrolled pelvic infection; intractable pain often aggravated by intercourse, dyspareunia; pregnancy, if the thread is visible; endometrial or cervical malignancy; uterine or cervical perforation; or any indication of partial expulsion.

(m) If the retrieval thread cannot be visualized it may have retracted into the uterus or have been broken off, or the Cu-7 may have been expelled. Localization usually may be made by feeling with a probe; if not, x-ray or sonography can be used. When the physician elects to recover a Cu-7 with the thread not visible, the removal instructions should be considered.

(n) If any patient with a Cu-7 suddenly develops overt clinical hepatitis or abnormal liver function tests, appropriate diagnostic procedures should be initiated.

Adverse Reactions: Perforations of uterus and cervix have occurred. Perforation into the abdomen has been followed by abdominal adhesions, intestinal penetration, intestinal obstruction, local inflammatory reaction with abscess formation and erosion of adjacent viscera. Pregnancy has occurred with the Cu-7 in situ and when the Cu-7 has been partially or completely expelled.

The incidence of spontaneous abortion, when conception occurs with intrauterine devices in situ, appears to be increased over that in unprotected women. Insertion cramping, usually of no more than a few seconds duration, may occur; however, some women may experience residual cramping for several hours or even days. Intermenstrual spotting or bleeding or prolonged or increased menstrual flow may occur.

Pelvic infection including salpingitis with tubal damage or occlusion has been reported. This may result in future infertility. Complete or partial expulsion of the Cu-7 may sometimes occur, particularly in those patients with uteri measuring less than 6.5 cm. by sounding. Urticarial allergic skin reaction may occur. The following complaints have also been reported with IUDs although their relation to the Cu-7 has not been established: amenorrhea or delayed menses, backaches, cervical erosion, cystic masses in the pelvis, vaginitis, leg pain or soreness, weight loss or gain, nervousness, dyspareunia, cystitis, endometritis, septic abortion, septicemia, leukorrhea, ectopic pregnancy, difficult removal, uterine embedment, anemia, pain, neurovascular episodes including bradycardia and syncope secondary to insertion, dysmenorrhea, and fragmentation of the IUD.

Directions for Use: The Cu-7 is to be placed within the uterine cavity. See the Procedure for Insertion for two insertion techniques.

The small diameter of the Cu-7 facilitates easy insertion in nulligravidous and nulliparous, as well as parous women. The optimal time of insertion is during the latter part of the menstrual flow or one or two days thereafter. The cervical canal is relatively more patent at this time, and there is little chance that the patient may be pregnant.

Present information indicates that efficacy is retained for 36 months. There is no evidence that contraceptive efficacy decreases with time up to three years of use, but until adequate data indicating a longer effective life become available, the Cu-7 must be removed within 36 months from the date of insertion and a new one inserted if desired. If partial expulsion occurs, removal is indicated, and a new Cu-7 may be inserted. Removal of the Cu-7 may also be indicated in the event of heavy or persistent bleeding.

The physician should become thoroughly familiar with the instructions for use before attempting insertion or removal of the Cu-7.

Clinical Efficacy: In clinical trials of the Cu-7 conducted by Searle Laboratories, use effectiveness was determined as follows for parous and nulliparous women, as tabulated by the life table method. (Rates are expressed as cumulative events per 100 women through 12, 24, and 36 months of use.)

This experience encompasses 387,131 woman-months of use, including 12 months for 11,51 women, 24 months for 7,895, and 36 months for 3,661.

	12 Months		24 Months		36 Months	
	Parous	Nulliparous	Parous	Nulliparous	Parous	Nulliparou
Pregnancy	1.9	1.7	2.9	2.6	3.4	3.4

How Supplied

Available in cartons of 6, 30 and 100 sterile units (Cu-7 with an inserter) and sufficient patient leaflet and identification cards.

Please see complete product labeling for additional information, including insertion and removal instructions.

Cu-7® intrauterine copper contraceptive

—the leading IUD

8B-

How much estrogen does it really take to control nature?
A lot less than everyone once thought. Just a few years ago, a 50-mcg dosage was considered low. Today, there's an effective combination oral contraceptive containing 30 mcg of estrogen: Loestrin 1.5/30.
In spite of a 40% reduction in the dose of estrogen, efficacy of Loestrin 1.5/30 is considered comparable to that of combination oral contraceptives containing higher levels of estrogen.
Irregular bleeding is somewhat more frequent with Loestrin 1.5/30 than with combinations containing larger doses of estrogen. With continued use, however, the frequency decreases.
And if you're concerned about your patients' intake of estrogen over an extended period of time, Loestrin 1.5/30 contains 30 mcg of ethinyl estradiol, so patient exposure to estrogen is reduced.
LOESTRIN® 1.5/30
(1.5 mg norethindrone acetate and 30 mcg ethinyl estradiol tablets, USP)
a 30-mcg alternative to higher estrogen
ualization of
mmalian ovulation.

See opposite page for prescribing information.

Brief Summary of Prescribing Information
LOESTRIN® 1.5/30
(1.5 mg norethindrone acetate and 30 mcg ethinyl estradiol tablets, USP) See section under Special Notes on Administration and How Supplied.

DESCRIPTION
Loestrin 1.5/30 Products are progestogen-estrogen combinations.

INDICATION AND USAGE
Loestrin 1.5/30 Products are indicated for the prevention of pregnancy in women who elect to use oral contraceptives.

In clinical trials with Loestrin 1.5/30 involving 17,139 therapy cycles, there was a pregnancy rate of 0.49 per 100 woman years.

Dose-related risk of thromboembolism from oral contraceptives: Studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. It is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance.

CONTRAINDICATIONS
1. Thrombophlebitis or thromboembolic disorders
2. A past history of deep-vein thrombophlebitis or thromboembolic disorders
3. Cerebral vascular or coronary artery disease
4. Known or suspected carcinoma of the breast
5. Known or suspected estrogen-dependent neoplasia
6. Undiagnosed abnormal genital bleeding
7. Known or suspected pregnancy (See No. 5 under WARNINGS.)

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, and hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well-established. Studies have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic.

Cerebrovascular disorders: In a collaborative study in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers, and the risk of thrombotic stroke was 4.0 to 9.5 times greater.

Myocardial infarction: An increased risk of myocardial infarction associated with oral contraceptives has been reported confirming a previously suspected association. These studies found that the greater the number of underlying risk factors (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) for coronary artery disease, the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor.

It has been estimated that users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are smokers have about a fivefold increased risk of fatal infarction compared to users who do not smoke, but about a tenfold to twelvefold increased risk compared to nonusers who do not smoke. The amount of smoking is also an important factor.

Risk of dose: In an analysis of data, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives; however, the quantity of estrogen may not be the sole factor involved.

Estimate of excess mortality from circulatory diseases: The risk of diseases of the circulatory system is concentrated in older women, in those with a long duration of use, and in cigarette smokers.

A study of available data from a variety of sources concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke.

The risk of thromboembolic and thrombotic diseases associated with oral contraceptives increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia, and especially by cigarette smoking.

The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders. Should any occur or be suspected, the drug should be discontinued immediately.

A fourfold to sixfold increased risk of postsurgery thromboembolic complications has been reported in users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

2. *Ocular lesions:* Neuro-ocular lesions, such as optic neuritis or retinal thrombosis, have been associated with the use of oral contraceptives. Discontinue the oral contraceptive if there is unexplained sudden or gradual, partial, or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions.

3. *Carcinoma:* Long-term continuous administration of estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver.

In humans, an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women has been reported. However, there is no evidence suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only oral contraceptives.

Studies found no evidence of increase in breast cancer in women taking oral contraceptives; however, an excess risk in users with documented benign breast disease was reported.

There is no confirmed evidence of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of users is, nevertheless, essential. In cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer, or who have breast nodules, fibrocystic disease, or abnormal mammograms, should be monitored with particular care.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with oral contraceptives. Because hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage, they should be considered in women presenting abdominal pain and tenderness, abdominal mass, or shock.

A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Usage in or Immediately Preceding Pregnancy. Birth Defects in Offspring, and Malignancy in Female Offspring:* During early pregnancy, female sex hormones may seriously damage the offspring.

An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of oral contraceptives in pregnancy.

There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives.

Pregnancy should be ruled out before continuing an oral contraceptive in any patient who has missed two consecutive menstrual periods. If the patient has not adhered to the schedule, the possibility of pregnancy should be considered at the time of the first missed period, and oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed.

Women who discontinue oral contraceptives with the intent of becoming pregnant should use an alternate form of contraception for a period of time before attempting to conceive.

Administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives.

7. *Carbohydrate and Lipid Metabolic Effects:* Because decreased glucose tolerance has been observed in a significant percentage of patients, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives.

An increase in triglycerides and total phospholipids has been observed.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving oral contraceptives. The prevalence in users increases with longer exposure. Age is also strongly correlated with development of hypertension. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure.

9. *Headache:* Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of oral contraceptives.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, nonfunctional causes should be borne in mind. In undiagnosed abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy.

Women with a past history of oligomenorrhea or secondary amenorrhea, or young women without regular cycles should be advised that they may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast Feeding:* Oral contraceptives may interfere with lactation. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs.

PRECAUTIONS
1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another examination.

2. Preexisting uterine leiomyomata may increase in size.

3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree.

4. Oral contraceptives may cause fluid retention and should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated.

5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice. If jaundice develops, the medication should be discontinued.

6. Steroid hormones may be poorly metabolized and should be administered with caution in patients with impaired liver function.

7. Users may have disturbances in normal tryptophan metabolism, which may result in a relative pyridoxine deficiency.

8. Serum folate levels may be depressed.

9. The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted.

10. Certain endocrine and liver function tests and blood components may be affected.
(a) Increased sulfobromophthalein retention. (b) Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. (c) Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone. (d) Decreased pregnanediol excretion. (e) Reduced response to metyrapone test.

Drug interactions: Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin and an association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and ampicillin.

ADVERSE REACTIONS
An increased risk of the following serious adverse reactions has been associated with oral contraceptives.

Thrombophlebitis; Pulmonary embolism; Coronary thrombosis; Cerebral thrombosis; Cerebral hemorrhage; Hypertension; Gallbladder disease; Benign hepatomas; Congenital anomalies.

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed. Mesenteric thrombosis, Neuro-ocular lesions, eg, retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related. Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms; breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma; breast changes; change in weight; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately post partum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature; intolerance to contact lenses.

The following adverse reactions have been reported and the association has been neither confirmed nor refuted.

Premenstrual-like syndrome; cataracts; changes in libido; chorea; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; vaginitis; porphyria.

Special Notes on Administration
Loestrin [21] 1.5/30 (1.5 mg norethindrone acetate and 30 mcg ethinyl estradiol tablets, USP) — Menstruation usually begins two or three days, but may begin as late as the fourth or fifth day, after discontinuing medication.

Loestrin [Fe] 1.5/30 — Menstruation usually begins two or three days, but may begin as late as the fourth or fifth day, after the brown ferrous fumarate tablets have been started.

Because of the relatively low estrogenic content, Loestrin 1.5/30 is not a good cyclic regulator. There are patients whose inherent hormone balance will require larger amounts of estrogen than that contained in Loestrin 1.5/30 to achieve cyclic regularity. These patients experience altered bleeding patterns, which do not conform to treatment schedules.

The physician should be alert to the fact that the irregular bleeding patterns could mask bleeding from organic cause, and appropriate diagnostic measures should be taken if the bleeding persists or continues after changing to a higher estrogen-content product.

After several months, bleeding may be reduced to a virtual absence; reduced flow may be a result of medication and not indicative of pregnancy.

HOW SUPPLIED
Loestrin [Fe] 1.5/30 is available in compacts each containing 21 green tablets and 7 brown tablets. Each green tablet contains 1.5 mg of norethindrone acetate and 30 mcg of ethinyl estradiol. Each brown tablet contains 75 mg of ferrous fumarate. Available in packages of five compacts and packages of five refills.

Loestrin [21] 1.5/30 is available in compacts each containing 21 tablets. Each green tablet contains 1.5 mg of norethindrone acetate and 30 mcg of ethinyl estradiol. Available in packages of five compacts and packages of five refills.

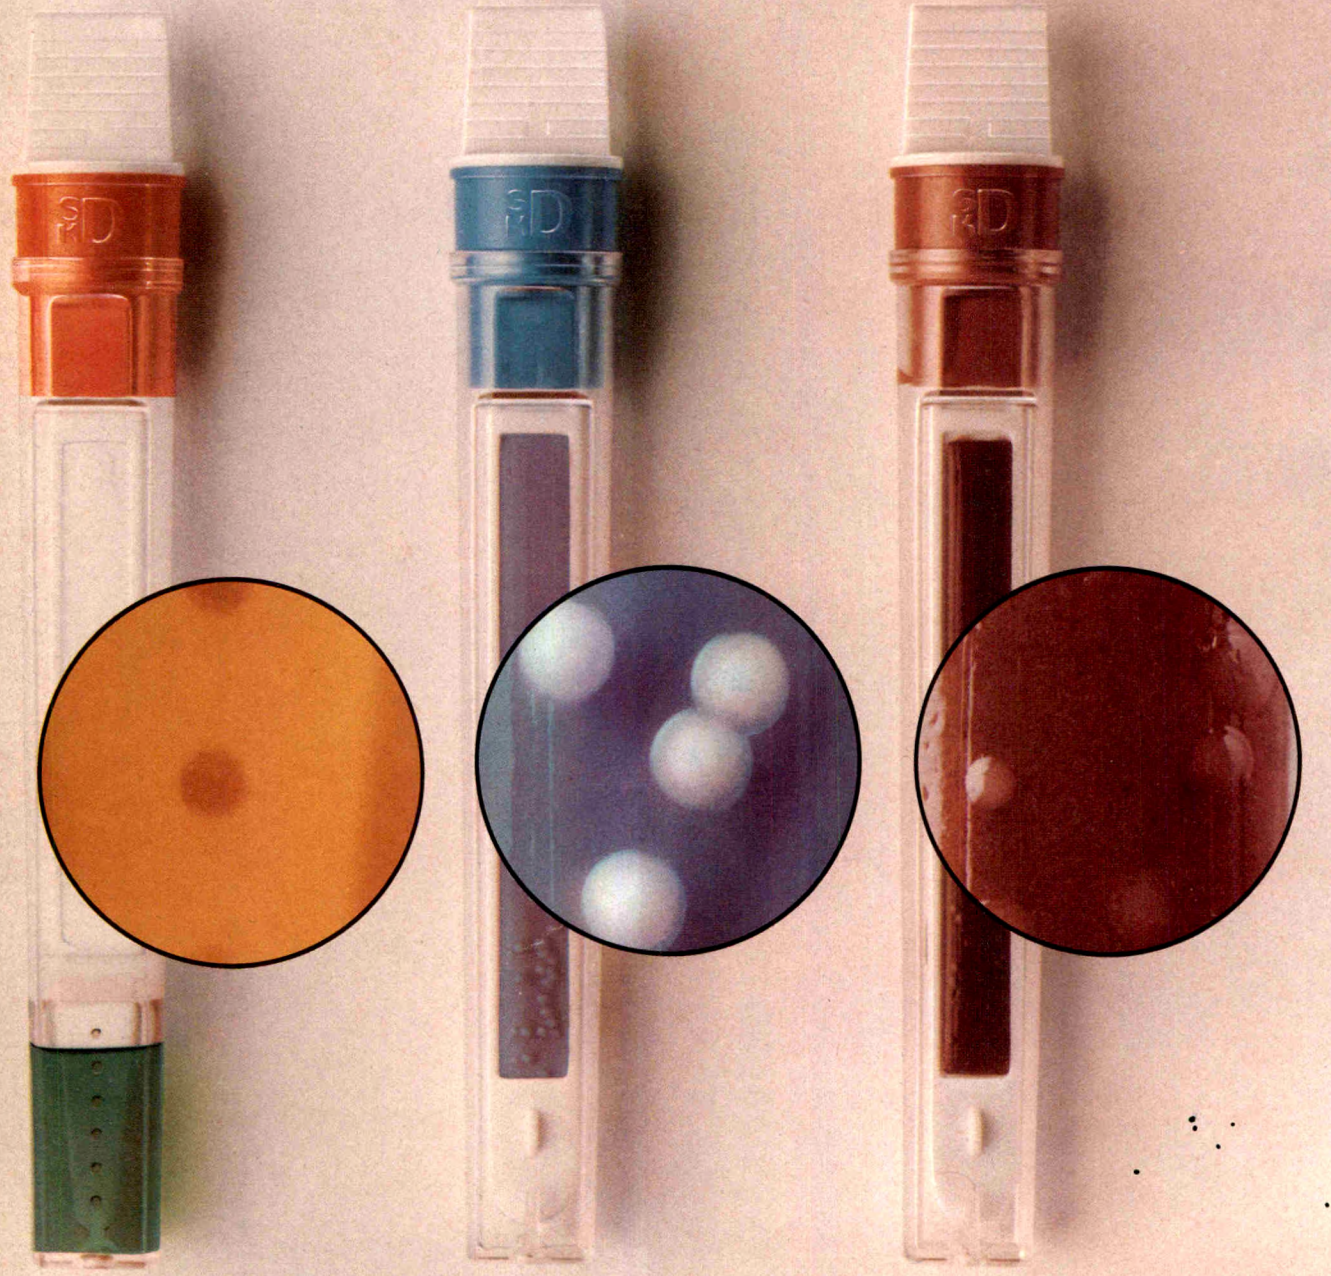
socult®

The inexpensive, in-office culture tests for *Trichomonas vaginalis*, Candida (Monilia), *N. gonorrhoeae*.

t's as simple as swabbing a specimen on the culture nedia, inserting the color-coded tube into a slot of an ffice incubator and reading results against an identifi-ation chart 24 to 48 hours later.



All three tests contain highly selective media that ive you the right results, right in your office. And here are also two combination tests that let you check or *N. gonorrhoeae* and Candida or *T. vaginalis* and Candida simultaneously.

You save time. You save space—the incubator is o bigger than your *PDR.* And you save money. You can cover the low cost of the 'Isocult' system and your professional time and still charge your patient less than the cost of a standard laboratory culture.

There's an 'Isocult' culture test for Bacteriuria too. It's reliable, rapid, inexpensive and easy to interpret (results are available within 18 to 24 hours).

'Isocult' is available through local distributors, nationwide. To order or for more information call toll free: (800) 538-1581. (In California call the number below, collect.)

Prescribe KOROMEX®...for her comfort and confidence.

Many women today are asking you about changing their contraceptive method, and with good reason. Contraceptives are supposed to promote confidence. You and your patients realize that pills and IUD's frequently lead to unpleasant side effects.

But KOROMEX products offer gentle, highly-effective barrier contraception. When you prescribe KOROMEX (coil spring) or KOROFLEX (arcing spring) vaginal diaphragms, and KOROMEX spermicidal creams, jellies, or foam, your patient benefits from one of the safest and increasingly accepted methods of contraception.

Unlike other jellies and creams, KOROMEX products do not have a strong perfume or medicinal odor. KOROMEX®-A Jelly and KOROMEX Foam can both be used alone for effective protection.

Fifty years of experience stand behind this non-hormonal birth control method.

While no contraceptive is 100% effective, Koromex products, when properly used, are highly effective against pregnancy.

EDITORS! REVIEWERS! AUTHORS!

For you . . . a new book that contains virtually everything you want to know about

THE SCIENTIFIC JOURNAL: EDITORIAL POLICIES AND PRACTICES

Guidelines for Editors, Reviewers, and Authors

In 1665 the first scholarly journal was published in France. Since that time, there has been no one source of editorial guidelines for journal editors. This new book now provides you with such a source.

YOU DECIDE YOUR OWN APPROACH!

Presenting the advantages and disadvantages of each specific decision, eminent editors offer you various recommendations, discussions, and opinions concerning the problems you may encounter:

"Because we are aware that there is no 'right' policy on most editorial matters, we have tried not to prescribe rules, but have, instead, explored various facets of the problems that confront the editor in his daily work."

The book is divided into two general sections: editorial policies, which usually require major decisions; and editorial practices, which involve minor decisions, often about format or mechanical style. You'll find essays exploring: the manuscript reviewing system; special types of manuscripts (abstracts, transactions, solicited manuscripts, book reviews). You'll value chapters which cover: information for authors; copyright; errata; references cited; copy-editing; journal cover; etc.

From "the purpose of scientific journals" to "binding practices," this new book contains virtually everything you want to know as editor, reviewer, or author. See for yourself!

By Lois DeBakey, Ph.D. In collaboration with: Paul F. Cranefield, M.D., Ph.D.; Ayodhya P. Gupta, M.D.; Franz J. Ingelfinger, M.D.; Robert J. Levine, M.D.; Robert H. Moser, M.D.; J. Roger Porter, Ph.D.; and F. Peter Woodford, Ph.D. August, 1976. 128 pages, 6″ × 9″. Price, $12.50.

For UTI in their sexually active years...

Macrodantin®
(nitrofurantoin macrocrystals)

Capsules: 25 mg, 50 mg, 100 mg

INDICATIONS: Macrodantin is indicated for the treatment of urinary tract infections when due to susceptible strains of *Escherichia coli*, enterococci, *Staphylococcus aureus* (it is not indicated for the treatment of associated renal cortical or perinephric abscesses), and certain susceptible strains of *Klebsiella* species, *Enterobacter* species, and *Proteus* species.

NOTE: Specimens for culture and susceptibility testing should be obtained prior to and during drug administration.

CONTRAINDICATIONS: Anuria, oliguria, or significant impairment of renal function (creatinine clearance under 40 ml per minute) are contraindications to therapy with this drug. Treatment of this type of patient carries an increased risk of toxicity because of impaired excretion of the drug. For the same reason, this drug is much less effective under these circumstances.

The drug is contraindicated in pregnant patients at term as well as in infants under one month of age because of the possibility of hemolytic anemia due to immature enzyme systems (glutathione instability).

The drug is also contraindicated in those patients with known hypersensitivity to Macrodantin, Furadantin® (nitrofurantoin), and other nitrofurantoin preparations.

WARNINGS: Acute, subacute and chronic pulmonary reactions have been observed in patients treated with nitrofurantoin products. If these reactions occur, the drug should be withdrawn and appropriate measures should be taken.

An insidious onset of pulmonary reactions (diffuse interstitial pneumonitis or pulmonary fibrosis, or both) in patients on long-term therapy warrants close monitoring of these patients.

There have been isolated reports giving pulmonary reactions as a contributing cause of death. (See Hypersensitivity reactions.)

Cases of hemolytic anemia of the primaquine sensitivity type have been induced by Macrodantin. The hemolysis appears to be linked to a glucose-6-phosphate dehydrogenase deficiency in the red blood cells of the affected patients. This deficiency is found in 10 percent of Negroes and a small percentage of ethnic groups of Mediterranean and Near-Eastern origin. Any sign of hemolysis is an indication to discontinue the drug. Hemolysis ceases when the drug is withdrawn.

Pseudomonas is the organism most commonly implicated in superinfections in patients treated with Macrodantin.

PRECAUTIONS: Peripheral neuropathy may occur with Macrodantin therapy; this may become severe or irreversible. Fatalities have been reported. Predisposing conditions such as renal impairment (creatinine clearance under 40 ml per minute), anemia, diabetes, electrolyte imbalance, vitamin B deficiency, and debilitating disease may enhance such occurrence.

Usage in Pregnancy: The safety of Macrodantin during pregnancy and lactation has not been established. Use of this drug in women of childbearing potential requires that the anticipated benefit be weighed against the possible risks.

ADVERSE REACTIONS: Gastrointestinal reactions: Anorexia, nausea and emesis are the most frequent reactions; abdominal pain and diarrhea occur less frequently. These dose-related toxicity reactions can be minimized by reduction of dosage, especially in the female patient. Hepatitis occurs rarely.

Hypersensitivity reactions: Pulmonary sensitivity reactions may occur, which can be acute, subacute, or chronic.

Acute reactions are commonly manifested by fever, chills, cough, chest pain, dyspnea, pulmonary infiltration with consolidation or pleural effusion on x-ray, and eosinophilia. The acute reactions usually occur within the first week of treatment and are reversible with cessation of therapy. Resolution may be dramatic.

In subacute reactions, fever and eosinophilia are observed less often. Recovery is somewhat slower, perhaps as long as several months. If the symptoms are not recognized as being drug related and nitrofurantoin is not withdrawn, symptoms may become more severe.

Chronic pulmonary reactions are more likely to occur in patients who have been on continuous nitrofurantoin therapy for six months or longer. The insidious onset of malaise, dyspnea on exertion, cough, and altered pulmonary function are common manifestations. Roentgenographic and histologic findings of diffuse interstitial pneumonitis or fibrosis, or both, are also common manifestations. Fever is rarely prominent.

The severity of these chronic pulmonary reactions and the degree of their resolution appear to be related to the duration of therapy after the first clinical signs appear. Pulmonary function may be permanently impaired even after cessation of nitrofurantoin therapy. This risk is greater when pulmonary reactions are not recognized early.

Dermatologic reactions: Maculopapular, erythematous, or eczematous eruption, pruritus, urticaria, and angioedema.

Other sensitivity reactions: Anaphylaxis, asthmatic attack in patients with history of asthma, cholestatic jaundice, drug fever, and arthralgia.

Hematologic reactions: Hemolytic anemia, granulocytopenia, leukopenia, eosinophilia, and megaloblastic anemia. Return of the blood picture to normal has followed cessation of therapy.

Neurological reactions: Peripheral neuropathy, headache, dizziness, nystagmus, and drowsiness.

Miscellaneous reactions: Transient alopecia. As with other antimicrobial agents, superinfections by resistant organisms may occur. With Macrodantin, however, these are limited to the genitourinary tract because suppression of normal bacterial flora elsewhere in the body does not occur.

Enterococcus:

One reason for failure...

It is well known that *Escherichia coli* causes most cases of UTI. Enterococcus (also called *Streptococcus faecalis* and *Streptococcus*, group D) has become the *second* most prevalent uropathogen[1,2]—particularly in sexually active women.[3]

MACRODANTIN offers superior in vitro* efficacy[4] against these pathogens: 96% against *E. coli*... 94% against enterococcus.

*In vitro data do not necessarily predict clinical efficacy.

...reason enough to choose

Capsules: 25 mg, 50 mg, 100 mg

Macrodantin®

(nitrofurantoin macrocrystals)

for UTI in their sexually active years

New! Available for the first time

The ten-year **cumulative author and subject index** to volumes 100-129 (1968-1977) of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY is now available for your journal collection. It is a complete and comprehensive reference guide to over 28,000 pages of authoritative articles published in the Journal during the past ten years.

The world-renowned "Gray Journal" is the oldest specialty journal devoted to obstetrics and gynecology.

Now these influential papers, appearing between 1968-1977, have been cross-referenced to include over 23,100 subject entries. Each entry lists the complete article title, author(s), volume, page, and year of publication.

The author index lists more than 13,850 contributors from this period, along with respective article title, author-to-author referral, volume, page, and publication date.

The 479-page index is handsomely presented in a rust and gold cloth-cover volume. It is a must for every library concerned with obstetrics and gynecology. Send for your copy of this valuable reference today!

FACULTY POSITION

The Department of Obstetrics and Gynecology at the University of Utah Medical Center announces the availability of a position in Maternal-Fetal Medicine at the Assistant Professor level on its full time faculty. Qualifications include Board certification or eligibility and demonstrated ability and interest in teaching, research and patient care. Preferred applicants are those completing a fellowship in Maternal-Fetal Medicine or who have a special interest in obstetrics with expertise in genetics, immunology or infectious disease. If interested, please send curriculum vitae and bibliography to:

James R. Scott, M.D.
Professor and Chairman

100 mcg

A step down...

PERSONALIZED LIBRARY CASES

Keep your personal copies of AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY in these specially designed library file cases. Designed to keep your journal copies near at hand in your office, library, or home.

Your case is heavy bookbinder's board in a rich red Kivar cover. Files are scuff-resistant and washable.

Lettering is stamped in gold leaf and the cases make a fit companion for the most costly binding.

Files are reasonably priced—only $4.95 each, postpaid (3 for $14., 6 for $24.). Add $1.00 postage per case for orders outside U. S. Satisfaction unconditionally guaranteed or your money back! Use the coupon for prompt shipment.

Jesse Jones Box Corporation (est. 1843)
P. O. Box 5120
Philadelphia, Pa. 19141
Please send me, postpaid ___ library cases for AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY at $4.95 each (3/$14., 6/$24.)

☐ **NEW SIZE (8¼" × 11") 3 cases/year**
☐ **OLD SIZE (7¼" × 10½") copies prior to 1975 (2 cases/year)**

Changing Your Address . . .

WHEN YOU MOVE, PLEASE:

(1) Notify us to change your address—allow us six weeks to make the change.

(2) Mention the name of this Journal. (We publish thirteen periodicals.)

(3) Give us your old address. If possible, return the addressed portion of the envelope in which we sent your last copy.

(4) Give us your new address—complete—including the Zip code number.

(5) Please print your name and address.

Thank You!

CIRCULATION DEPARTMENT, The C. V. Mosby Company, Publishers

OJ 1714-A

MPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and herefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the omplete prescribing information certain text, tables, and references. The physician should be thoroughly familiar with the omplete prescribing information and patient information before prescribing the product.

NDICATION: CONTRACEPTION. The pregnancy rate in women using conventional combination oral contraceptives (containing 5 mcg or more of ethinyl estradiol or 50 mcg or more of mestranol) is generally reported as less than one pregnancy per 00 woman-years of use. Slightly higher rates (somewhat more than one pregnancy per 100 woman-years of use) are eported for some combination products containing 35 mcg or less of ethinyl estradiol, and rates on the order of three regnancies per 100 woman-years are reported for the progestogen-only oral contraceptives. Table 1 gives ranges of regnancy rates reported in the literature for other means of contraception. The efficacy of these means of contraception except the IUD) depends upon the degree of adherence to the method.

able 1: Pregnancies Per 100 Women-Years. IUD, less than 1-6; Diaphragm with spermicidal product (creams or jellies) 2-20; ondom, 3-36; Aerosol foams, 2-29; Jellies and creams, 4-36; Periodic abstinence (rhythm) all types, less than 1-47; 1. alendar method, 14-47; 2. Temperature method, 1-20; 3. Temperature method—intercourse only in postovulatory phase, ess than 1-7; 4. Mucus method, 1-25; No contraception, 60-80. **DOSE-RELATED RISK OF THROMBOEMBOLISM FROM ORAL ONTRACEPTIVES:** Two studies have shown a positive association between the dose of estrogens in oral contraceptives and he risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize xposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which ontains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is ecommended that new acceptors of oral contraceptives be started on preparations containing .05 mg or less of estrogen.

ONTRAINDICATIONS: Oral contraceptives should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed, abnormal genital bleeding. 7. Known or suspected pregnancy (see WARNINGS, No. 5).

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Four principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. Overall excess mortality due to pulmonary embolism or stroke is on the order of 1.0 to 3.5 deaths annually per 100,000 users and increases with age. **CEREBROVASCULAR DISORDERS:** In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than in nonusers and the risk of thrombotic stroke was 4.0 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION: An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia), the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. The annual excess case rate (increased risk) of myocardial infarction (fatal and nonfatal) in oral contraceptive users was estimated to be approximately 7 cases per 100,000 women users in the 30-39 age group and 67 cases per 100,000 women users in the 40-44 age group. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10-to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent. **Risk of Dose:** In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only oral contraceptives have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk. The risk of thromboembolic and thrombotic disorders, in both users and nonusers of oral contraceptives, increases with age. Oral contraceptives are, however, an independent risk factor for these events. **ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES:** A large prospective study carried out in the United Kingdom estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of oral contraceptives according to age, smoking habits, and duration of use. The overall excess death rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking, and duration of use, nor to compare the effects of continuous versus intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for five or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for five or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. This study reports that the increased risk of circulatory diseases may persist after the pill is discontinued. Another study published at the same time confirms a previously reported increase of mortality in pill users from cardiovascular disease. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of oral contraceptives) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The findings of this analysis are shown in Figure 1 below. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke. (The rates given for pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 cigarettes a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50 percent.) The mortality associated with oral contraceptive use in nonsmokers over 40 is higher than with any other method of contraception in that age group. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia and especially by cigarette smoking. The risk of myocardial infarction in oral contraceptive users is substantially increased in women age 40 and over, especially those with other risk factors. Based on the data currently available, the following chart gives a gross estimate of the risk of death from circulatory disorders associated with the use of oral contraceptives.

SMOKING HABITS AND OTHER PREDISPOSING CONDITIONS—RISK ASSOCIATED WITH USE OF ORAL CONTRACEPTIVES

Age	Below 30	30-39	40+	
Heavy smokers	C	B	A	A—Use associated with very high risk.
Light smokers	D	C	B	B—Use associated with high risk.
Nonsmokers (no predisposing conditions)	D	C,D	C	C—Use associated with moderate risk.
Nonsmokers (other predisposing conditions)	C	C,B	B,A	D—Use associated with low risk.

The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four- to six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2. OCULAR LESIONS: There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue oral contraceptive medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions and institute appropriate diagnostic and therapeutic measures. 3. CARCINOMA. Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in oral contraceptives, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on oral contraceptives. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time oral contraceptives were first given, polycystic ovaries), nearly all occurred in women who had used a sequential oral contraceptive. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only oral contraceptives. Several studies have found no increases in breast cancer in women taking oral contraceptives or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with oral contraceptives, found an excess risk in the subgroups of oral contraceptive users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of oral contraceptives has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. *Trademark

4. HEPATIC TUMORS. Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study showed that oral contraceptive formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of oral contraceptives. Two studies relate risk with duration of use of the contraceptive, the risk being much greater after four or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time. 5. USE IN OR IMMEDIATELY PRECEDING PREGNANCY, BIRTH DEFECTS IN OFFSPRING, AND MALIGNANCY IN FEMALE OFFSPRING. The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be on the order of 1 to 4 in 1000 exposures. Although there is no evidence at the present time that oral contraceptives further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including oral contraceptives, in pregnancy. One case control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if the progestogen-only oral contraceptives are used), and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy. 6. GALLBLADDER DISEASE. Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives and estrogens. In one study, an increased risk appeared after two years of use and doubled after four or five years of use. In one of the other studies, an increased risk was apparent between six and twelve months of use. 7. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. An increase in triglycerides and total phospholipids has been observed in patients receiving oral contraceptives. The clinical significance of this finding remains to be defined. 8. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in patients receiving oral contraceptives. In some women hypertension may occur within a few months of beginning oral contraceptive use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two and a half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in oral contraceptive users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. Hypertension that develops as a result of taking oral contraceptives usually returns to normal after discontinuing the drug. 9. HEADACHE. The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of oral contraceptives and evaluation of the cause. 10. BLEEDING IRREGULARITIES. Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Postuse anovulation, possibly prolonged, may also occur in women without previous irregularities. 11. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. 12. BREAST FEEDING. Oral contraceptives given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of oral contraceptives should be deferred until the infant has been weaned. **PRECAUTIONS: General:** 1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another physical examination being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by oral contraceptive therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping oral contraceptives, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. **INFORMATION FOR THE PATIENT: (See Patient Package Insert). DRUG INTERACTIONS:** Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and ampicillin. **CARCINOGENESIS, PREGNANCY, NURSING MOTHERS: See CONTRAINDICATIONS and WARNINGS. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS): Thrombophlebitis. Pulmonary embolism. Coronary thrombosis. Cerebral thrombosis. Cerebral hemorrhage. Hypertension. Gallbladder disease. Liver tumors. Congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis. Neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea, usually the most common adverse reaction. Vomiting, occurs in approximately 10% or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Dysmenorrhea. Amenorrhea during and after treatment. Temporary infertility after discontinuance of treatment. Edema. Chloasma or melasma which may persist. Breast changes: tenderness, enlargement, and secretion. Change in weight (increase or decrease). Change in cervical erosion and cervical secretion. Possible diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Increase in size of uterine leiomyomata. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome. Cataracts. Changes in libido. Chorea. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. (ORTHO-NOVUM 1/50 21 and ORTHO-NOVUM 1/50 28 contain tartrazine. Allergic reactions have been reported with the ingestion of this dye in some patients.) **ACUTE OVERDOSE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Information for authors

Submission of contributions. Manuscripts should in general be sent to a particular Editor according to the following plan: If it is from the southeastern quadrant of the United States or from Canada, or if it has been presented before one of the official sponsoring societies, to Dr. Brewer; if from the northeastern quadrant (including Ohio), or if it is a Clinical Opinion or a Letter to the Editors, to Dr. Zuspan; if from the north central states, any of the United States west of the Mississippi, Hawaii, Alaska, or abroad, to Dr. Quilligan.

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. Therefore, all manuscripts must be accompanied by the following written statement, signed by one author: "The undersigned author transfers all copyright ownership of the manuscript (title of article) to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

All articles published in this JOURNAL must be contributed to it exclusively. Articles previously published in another language are not acceptable.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority.

Articles dealing with human experimentation cannot be accepted unless the experiment was approved by the author's local Human Experimentation Committee.

Statements and opinions expressed in the articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantee, warrant, or endorse any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

Manuscripts. Manuscripts should be typewritten on one side of the paper only, with double spacing and liberal margins. The original and one copy of the manuscript are required. References should be placed at the end of the article. They should include name of author(s), article title, name of periodical, volume, page, and year. Name of periodical should conform to that shown in latest *List of Journals Indexed in Index Medicus*. For reference style see current issue of JOURNAL. Authors are encouraged to limit references to *16, except* for Communications in Brief, limited to 2, Current Investigation and Clinical Opinion, limited to *6*, and Current Developments, for which there is *no* limit. Illustrations accompanying manuscripts should be numbered, provided with suitable legends, and marked lightly on the back with the author's name. Authors should indicate on the manuscript the approximate position of tables and text figures.

Tables should be typed on separate sheets of paper, not in the text, with one table to a page. They should be numbered in sequence and each must be referred to at an appropriate point in the text. Captions of the tables should be brief, yet indicate clearly the purpose or content of each table. Rows and columns in the table should precisely define the nature of the data in each. Abbreviations in tables should be used as little as possible and if abbreviations are used they should be explained in a footnote to the table.

An abstract of 50 to 150 words, to be published as an introduction, should accompany each manuscript and should be typed on a separate sheet of paper.

A footnote should be included which gives the name and complete mailing address of the person to whom reprint requests and correspondence should be sent.

A Guide to Writing for the American Journal of Obstetrics and Gynecology may be obtained from the Publisher on request.

Illustrations. A reasonable number of halftone illustrations will be reproduced free of cost to the author, but special arrangements must be made with the Editors for color plates, elaborate tables, or extra illustrations. Original drawings or graphs should be drawn with black India ink. Typewritten or freehand lettering is not acceptable. All lettering must be done professionally. **Do not send original art work, x-ray films, or ECG tracings.** Glossy print photographs are preferred, for good black and white contrast is essential.

Announcements. Announcements of meetings must be received by Dr. Brewer at least 2½ months prior to the time of the meeting. Such announcements should concern major meetings and other significant activities. Announcements of symposia or seminars for which fees are charged are not published in the scientific pages of the JOURNAL but may be submitted for paid advertisements, if desired.

Letters to the Editors. A brief Letter to the Editors commenting upon some article which has appeared in the JOURNAL will be considered for publication. The writer of the original article will have an opportunity to reply to unfavorable comments. A brief case presentation of special interest in the form of a Letter to the Editors will also be considered for publication. All such letters should be sent to Dr. Zuspan.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie.

Reprints. Reprints of articles must be ordered from the Publishers, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63141, who will send their schedule of prices. Individual reprints of an article must be obtained through the author.

LIBRARY

THE DIABETIC PREGNANCY

A Perinatal Perspective

Edited by IRWIN R. MERKATZ, M.D. and PETER A. J. ADAM, M.D.

This book presents recent advances in the basic concepts of pregnancy complicated by maternal diabetes and relates this scientific knowledge to an evolving rationale for clinical practice. In the first part of the book, metabolic adjustments to normal and diabetic pregnancies are discussed, and the clinical management of such disorders as diabetic nephropathy and proliferative retinopathy in relation to pregnancy is established. The authors assess the roles of psychology, nutrition and family planning in the management of the pregnant diabetic woman. The second part of the book considers the effects of maternal diabetes on the placenta and fetus, and the third part is concerned with the biochemical, physiologic and pathologic implications for the infant of the diabetic mother.

1979, 384 pp., $34.50 ISBN: 0-8089-1175-9

BREAST DISEASE

Edited by DOUGLAS J. MARCHANT, M.D. and ISTVAN NYIRJESY, M.D.

Proceedings of an International Symposium held in New Orleans, May 1978.

This book reflects the involvement of many specialties. The family physician is interested in identifying high risk patients and promoting breast self examination and early detection. The obstetrician/gynecologist, the primary physician to women, is most frequently consulted for the diagnosis and treatment of benign conditions appearing principally during the reproductive years. Alterations in the hormone milieu which produce amenorrhea and/or galactorrhea provide a unique interface between obstetrics, gynecology and endocrinology. The chapters provide an overview of breast disease including pathophysiology, detection, diagnosis and treatment. A persuasive case is made for the selective and non-operative treatment of breast carcinoma. Diagnostic studies include the thermographic measurement of metabolic activity of tumors and the interpretation of increasingly sophisticated imaging techniques—sonography and mammography.

1979, 336 pp., $19.50 ISBN: 0-8009-1177-5

REVERSIBILITY OF FEMALE STERILIZATION

Edited by I. BROSENS and R. WINSTON

The book comprises the proceedings of a symposium devoted to sterilization and its reversal. Emphasis is on technical aspects with discussions of basic Fallopian tube anatomy, physiology, and pathology, and the application of microsurgical techniques. The chapters provide practical guidelines for the gynecologist and also a stimulus for further investigation of this important aspect of human reproduction.

Edition for the Americas published by Grune & Stratton

1978, 204 pp., $15.50 ISBN: 0-8089-1150-3

NEW ADVANCES IN THE TREATMENT OF CANDIDAL VAGINITIS

Edited by D. GOUGH

Royal Society of Medicine International Congress and Symposium Series

The chapters include: Cure and Relapse of Candidal Vaginitis Following Treatment with Miconazole, Clotrimazole and Nystatin; The Efficacy of Seven Day Administration of Miconazole in Candidal Vaginitis. The Influence of Dosage and Times of Administration of Miconazole on Cure of Candidal Vaginitis; New Gynecologic Formulations of Miconazole; A Study of the Cure and Relapse of Candidal Vaginitis With A Novel Formulation of Miconazole.

Edition for the Americas published by Grune & Stratton

1979, softcover, 48 pp., $9.25 ISBN: 0-8089-1188-0

Future volumes in the ROYAL SOCIETY OF MEDICINE INTERNATIONAL CONGRESS AND SYMPOSIUM Series are now available on a Continuation Order basis. Your Continuation Order authorizes us to ship and bill each future volume in the series automatically, immediately upon publication. This order will remain in effect until cancelled.

U.S. customers please note: On prepaid orders—payment will be refunded for titles on which shipment is not possible within 120 days.

Send payment with order and save postage and handling charge. *Prices are subject to change without notice.*

Fergon®
brand of
ferrous
gluconate

When she needs iron replacement

Fergon is ideal as iron replacement therapy for hypochromic anemia of pregnancy, because it provides the three advan-ages you want in oral iron therapy: excellent tolerance • proven effectiveness economy.

Fergon encourages a rapid hemoglobin response and it is well tolerated and non-constipating in the great majority of patients. It is soluble throughout the en-re pH range of the g.i. tract and is available for absorption at the upper in-estinal site of maximum absorption.

ach tablet contains 320 mg (5 grains) ferrous gluconate equal to approximately 36 mg ferrous iron. Dosage: dults, one or two tablets three times daily; Children, 6-12 years, one tablet one to three times daily, as directed y the physician. Supplied: Bottles of 100 and 1000. Each capsule contains 435 mg ferrous gluconate equal to pproximately 50 mg ferrous iron. Dosage: Adults, one daily or as directed; Children, as directed. Supplied: ottles of 30.

CLINICAL OPINION

This section reports opinion on the handling of clinical situations, i.e., the clinical diagnosis and management of certain disease entities. Papers should range from eight to twenty typed pages, including illustrations, tables, and figures which clarify the author's management. References are limited to sixteen citations. Mail to Frederick P. Zuspan, M.D., Editor.

Modern management of the breech delivery

LEON I. MANN, M.D.
JANICE M. GALLANT, P.A.-C.
Burlington, Vermont

Retrospective review of 457 breech deliveries failed to reveal a significant improvement in neonatal mortality and morbidity rates for those delivered by cesarean section vs. vaginal delivery. A slight but insignificant improvement in salvage was found for the 1,000 to 1,500 gram weight category when delivery was by cesarean section. Most of the deaths in the less than 1,500 gram breech presentation were associated with hyaline membrane disease or congenital defects incompatible with life and sepsis rather than directly related to the manner of breech delivery. (AM. J. OBSTET. GYNECOL. 134:611, 1979.)

PROPER OBSTETRIC management of the breech presentation has been discussed and debated for many years.[1-3] There is still no unanimity of opinion regarding the safest method of delivery. In an attempt to decrease the incidence of intrapartum breech, external cephalic version prior to labor has been recommended, particularly since the introduction of uterine relaxing agents. This procedure, however, has not gained widespread acceptance so that the same number of intrapartum breech presentations continues to occur per year. Increased concern with perinatal death, quality of life in terms of short- and long-term morbidity, and the threat of malpractice litigation resulting from poor obstetric outcome has led some to suggest that all breech presentations should be delivered by cesarean section. Management based upon objective criteria of pelvic capacity, fetal size, and progress of labor and subjective evaluation by training and experience has been said to have no place in the modern management of the breech presentation. Many obstetricians and institutions have instituted management protocols that involve cesarean section for all breech presentations. As a result, the rate of cesarean section for breech

presentations has risen dramatically during the past decade. This has occurred simultaneously with an increased rate of cesarean section for other perinatal complications. The obstetric community is now being challenged to defend this increased cesarean section rate. Review of the literature reveals few articles that provide a scientific—much less statistical—basis to support cesarean section for all breech presentations. The present study was undertaken to evaluate our own experience with vaginal vs. abdominal delivery for the breech presentations.

Study population and methods

The study involved 457 breech deliveries that occurred during a total of 11,338 deliveries—an incidence of 4%. The charts were reviewed for age, parity, type of breech, Apgar scores at 1 and 5 minutes, and fetal and neonatal deaths. Twins were included in the study only when Twin A presented as a breech. There was no established protocol for management of the breech during the time period of the study. Spontaneous delivery to the umbilicus followed by rapid general anesthesia and assisted breech delivery was the method used in most cases of vaginal delivery. Forceps to the aftercoming head were not applied routinely. A low-flap transverse uterine incision was used for the cesarean section. An anesthesiologist and neonatologist were in attendance at delivery. Long-term evaluation of the infant was unavailable for analysis.

Statistical analysis was accomplished by the comparison of two proportions. A P value of less than 0.05 was accepted as significant.

Results

General characteristics. The age, parity, and type of breech are presented in Table I: 63% of the patients were between the ages of 21 and 30 years; 43% of the patients were primiparas and 57% multiparas. The most common type of breech was the frank (44%); the complete and footling variety represented 32 and 24% of the cases.

Incidence of cesarean section by weight. The incidence of cesarean section by weight is shown in Table II. Of the 436 liveborns, 149 (34%) were delivered by cesarean section. Of the five patients delivered by cesarean section in the 500 to 999 gram category, four weighed more than 900 grams. The highest percentage of cesarean section occurred in the 1,000 to 1,499 gram category (40%).

Method of delivery and Apgar score. The Apgar scores at 1 and 5 minutes, grouped by method of delivery, are shown in Tables III and IV: 36% of the neonates had a 1 minute Apgar score between 1 and 6; 9.6% a 5 minute Apgar score between 1 and 6. There were no significant differences in depressed Apgar scores when analyzed by method of delivery and newborn weight.

Perinatal and neonatal deaths by method of delivery. Perinatal deaths for infants weighing more than 500 grams and 1,000 grams are shown in Table V. The perinatal mortality rate for the group over 1,000 grams was 56/1,000 which is approximately 6 times that for the year 1977 at the Medical Center Hospital of Vermont (9.8/1,000).

Tables VI and VII show the absolute neonatal mortality incidence and the neonatal mortality rate expressed per 1,000 live births. Neonatal death was chosen specifically as a means of evaluating method of delivery rather than perinatal death, which includes fetal deaths. There were 21 fetal deaths in the study. There was one neonatal death in 334 fetuses weighing more than 2,000 grams. This death occurred following an elective cesarean section and was the result of congenital pulmonary hypoplasia. There was no effect of parity or timing of the cesarean section, whether elective or following labor, on neonatal outcome.

The actual neonatal mortality rate per 1,000 live births in the 1,500 to 1,999 grams category was slightly higher for the cesarean section category. Of the four deaths in this weight group, two were associated with congenital defects incompatible with life, one with sepsis, and one with hyaline membrane disease.

Ten of the 25 neonates in the 1,000 to 1,499 gram group died during the neonatal period. There was a slightly improved neonatal mortality rate in the group delivered by cesarean section. This was not statistically significant. Four of these 10 deaths were associated with congenital defects incompatible with life and three were associated with sepsis and hyaline membrane disease.

Comment

The observations reported in this study do not support the recommendation that all breech presentations should be delivered by cesarean section. The results clearly indicate that the fetus weighing 2,000 grams or greater, at approximately 34 weeks or longer, need not be delivered routinely by cesarean section to improve the perinatal mortality and morbidity rates. Only one fetal death occurred in this group and that was unrelated to the breech presentation. Improved perinatal salvage following cesarean section could not be confirmed whether the patient was primiparous or multiparous or whether the section was performed electively or following a course of labor. This does not mean, however, that all breech presentations weighing 2,000 grams or more can be safely delivered vaginally. Rather, it would seem to indicate that in this weight group of breech presentations, the mother can be allowed to labor after proper evaluation of fetal-pelvic relationships and documented evidence of continuous progress by objective criteria of effacement, dilatation, and descent without arrest. Intrapartum monitoring should be conducted routinely. If hyperextension of the fetal head, fetal-pelvic disproportion, or arrest of labor were observed, cesarean section should be performed. While forceps application to the aftercoming head was not performed routinely during vaginal delivery in this study, the literature would seem to substantiate the routine application of forceps.[4] The aftercoming head of the breech that is delivered through a uterine incision similarly requires adequate room so that a wide transverse incision or a low vertical incision would seem appropriate. With this method of management of the breech presentation, a higher section rate than for vertex presentation should be anticipated. What the ideal cesarean section rate will be is difficult to state, but a range of 20 to 30% seems appropriate.

Results obtained in the present study for the breech fetus weighing more than 1,500 grams but less than 2,000 grams show an increased mortality rate when compared to those over 2,000 grams. Cesarean section did not, however, improve the mortality rate in this

group. None of the neonatal deaths was related to the breech delivery per se. Other reports have revealed similar findings.

For the total group above 1,500 grams, therefore, no improvement in the perinatal mortality rate could be demonstrated by cesarean section. These results are in disagreement with the large retrospective study of breeches reported from Finland.[5] The differences are not readily explicable.

The breech fetuses weighing between 1,000 and 1,500 grams were too few to allow conclusions to be made regarding the proper method of management for this weight group. There was no statistically significant difference between groups, although a slightly better rate was obtained when delivery was by cesarean section. Similar observations have been reported by others for this weight category.[6] It may be that it is this group that is best managed by cesarean section. This argument must be countered, however, by the observation that most of these fetuses died of congenital defects incompatible with life, infection, or hyaline membrane disease rather than as a direct result of the breech delivery. The neonatal mortality rate is significantly higher whether delivery is vaginal or by cesarean section so that it is impossible to conclude from available data the safest route of delivery for this weight group of breech fetuses. Each case must clearly be individualized and cesarean section selected after careful evaluation. However, a positive statement for routine cesarean section for this group does not seem warranted at this point.

This study was not prospective nor controlled and must be interpreted accordingly. In addition, it does not address long-term morbidity as it relates to the method of breech delivery. Within the constraints of the data provided by the study, however, it would seem proper to summarize that all breech presentations do not require cesarean section for safe delivery.

Vaginal breech delivery or cesarean section

B. VICTOR LEWIS, M.D., F.R.C.O.G.
H. R. SENEVIRATNE, M.B., M.R.C.O.G.
Hertfordshire, United Kingdom

In 579 singleton breech deliveries the total perinatal mortality rate was 10.4% and the corrected perinatal mortality rate was 0.67%. There were 452 babies delivered vaginally (78.1%) and 127 delivered by cesarean section (21.9%). The perinatal mortality rate was very high in the premature breech delivery and in the low-birth-weight infant. Cesarean section should be used to avoid a traumatic vaginal delivery and it should be used more liberally in the mature breech, but it is unlikely that cesarean section rates in excess of 50% will significantly reduce the perinatal mortality rate. More information is required as to whether extending the indications for cesarean section in the low-birth-weight infant will further reduce the perinatal mortality rate. (AM. J. OBSTET. GYNECOL. 134:615, 1979.)

IN 1977 ONE OF US (B.V.L.) visited obstetric centers in North America. During discussions with residents and staff it was apparent that there were many conflicting views as to the management of breech confinement.

The question was raised again at a debate by the Section of Obstetrics in the Royal Society of Medicine, London. Drs. H. Roberts and Fraser of London proposed that all breech presentations should be delivered by cesarean section. The motion was opposed by Drs. Edward Cope, from Oxford, and A. Barry, from Dublin. Following debate the motion was overwhelmingly defeated by the members present.

Because of the widely divergent views in the management of a common obstetric problem it seemed relevant to review, retrospectively, a relatively large number of breech confinements in a single obstetric unit.

Accordingly, 579 breech deliveries are reviewed.

Results

Between 1970 and 1976 inclusive there were 13,607 deliveries, of which 579 were singleton breech presentations—an incidence of 4.3%. The uncorrected perinatal mortality rate for all breech deliveries, both abdominal and vaginal, was 10.4% (Table I).

Of the 579 breech deliveries, 452 (78.1%) were delivered vaginally and 127 (21.9%) were delivered by cesarean section. Vaginal delivery was usually accomplished by a resident using bilateral pudendal block or epidural anesthesia and assisted or spontaneous delivery of the trunk. The arms were delivered from a flexed position across the chest or Lövset's maneuver was used to deliver the extended arms. In the United Kingdom the Burns-Marshall method is usually preferred for the aftercoming head. Forceps were frequently applied and in all cases a generous episiotomy was performed.

Table I. Singleton breech deliveries—Watford General Hospital, 1970 to 1976

Total deliveries	*Singleton breech*	*Uncorrected perinatal deaths*
13,607	579 (4.3%)	62 (10.4%)

Cesarean section was performed if the pelvic measurements were small, when there was a bad obstetric history or an elderly primigravida, especially if there had been a problem of infertility. Other relative indications included antepartum bleeding, large fetus, flexed legs, and pre-eclampsia. In labor absolute indications were fetal distress, prolapse of the umbilical cord, and failure to progress. Of the 127 cesarean sections performed 72 (56.7%) were elective and 55 (43.3%) were emergency (Table II). Seventy-five per cent of primigravidas and 81.1% of multigravidas were delivered vaginally (Table III).

Of primigravidas under 20 years of age, 85.7% were delivered vaginally compared with 33.3% of primigravidas over 35 years of age (Table IV).

Method of delivery in relation to gestational age and fetal weight. Of all breech deliveries, 86.7% had

completed 35 weeks, leaving 13% delivered prior to week 36 of pregnancy. The hospital rate for deliveries before week 36 varied between 4 and 7%, so that there was a preponderance of breech deliveries in the premature group. Almost a quarter of all breeches delivered (24.2%) weighed less than 2,500 grams, so that there was a higher proportion of light-for-dates babies in those who had completed 35 weeks of pregnancy.

Perinatal deaths in breech pregnancies. The uncorrected perinatal death rate in all breech deliveries was 10.4% (62 out of 579), of which 38 babies (61.3%) were stillborn and 24 babies (38.7%) died within the first 7 days. The corrected perinatal death rate (corrected for low birth weight, congenital abnormality, antepartum stillbirth, Rh incompatability, etc.) was 0.67%, i.e., four deaths directly attributable to the breech presentation and errors of management (Table V). There was also a group of babies who died from multiple causes in which the breech delivery could have been a factor. Included in this group were severe pre-eclampsia, respiratory distress, and cord complications.

Perinatal death and birth weight. In babies born weighing less than 1,000 grams the perinatal mortality rate was 100%. With increasing increments in birth weight the perinatal mortality rate progressively fell until a perinatal mortality rate of 1.6% was achieved for breech babies born weighing over 2,500 grams (Table VI). The numbers involved were relatively few but there seemed to be a preponderance of stillbirths over neonatal deaths in babies whose birth weight was greater than 1,500 grams, whereas most of the neonatal deaths were in the very small weight category.

Perinatal death and gestational age. Perinatal deaths fell from 93.75% at a gestational age of less than 28 weeks to 1.9% between the end of week 37 and term. Again numbers are small but there seems to be a high perinatal mortality rate in the 34 to 36 week age.

Perinatal death and method of delivery. In the 452 patients delivered vaginally the perinatal mortality rate was 11.9% or, if macerated stillborn infants are excluded, 8.2%. In the 127 patients delivered by cesarean section the perinatal mortality rate was 6.3%. Thus the total uncorrected perinatal mortality rate for all modes of delivery was 10.4%.

Fetal loss due to breech. There were four babies who died in which the breech presentation was the cause. Retrospective review of the details show that cesarean section was delayed. Elective cesarean section would most likely have resulted in healthy babies.

Comment

We have dealt solely with perinatal deaths (stillbirths and first week deaths) and have excluded other information. We have not discussed Apgar scores at birth, birth injury, or long-term follow-up.

The 1 minute Apgar score is reduced in vaginal breech delivery.[1, 2] Kauppila[1] found, as expected, that the lowest Apgar scores occur in breech deliveries when the infants are injured by a traumatic delivery or when difficulty occurred during partial breech extraction. These factors should be avoided by cesarean section.

Most specialist units ensure that all breech deliveries are carried out in the presence of an experienced pediatrician immediately available to resuscitate the baby.

Birth injury may be increased during a vaginal breech delivery,[1, 3] but the injuries occur during difficult delivery. Extraction of a breech presentation by cesarean section may also cause birth injury.[3]

Long-term follow-up may fail to take into account factors other than breech presentation. Of special importance are prematurity and growth retardation, both of which seem to be more frequent in breech presentation.[1]

In assessing the role of cesarean section in breech delivery it is helpful to consider first the premature breech and then the mature breech, bearing in mind the fact that there is an excess of babies weighing less than 2,500 grams who have completed 35 weeks' gestation.

The premature breech. The perinatal mortality rate is higher in the premature breech than the premature vertex.[1, 2] Kauppila found that the perinatal death rate in single fetation breech deliveries was 38.7% in babies weighing 1,251 to 2,500 grams and 93.2% in babies weighing 601 to 1,250 grams. This compares with perinatal death rates of 19.5% and 80.1% in similar weight groups other than breech deliveries. These data refer to babies born between 1952 and 1961. Intrapartum deaths in small babies also occur more frequently during a vaginal breech delivery.[1, 5]

Thus it is established that premature vaginal breech delivery has a higher perinatal mortality rate and more intrapartum stillbirths than premature vertex delivery. It is not yet established that cesarean section can reduce this high perinatal loss.

The data of Goldenberg and Nelson[5] might suggest that the corrected perinatal mortality rate was marginally improved by cesarean section over vaginal breech delivery in very low-birth-weight infants (500 to 1,249 grams) but the numbers are too few for statistical analysis. Between 1,500 and 2,499 grams the perinatal mortality rate in babies delivered by cesarean section exceeded the perinatal mortality rate of vaginal breech delivery. This is the corrected figure which excludes major congenital abnormality. But congenital abnormality is more common in premature breech delivery,[1] so the uncorrected figure of perinatal deaths in premature babies delivered by cesarean section is higher still. Thus 4.2% of cesarean sections in premature babies resulted in delivery of a baby with a major congenital abnormality.[5] Goldenberg and Nelson suggested that a prospective evaluation of prophylactic cesarean section in unstressed breech presentation in infants under 1,500 grams is indicated. Such an approach is in our view contraindicated without first evaluating the present methods of intensive care in the premature breech labor.

Under optimal conditions the following management criteria should be followed: continuous fetal heart rate monitoring and fetal blood sampling from the buttock,[6] forceps to the aftercoming head,[7] continuous epidural or caudal anesthesia, an episiotomy, early vaginal examination to exclude cord prolapse, the avoidance of occipital diastasis due to hyperextension of the fetal head,[8] or manual pressure on the head via the abdomen. Intravenous dexamethasone in early labor is desirable, and skillful and immediate resuscitation at delivery is essential. The results of cesarean section in the premature breech must be compared to the above if any meaningful opinion is to result. There are, however, certain complications of premature breech delivery where the mortality and morbidity rates are so high that cesarean section is invariably justified. These include evidence of increasing asphyxia and prolapse of cord or hand.

The mature breech. As the cesarean section rate increases in mature breech presentations the perinatal mortality rate falls,[1, 2] so that the liberal use of cesarean section is indicated. In the two hospitals considered by Kauppila,[1] one had a cesarean section rate of 10.9% with a corrected perinatal mortality rate of 2.24%; the other had a cesarean section rate of 28.3% with a corrected perinatal mortality rate of 0.49%. Although cesarean section rates have increased with a corresponding drop in perinatal mortality rate, the rates reported by Kauppila would still be considered low by many standards, particularly in the United States. In our own series the total section rate was 21.9% and the total corrected perinatal mortality rate was 0.67% for all breeches. Since there is a general consensus that difficult breech delivery should be avoided because of the high fetal mortality and morbidity rates, cesarean section should be performed for a large baby and breech extractions must be avoided. Failure to progress in labor should be regarded as evidence of disproportion. Early fetal asphyxia, recognized by continuous fetal heart rate monitoring or buttock pH estimations,[6] should be treated by abdominal delivery. The flexed breech has a greater risk of prolapse of the umbilical cord[1] so consideration should be given to elective ce-

sarean section. Early recognition of prolapse of the umbilical cord is essential. Thus vaginal examination should be performed when the membranes rupture or when fetal dips appear on the electrocardiographic tracing. The mortality rate for cesarean section in cord prolapse is low.[9]

Cesarean section as a method of management of a complicated breech delivery obtains the best results in terms of fetal survival. There is, however, no information to suggest that extrapolation of incidence rates beyond 50% will further reduce the perinatal mortality rate. This information is required if the simple uncomplicated breech delivery is to be replaced by a major abdominal operation with the attendant increase in maternal morbidity and cost.

GYNECOLOGY

Luteinizing hormone–releasing hormone levels in human plasma: A radioimmunoassay method

SEZER AKSEL, M.D., F.A.C.O.G.
REGINA GLASS, M.T.
Mobile, Alabama

A sensitive double-antibody radioimmunoassay, developed to measure luteinizing hormone–releasing hormone (LHRH) levels in fetal brain tissues, has been modified to quantitate LHRH in unextracted plasma samples. Pure, synthetic LHRH was iodinated with ^{125}I for tracer and was also used as standard. The antibody utilized was specific for LHRH and did not cross react with other hypothalamic or pituitary hormones. The separation of free from antibody-bound tracer was performed by dextran-coated charcoal. The sensitivity of the assay was 2.5 pg/tube. The intra-assay and interassay coefficients of variation were 5.9 and 6.1% for 50 pg/ml and 11.8 and 14.9% for 25 pg/ml samples. Recovery of known amounts of LHRH added to plasma samples that had no detectable hormone was 96.4 ± 8.8%. Whether these samples were previously prepared and kept frozen at −20° C or freshly prepared, the recovery of LHRH was consistent and quantitatively stable in each assay. Serial determinations of LHRH in plasma obtained from ovulatory volunteers averaged between 20.5 ± 2.1 pg/ml in the follicular phase and 19.4 ± 4.5 pg/ml in the luteal phase. At midcycle, coincident with the luteinizing hormone surge, LHRH levels averaged 17.6 ± 4.4 pg/ml. (AM. J. OBSTET. GYNECOL. 134:619, 1979.)

BY EMPLOYING invasive procedures into the hypothalamus, a luteinizing hormone–releasing hormone (LHRH) surge has been measured in the rat, rabbit, and rhesus monkey which has correlated well with a preovulatory LH surge.[1–3] Investigators have attempted to demonstrate similar findings in the human being and have measured LHRH in the peripheral plasma at midcycle by bioassays and radioimmunoassays.[4–7] Most of these involved laborious extraction procedures and required large volumes of plasma to measure this decapeptide produced in the hypothalamus and greatly diluted in the peripheral circulation. Some contradictory and inconsistent results have also been obtained.[8–10]

The quantitation of LHRH has posed many problems. Rapid inactivation by plasma enzymes, loss of immunoreactivity during processing of samples,[11, 12] and very low concentrations detected in plasma of women in the reproductive age[7, 8] have been reported. Investigators have been cautioned about the specificity of antibody used, iodination technique, and the cross-reactivity of tracer with serum proteins.[12, 13] This study was planned to measure LHRH in plasma samples of 10 normal ovulatory women during a complete menstrual cycle by a simple radioimmunoassay which has been modified from a sensitive, reproducible, double-antibody method developed to measure LHRH levels in the fetal hypothalamus.[14]

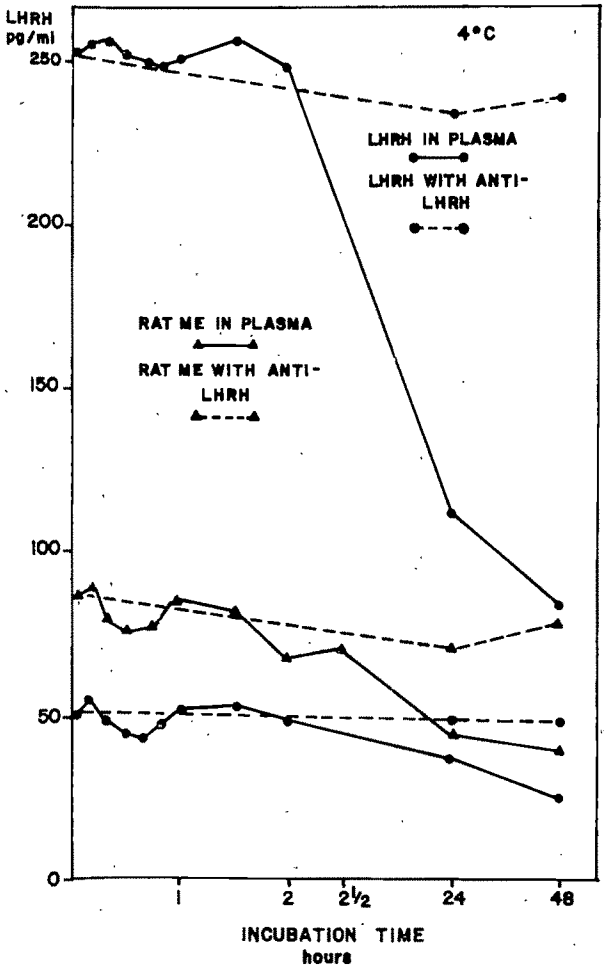

Fig. 1. Time course of plasma LHRH immunoreactivity at 4° C in comparison to LHRH values when samples were incubated with anti-1 LHRH.

Material and methods

Iodination. This method has been previously published.[14] The specific activity of the hormone obtained has varied between 52 and 76 μCi/μg. Labeling the hormone at a higher specific activity reduced its immunoreactivity. Tracer was repurified on a column (0.9 × 12 cm) of Sephadex G-25 prior to use for each radioimmunoassay.

Radioimmunoassay. Synthetic LHRH and tracer dilutions were made in phosphate-buffered saline (PBS) solution containing 1% gelatin at pH 6.5. The antisera was diluted in a solution of PBS containing 1/400 normal rabbit serum with EDTA and used at a working dilution of 1/100,000. The assay was conducted at 4° C and the reagents utilized were also kept at this temperature. Standards and samples contained 300 μl of buffer and 200 μl of plasma. The plasma utilized in standard tubes (0 plasma) was sterile, pooled, outdated, male plasma obtained from the blood bank, incubated at 22° C for several days, and recorded to have no LHRH activity after multiple extraction studies. Following a 24 hour incubation with 200 μl of antiserum (1/350,000 final dilution), 100 μl of LHRH tracer (150 pg) was added and incubation continued for another 24 hours. The separation of free and antibody-bound tracer was performed with the addition of ½ ml of ice-cold, dextran-coated charcoal suspension, prepared by adding 800 mg activated charcoal (Norit A-176) and 80 mg dextran T-70 to 100 ml of PBS, pH 6.5. A preliminary evaluation showed that 99% of unbound tracer could be removed in this manner. After centrifugation at 2,000 rpm at 4° C for 15 minutes, the supernatant was transferred to 12 by 75 mm plastic tubes by decanting, sealed with caps, and counted in a Beckman 310 gamma counter with a 70% counting efficiency, for 10 minutes or to 10,000 counts. Control tubes were routinely set up without antisera for determination of nonspecific binding for each assay.

Table I. Recovery of LHRH from heparinized blood

	Synthetic LHRH (100 pg/ml)		*Endogenous LHRH*

45	189.5	181.4	16.2	13.6

Collection of samples. Ten milliliters of heparinized blood was obtained by venipuncture from normal cyclic volunteers who had agreed to participate in the study and signed informed consent. The sample was spun within 10 minutes of withdrawal at 4° C. The plasma was separated into three aliquots, rapidly frozen, and kept at −20° C until assay. All samples from the same volunteer were run in the same assay. If a repeat run of a sample was necessary, an unthawed sample tube was used for the repeat LHRH determination.

Results

Stability of LHRH in heparinized blood and plasma. In view of temperature and time-related loss of LHRH activity in plasma,[11, 12] an appropriate method had to be devised for handling and storing of specimens prior to assay. The following experiments were performed to check the stability of LHRH in samples obtained with respect to time, temperature, and concentration.

Experiment 1: Stability of LHRH in blood specimens. To

ME = Median eminence.
*Incubation with antisera.

freshly drawn, heparinized, whole blood from a male volunteer (hematocrit 45%, baseline LHRH concentration 16.4 pg/ml), 100 pg. of synthetic LHRH was added per milliliter of blood. The blood sample was aliquoted into centrifuge tubes and half of the samples were kept at 4° C and the other half at 22° C. At 5, 10, 20, 30, and 45 minute intervals, the tubes were centrifuged at 4° C and the plasma was quickly frozen and kept at −20° C until assay. Heparinized blood was also obtained from a postmenopausal volunteer to evaluate the effects of delayed centrifugation on endogenous LHRH levels. After the samples were aliquoted into centrifuge tubes and kept at 4° and 22° C, respectively, they were centrifuged at 5, 15, 30, and 45 minutes. The results are shown in Table I. The endogenous LHRH decreased 20.9% and 18.9% from its baseline value at 4° and 22° C, respectively, when centrifugation was performed 15 minutes after the specimen was obtained. However, when the specimen was centrifuged 45 minutes later, there was a 45% and a 50% loss of immunoreactivity at 4° and 22° C, respectively. With a higher concentration of synthetic LHRH in heparinized blood, there was only 10.1% and 12.5% loss of immunoreactivity when the specimen was kept at 4° and 22° C for 45 minutes. Therefore, since the daily samples were expected to contain small concentrations of LHRH, the lab personnel strictly adhered to the rule of centrifugation of the blood specimen immediately after it was obtained.

Experiment 2: Stability of LHRH in plasma. Although the radioimmunoassay procedure was conducted at 4° C and completed within 48 hours, it was essential to determine if the LHRH levels remained stable during the preparation of the radioimmunoassay and during the incubation period. Table II shows the results of studies with 50 and 250 pg/ml concentrations of synthetic LHRH and rat median eminence extract diluted to 90 pg/ml concentration to be added to 0 plasma and incubated at 4, 22, and 37° C. Samples were rapidly frozen at 10 to 30 minute time intervals up to 2½ hours, then at 24 to 48 hour periods. Neither the synthetic LHRH nor the rat median eminence extract showed any significant decrease in LHRH immunoreactivity at 4° or 22° C within 90 minutes. The amount of decrease in LHRH activity appeared to be more pronounced at 37° C (Table II). However, when the 24 and 48 hour incubations were performed with the addition of antisera to the sample at 4° C, there was no loss of LHRH immunoreactivity (Fig. 1).

With these findings, the assay was carried out at 4° C. The addition of 0 plasma to the standard tubes and the addition of antisera to the assay were accomplished within 30 minutes. This alleviated the possible loss of immunoreactive LHRH during the preparation of the assay.

Experiment 3: Stability of LHRH in samples that were thawed and refrozen prior to assay. The LHRH value of a postmenopausal volunteer's plasma specimen was determined to be 55 pg/ml. This specimen was thawed and quick-frozen three times as aliquots for radioimmunoassay were obtained. The LHRH levels were as follows: first thaw, 53.6 pg/ml; second thaw, 46.5 pg/ml; and third thaw, 43.1 pg/ml. There was a 21% loss of measurable LHRH in the same sample if it was thawed for the third time. Therefore it was felt that if each plasma sample was aliquoted into three separate

Table III

Hormone	*Quantity (ng/tube)*	*Displacement*
LHRH	2.5	Complete
TRH	25.0	0
LH	25.0	0
FSH	25.0	0
Prolactin	25.0	0
Oxytocin	800.0	0

storage tubes, when a repeat radioimmunoassay was necessary, an unthawed specimen could be utilized to alleviate errors in measurement of LHRH.

Assay sensitivity and reliability. The assay sensitivity was 2.5 pg/tube. This amount of unlabeled LHRH produced an 8% to 10% fall in binding of tracer, whereas 2.5 ng. produced nearly complete displacement. Based on ten replicate samples containing 25 and 50 pg/ml of synthetic LHRH, the intra-assay coefficients of variation were 11.8% and 5.9%, respectively. The mean interassay variations of samples of similar concentrations in 12 different assays were 14.9% and 6.1%, respectively. Control samples utilized in each assay, containing physiologic and pharmacologic concentrations of LHRH, produced reproducible results in 25 assays. Whether these samples were freshly prepared for that particular assay or previously prepared and kept frozen at −20° C, the LHRH values were consistent and quantitatively stable in each assay.

The nonspecific binding of tracer was between 2.5% and 3%. The addition of plasma to assay buffer did not change the binding of tracer. In determination of maximum binding, the mean percentage bound was 69.5 ± 6.7 in 10 consecutive assays. This value was 15% higher than the mean percentage bound without the addition of 200 μl of 0 plasma which appeared to enhance antibody binding to tracer. On the curve, the point of 50% displacement varied between 52 and 58 pg/tube. The mean of the slope (least-squares linear regression of B/B^0 versus log dose of standard LHRH) in 10 consecutive assays was −2.52 ± 0.19.

Recovery of synthetic LHRH added to 0 plasma at 15, 25, 35, 50, 100, and 250 pg/ml concentration was 96.4% ± 8.8%.

Assay specificity. The curve generated by serial dilutions of rat median eminence extract in 0 plasma was parallel to the standard curve. Although 2.5 ng of LHRH produced almost complete displacement of tracer from antibody, there was no reaction with thyrotropin-releasing hormone (TRH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), prolactin, and oxytocin, as shown in Table III.

Human plasma assay. LHRH concentrations in daily plasma of 10 normal ovulatory women during the follicular and luteal phases of the cycle varied between 10 and 35 pg/ml with a mean of 20.5 ± 2.1 pg/ml during the follicular phase and 19.4 ± 4.5 pg/ml during the luteal phase. Mean LHRH measured on the day of the LH surge in 10 samples was 17.6 ± 4.4 pg/ml.

Comment

Direct evidence for the existence of LHRH in the human peripheral circulation has provided the stimulus to many investigators to develop sensitive radioimmunoassays to quantitate the levels of this hypothalamic hormone. Reports have demonstrated that LHRH is more readily measurable in the postmenopausal than the perimenopausal women.[7, 15]

In view of the very small amounts of hormone detectable in the human plasma, many investigators have refined the assay sensitivity and cautioned the researchers about the pitfalls in measuring LHRH in the peripheral circulation.[8, 12, 13] A variety of extraction methods have been utilized to prevent the rapid degradation of this decapaptide in plasma but the recoveries have been problematic in the quantitation of the hormone.[4, 5, 7–9] In our laboratory, ethanol and methanol extractions using a 3 to 1 ratio have resulted in 25.6% to 44.2% recoveries, depending on the concentration of synthetic LHRH added to the sample. In view of the very small quantities of hormone present in the plasma samples, extraction procedures with small volumes of plasma will not yield significant results.

Enzyme inhibitors such as Trasylol or Benzamidine have been used to prevent degradation of LHRH in plasma.[9, 12] We have used Benzamidine in heparinized blood samples. When the plasma obtained was extracted, a higher level of LHRH was recorded in comparison to the sample without Benzamidine. Extraction of 0 plasma contaminated with Benzamidine at 0.005M or 0.01M concentration per milliliter demonstrated 25% and 45% displacement of tracer, respectively. Therefore, utilization of enzyme inhibitors ought to be evaluated for cross-reactivity with antisera.

Obtaining blood samples and centrifugation should be performed in a uniform and prompt manner. Since endogenous LHRH exists in such small quantities in plasma, there is rapid loss of immunoreactivity. Obtaining specimens for plasma rather than for serum allows for rapid centrifugation.

The data suggest that the addition of antisera to plasma samples at 4° C appears to protect LHRH from degradation in the specimens during a 48 hour incubation period, preventing loss of hormone activity in these samples. The iodinated tracer should be purified

prior to each use. The eluates with the lower specific activity recovered from the descending limb of the purification procedure have more immunoreactivity with the antibody, which is essential for assay sensitivity.

Determination of LHRH in normal ovulatory women does not appear to be of any clinical value. No specific pattern of LHRH concentration was observed in 10 normal menstrual cycles. During the day of the LH surge, no LHRH elevation was noted in 10 peripheral samples.

The synthetic LHRH and anti-LHRH were provided by W. C. Dermody, Ph.D., of Parke Davis & Company, Detroit, Michigan. The rat median eminence extract was provided by the National Institute of Arthritis, Metabolism, and Digestive Diseases, Bethesda, Maryland.

Cellular and humoral immune status in women with chronic *Candida* vaginitis

RAE ELLEN SYVERSON, Sc.D.
HELEN BUCKLEY, PH.D.
JUDITH GIBIAN, B.A.
GEORGE M. RYAN, JR., M.D., M.P.H., F.A.C.O.G.
Boston, Massachusetts

The cellular and humoral immune responses of nine women with chronic *Candida* vaginitis and 29 control subjects were evaluated. Agglutinating and precipitating antibodies were studied and tests of lymphocyte transformation, lymphokine production, and cutaneous delayed hypersensitivity were performed. The results suggest a lack of cellular immune response to *Candida* antigens in women with chronic *Candida* vaginitis. (AM. J. OBSTET. GYNECOL. 134:624, 1979.)

CANDIDA ALBICANS can be isolated from the vagina of approximately 16% of the nonpregnant female population of childbearing age.[1-3] The incidence of vaginitis due to this organism in the same population is approximately 6%[2, 4] or about 40% of women presenting with vaginitis.[5, 6] It is the most common infectious agent isolated from women attending venereal disease clinics.[3, 7]

The conversion of *C. albicans* from commensal to pathogen may be precipitated by a number of well-defined predisposing factors including pregnancy, diabetes, antibiotic or steroid therapy, antitrichomonal therapy, and iron-deficiency anemia. In addition, oral contraceptives have been incriminated as a cause of an increased indidence of *Candida* in the vagina[1, 3] and/or an increased incidence of *Candida* vaginitis among those harboring the yeast.[4, 8]

Recurrent vaginal candidiasis, a frequent sequel of a primary infection, may follow inadequate treatment or result from reinfection. Sources of reinfection are the patient's gastrointestinal tract[9] and the sexual partner.[10]

Impaired cellular immunity to *C. albicans* has been reported in patients with vaginal candidiasis. In studies of vaginal candidiasis in pregnancy[11] and in denture wearers with *Candida* denture stomatitis.[12] *Candida* infections were associated with a depressed cellular hypersensitivity to *Candida* antigens. While *C. albicans* readily induces a humoral antibody response, antibodies do not appear to offer any protection against current or subsequent infection.

The primary role of cell-mediated immunity in defense against *Candida* infections can be inferred from clinical data. Defective development or function of the thymus, endocrinopathies, leukemia, and immunosuppresive therapy are representative of conditions With concomitant defects in cellular immunity and frequent *Candida* infections.

The in vitro tests of cellular immunity most often performed are tests of lymphocyte transformation and lymphokine production, e.g., the testing of human lymphocytes for ability to produce leukocyte inhibition factor. These tests measure different aspects of the immune response. With these two tests and the in vivo test of cutaneous delayed hypersensitivity (skin test), the cellular immune status of a patient can be assessed. The goal of this cross-sectional study was to evaluate the cellular and humoral immune responses of women with chronic *Candida* vaginitis.

Material and methods

The subjects of this study attended the Gynecology Clinic of the Boston Hospital for Women or were seen

in a private-practice setting between February and June of 1976. The patients were screened to rule out diabetes, pregnancy, steroid therapy, severe or debilitating disease, neoplasm, bilateral oophorectomy, and vaginal infections other than candidiasis (Table I). All patients were between the ages of 18 and 47. Twenty-nine control subjects were selected from women seen for yearly examination or for contraceptive measures (Group 1). Nine women who had chronic *Candida* vaginitis, i.e., more than three clinically diagnosed vaginal infections with *C. albicans*, were identified (Group 2). Criteria for the diagnosis of *Candida* vaginitis included irritating discharge and, on examination, reddening of the mucosa of the labia minora, the introitus, and the lower third of the vagina and the presence of white, lardlike patches. The diagnosis was confirmed by microscopic observation of the yeast or the mycelium or by isolation of the organism on modified Sabouraud's agar or on Mycosel prepared with 5% agar.

Specimens obtained at the time of the clinical examination included blood for complete blood count, dry swabs for mycologic examination from the middle third of the vaginal wall, wet swabs for mycologic examination taken from the rectum, wet swabs for microscopic examination taken from the vagina and examined immediately for trichomonad and yeast cells, and dry swabs for gonorrheal examination taken from the cervix. Women who were shown to be infected with *Trichomonas vaginalis or Neisseria gonorrhoeae* were excluded from the study.

Intradermal forearm injections of 0.1 ml of a 1:100 dilution of *C. albicans* 1:10 mold bulk extract (Hollister-Stier) and 40/10 U of streptokinase-streptodornase* were performed on all women. These tests were read at 48 hours. Induration of less than 5 mm was considered negative; 5 to 10 mm, intermediate; and greater than 10 mm, positive.

Lymphocyte transformation studies were performed on cells cultured by a modification of the procedure described by Chess and associates.[13, 14] The presence of leukocyte inhibition factor, as measured by its effect on the migration of leukocytes, was determined by a modification of a method developed by Castro and associates.[15]

Precipitating antibodies were detected by double immunodiffusion with the procedure of Murray and associates,[16] using a soluble yeast-phase antigen prepared as described by Syverson and associates.[17] Agglutinating antibodies were titrated by the method of Murray and Buckley,[18] using whole formalized *C. albicans* blastospores as the antigen.

Table I. Potential confounding factors

Possible confounding factor	*Associated with*		*Method of control*
	Candidiasis	*Deficient cell-mediated immunity*	
Diabetes	Yes	Yes(?)	R
Pregnancy	Yes	Yes(?)	R
Iron-deficiency anemia	Yes(?)	Yes	N/A
Steroid therapy	Yes	Yes	R
Broad-spectrum antibiotic therapy	Yes	Yes(?)	N/A
Oral contraceptives	Yes	No(?)	A
Chronic disease	Yes	Yes	R
Neoplasm, malignancy	Yes	Yes	R
Alcoholism	Yes	Yes	N/A
Oophorectomy (complete)	Yes	?	R
Age	Yes	Yes	R
Other vaginal infections	?	?	R

R = Restriction (not permitted into study as case or control); A = analysis (upon completion of the study, factors labeled A were examined to see if they were, in fact, confounding); N/A = not present in any patient in this study.

Table II. Incidence of *C. albicans* isolation from vagina and rectum

Group	*Positive cultures for* C. albicans	*Site of positive culture*		
		Vagina	*Vagina/rectum*	*Rectum*
1 (29 cases)	3	3	0	0
2 (9 cases)	5	0	5	0

Results

Cultures. *C. albicans* was isolated from three of 29 control subjects (10%) and five of nine Group 2 women (55%). All positive cultures from the control subjects were from vaginal swabs while all of the infected patients had positive vaginal and rectal cultures (Table II).

Skin tests. The responses of the subjects to skin testing are shown in Table III. Intermediate and positive results to *C. albicans* antigens in Groups 1 and 2 totalled 50%, which is consistent with the observations of other authors.[12, 19] Three Group 2 women did not develop a positive skin test reaction to *C. albicans* despite a history of chronic *Candida* vaginitis. Intermediate and positive results in Groups 1 and 2 to SKSD equaled 31%.

Lymphocyte transformation test. The mean scintillation index (SI) values for the lymphocyte transformation test to *C. albicans* antigens are shown in Table IV. Results have been transformed to the log normal scale to normalize the distribution. The mean SI value for Group 1 was 6.67. There was a good correlation of skin test and lymphocyte transformation (Pearson cor-

C. albicans			
≥10 mm	8 (28%)	5 (56%)	13 (34%)
5-10 mm	5 (17%)	1 (11%)	6 (16%)
<5 mm	16 (55%)	3 (33%)	19 (50%)
SKSD			
≥10 mm	7 (24%)	3 (33%)	10 (26%)
5-10 mm	1 (3%)	1 (11%)	2 (5%)
<5 mm	21 (72%)	5 (56%)	26 (68%)

Table IV. A summary of the scintillation index for lymphocyte transformation to *C. albicans*

Group	*Geometric mean*	*Confidence limits*	*Range*
1	6.67	5.31-8.38	1-116
2	7.27	4.49-11.77	1-118

Table V. A summary of the migration index of leukocyte inhibition tests of *C. albicans*

Group	*Mean and standard error*	*Range*
1	0.84 ± 0.06	1-0.61
2	0.81 ± 0.03	1-0.71

relation coefficient of 0.92) in this group. Although all members of Group 2 were chronically infected with *C. albicans*, the mean SI of this group was only 7.27 with a correlation coefficient of 0.61. No significant difference exists between the mean SI of Groups 1 and 2. No difference was observed between Groups 1 and 2 in the results of the lymphocyte transformation test to SKSD.

Leukocyte inhibition factor test. The mean migration index (MI) values of the leukocyte inhibition factor test for *C. albicans* are shown in Table V. No significant difference exists between the mean MI of Group 1 and Group 2. The Pearson correlation coefficients for the skin test and the leukocyte inhibition factor tests in Groups 1 and 2 were 0.62 and 0.59, respectively. No difference was observed between Groups 1 and 2 in the results of the leukocyte inhibition factor test for SKSD.

Antibody studies. None of the 29 women in Group 1 had precipitating or agglutinating antibodies to *C. albicans* detected in sera. Sera from four subjects (44%) in Group 2 had antibodies to *C. albicans*. Of these four sera, two contained agglutinating antibodies and two contained precipitating antibodies to this organism. The presence or absence of antibodies showed little correlation with skin tests or in vitro tests of cellular immunity in either the study or control groups.

Comment

The results of this study show that women with chronic *Candida* vaginitis cannot be consistently distinguished by four immunologic tests from women with no history of yeast infections. This implies either that the tests themselves cannot distinguish infected from uninfected patients or that women with chronic *Candida* vaginitis lack an immune response to *C. albicans*. The former assumption is probably false. The in vivo and in vitro tests of cellular immunity used in this study have been shown to become positive following active infections and to be specific in both animal models and human studies.[12, 20] Yet in this study of women with active infection the mean values for the skin test, the lymphocyte transformation test, and the leukocyte inhibition factor test did not differ significantly between infected and uninfected women.

In general, in vitro tests of cellular immunity show good correlation with the skin test in subjects previously exposed to the pathogen but without current disease.[19, 21] In a study of *Candida* denture stomatitis,[12] only nine of 29 patients with the disease reacted positively in a leukocyte migration test as compared to 25 of 28 skin test–positive patients without stomatitis. In the present study, a similar correlation is noted in that all 15 uninfected women with positive skin tests to *C. albicans* reacted positively to the leukocyte inhibition factor test, while of the nine women with chronic *Candida* vaginitis only three reacted positively in the lymphocyte transformation tests and four in the leukocyte inhibition factor tests. The observed discordance in infected women may be due to variable stimulation of the immune response, interaction of *C. albicans* or its products with components of the immune response, or inherent defects in the immune response of those women who develop chronic *Candida* vaginitis.

Oral contraceptives were associated with an increased incidence of *Candida* vaginitis (56% of Group 2 women were using oral contraceptives as compared to 28% of Group 1 women). However, no significant differences in the results of tests of cellular immunity were found among women using and not using oral contraceptives in Group 1. Dwyer and associates[19] reported a similar observation based upon comparison of skin tests and lymphocyte transformation tests in 40 healthy women. Thus, it appears that the use of oral contraceptives does not alter the immune response as measured by skin tests, lymphocyte transformation, or migration inhibition tests and thus, by definition, cannot be a confounding factor. However, the usage of oral contraceptives has been repeatedly associated with a higher than normal incidence of vaginal candidiasis.

The interaction of these agents with the vaginal microenvironment, e.g., epithelia, flora, secretions, and glucose content, may influence the extent and duration of colonization by *C. albicans*. This, in turn, should affect the immune response. The relationship between oral contraceptives, vaginal candidiasis, and the resultant immune response remains to be defined.

All of the chronically infected patients from whom yeast was isolated had yeast on rectal culture. Similar findings were recently reported by Miles and associates.[22] The high failure rate of many intravaginal therapeutic agents for vaginal candidiasis relates to these findings. The implication is that oral and vaginal therapy is indicated in chronically infected patients.

Resolution of infection with *C. albicans* has been associated with conversion from negative to positive results in tests of cellular immunity.[23, 24] A prospective study of women with chronic *Candida* vaginitis may show whether temporary eradication of infection through chemotherapy results in the development of positive responses to the in vivo and in vitro tests of cellular immunity. Such a study may detect fluctuations in the immune response which permits the conversion of *C. albicans* from commensal to pathogen or it may show that a depression of cellular immunity occurs only following an acute episode of *Candida* vaginitis. The present study suggests a lack of a cellular immune response to *Candida* antigens in women with chronic *Candida* vaginitis; the reasons for such chronicity remain to be elucidated.

WILLIAM A. URICCHIO, PH.D.**
Los Angeles, California

Data accumulated to date from the Los Angeles study indicate that the total termination rate for 12 months from the beginning of the training period and from formal entry into the study was high for the ovulation method (OM), and symptothermal method (STM). Voluntary withdrawal was the highest single reason for termination in both methods. The 12 month voluntary withdrawal rate, measured from formal entry into the study, was significantly higher for OM users. Pregnancy rates measured from both the beginning of training and formal entry into the study were significantly higher for OM users than for STM users. Complete analysis of the data collected during the study is currently in progress. It is anticipated that some of the causes for the differences in pregnancy rates and withdrawal rates between the two methods can be identified. (AM. J. OBSTET. GYNECOL. 134:628, 1979.)

THERE HAS BEEN a resurgence of interest in natural family planning. This may reflect increasing dissatisfaction with the adverse side effects of oral contraceptives and intrauterine contraceptive devices. "Natural" methods are devoid of the side effects associated with chemical and mechanical methods. Abstaining from genital contact during the fertile phase of the cycle is the basis of natural methods. Several methods have been used to determine the fertile and infertile phases of the menstrual cycle. These include calendar rhythm, basal body temperature, and cervical mucus observation. In the present study, the ovulation method (OM)[1–3] was compared to the symptothermal method (STM).[3–5]

The OM of natural family planning relies on observation of the cervical mucus pattern to identify the fertile phase of the menstrual cycle. Use of this method to avoid pregnancy requires abstinence during times of fertility. Sexual relations are permitted during the early preovulatory phase of the cycle up until the day on which mucus is first observed (vulvar sensation of wetness or lubrication). Abstinence begins on the first day of mucus secretion and continues until the evening of the fourth day past the "peak" or maximal mucus secretion. The "peak" mucus secretion occurs near the time of ovulation. Sexual relations are then permitted through the postovulatory phase of the cycle. Abstinence resumes at the onset of menses and continues until the period has subsided and reliable mucus observations are again possible.

The STM of natural family planning employs not only cervical mucus observation but also a calendar calculation in the preovulatory phase and the basal body temperature shift in the postovulatory phase of the menstrual cycle to determine the time of fertility. The calendar calculation (21 is subtracted from the shortest cycle length in the preceding 6 months) establishes the last day on which sexual relations are permitted during the preovulatory phase. Abstinence begins before this day if mucus is noted. Abstinence continues until the third day of the basal body temperature rise. After this day, sexual relations may be resumed until the onset of menses.

From January 1, 1976, to August 31, 1978, 1,377 volunteer couples were enrolled in the study. The data presented were obtained from 838 couples who had (1) completed training, (2) dropped out of training, (3) dropped out of the study, and/or (4) completed 12 months of participation in the study. There were 539 couples in active training as of August 31, 1978; however, data from these couples were not included in this analysis but will be included in subsequent analysis. Eligibility criteria included: a stable couple relationship for at least 3 months prior to enrollment and a female partner between 20 and 39 years of age with menstrual intervals of 24 to 36 days. In addition, a normal history and physical examination of both partners and a negative pregnancy test were required. The couples gave a statement of motivation to avoid pregnancy, agreed to participate in the study for at least 12 months, and agreed to follow rules of the method assigned to them.

After informed consent was obtained, couples were randomly assigned to one of the two methods. Both partners were instructed in the use of the method by a professional teacher. The teachers were women who had previously used the method and/or had formalized training in teaching the method. The female partner met individually with her teacher, once per menstrual cycle, to review charting observations and proper use of the method. A serum or urine radioimmunoassay of the beta subunit of human chorionic gonadotropin was performed at each visit. Following a 3 to 5 month training phase, couples were formally entered into the study only if they had demonstrated proper use of the method.

After formal entry into the study, couples who violated the study protocol (missed appointments and/or occasional failure of abstinence) were allowed to continue in the study. However, couples who flagrantly violated the protocol (many missed appointments and multiple failures of abstinence) were dropped from the study. At the monthly clinic visits, couples who indicated that they were no longer interested in avoiding pregnancy were dropped from the study. Those who became pregnant were permitted to re-enter the study after termination of the pregnancy. All pregnancies occurring prior to formal dropout were included in the pregnancy rates. Pregnancies were categorized as

either method failures or user failures. Method failures were those pregnancies judged to be due to an inherent deficiency in the method (i.e., a pregnancy occurred despite apparent proper use of the method). All other pregnancies were categorized as user failures. Six method failures and 48 user failures occurred during the formal study period. Seventy-eight pregnancies occurred during the training period. In this analysis, however, all pregnancies are grouped into a single category.

Table I summarizes some of the pertinent characteristics of randomized couples. Generally, the couples tended to be sexually active and in their late 20's, have a small family and a high educational level, and be predominantly white.

Couples dropping out during the training period tended to be younger than couples completing training and entering the study. Also, they had lived together a shorter period of time, were more active sexually, and had fewer children and a lower educational attainment than the couples who completed training. Less than half of the couples randomized completed training and entered the study.

The cumulative probabilities of termination for various causes during the first year following the beginning of training and the first year following formal entry

into the study were analyzed. These data are summarized in Tables II and III. The life-table method employed is a modification of the approach described by Potter.[6]

In the preparation of life tables, allowance was made for four types of decrement: pregnancy, voluntary withdrawal, involuntary termination, and moved away or lost to follow-up. The voluntary withdrawal group included couples who dropped out because of lack of interest or dissatisfaction with the method, desire for pregnancy, relationship ended, vaginal discharge or difficulty with mucus identification, menstrual irregularity, and/or miscellaneous other reasons. Cumulative proportions of couples terminating for these reasons during the first year following the beginning of training are shown in Table II. The involuntary withdrawal and lost to follow-up groups were combined because of the relatively small numbers involved. At the end of the first year following enrollment in training, the life-table cumulative termination rate for all causes was 75.9% for OM couples and 64.7% for STM couples.

Voluntary withdrawal accounted for the highest proportion of terminations in each method (46.1% for OM and 44.7% for STM). Pregnancy was the next highest, with 22.9% of OM (SE = 2.21) and 11.2% of STM couples (SE = 1.65) terminating for that reason. This difference in pregnancy rates is highly significant.*

Cumulative proportions of couples terminating during the first year following formal entry into the study are shown in Table III. The 12 month life-table cumulative rate for all causes was 69.7% among OM couples and 45.2% among STM couples. Voluntary withdrawals accounted for the highest proportions in each of the two groups—36.6% of OM users (SE = 3.74) and 26.2% of STM couples (SE = 3.35). The pregnancy rate was 24.8% among OM users (SE = 3.93) and 9.4% among STM users (SE = 2.33). These differences between methods in pregnancy rates and in voluntary withdrawal rates are significant; however, the number of women exposed during ordinal months 7 through 12 was less than 100.

We wish to acknowledge the professional support given this study by The Human Life and Natural Family Planning Foundation, Washington, D. C.

*The test statistic used was $z = (P_1 - P_2)/[(SE)_1^2 + (SE)_2^2]^{1/2}$ where P_1 and P_2 are cumulative pregnancy rates of the two groups and SEs are standard errors of the respective cumulative pregnancy rates.

Human chorionic gonadotropin β-subunit–like immunoreactive material in the plasma of women wearing an intrauterine progesterone contraceptive system

V. S. ORLOFF
S. YAMAMOTO
F. C. GREENWOOD
G. D. BRYANT-GREENWOOD
Honolulu, Hawaii

A systematic study of the presence of human chorionic gonadotropin β-subunit–like (hCGβ-like) material in the plasma of one woman sampled daily throughout one menstrual cycle and in nine women studied on a selected bleeding schedule has been carried out. Peaks of immunoreactive hCGβ-like activity were found in the follicular and luteal phases of these menstrual cycles which could not be explained by a cross-reaction of luteinizing hormone (LH) in the plasma. The same nine women were studied again 1 month after the insertion of the intrauterine progesterone contraceptive system (IPCS) and again 6 to 8 months later. Although the presence of hCGβ-like immunoactivity correlated with LH values in the cycles studied, there was a significant decrease in its presence 1 month after IPCS use and a highly significant decrease after 6 to 8 months of use. (AM. J. OBSTET. GYNECOL. 134:632, 1979.)

IT HAS BEEN suggested that approximately 12% to 19% of women wearing an intrauterine contraceptive device (IUD) become transiently pregnant, a prediction based on elevated human chorionic gonadotropin β-subunit–like (hCGβ-like) material in the plasma of these women.[1] The endocrine changes in women wearing the intrauterine progesterone contraceptive system (IPCS) have been studied in some detail by Bryant-Greenwood and associates.[2] It was shown that ovulation occurred in all the cycles studied despite significantly elevated levels of plasma estradiol-17β and decreased levels of prolactin and relaxin immunoactivities by the sixth to eighth month of follow-up.

The purpose of this study was to determine whether any of these same nine women were covertly or transiently "pregnant" after insertion of the IPCS, that is, whether fertilization occurred without subsequent implantation as judged by a specific radioimmunoassay for hCG when applied to these plasma samples.

Material and methods

Radioimmunoassay for hCG β-subunit. Highly purified hCG (Serono), radioimmunoassay potency 6,100 IU/mg, was used for labeling with I^{125} by the chloramine T method of Hunter and Greenwood.

The antiserum of hCG β-subunit was from rabbit No. 1 and a gift from Drs. Kosasa and Taymor.

Since it is anticipated that only low levels of hCG might be detectable in these "early pregnancy" cycles an assay was developed for maximum sensitivity. Standard hCG, 0.2 ml of solutions containing 800, 400, 200, 100, 50, 25, 12.5, 6.25, and 3.1 pg/ml in a 1:2 dilution of horse serum (Grand Island Biological Company) in 0.05M barbitone buffer, pH 8.6, was used, or plasma (0.2 ml) of eight dilutions from 1:4 to 1:512 in 1:2 horse serum in barbitone buffer was added to polystyrene incubation tubes (6 by 1 cm, Luckhams Ltd.). Antiserum to hCG β-subunit (0.05 ml of 1:7,000 dilution in barbitone buffer, pH 8.6) was added to each tube.

Table I. Interassay variability of the standard curve over a 4 month period

Amounts of hCG (Serono) (pg/ml)	*% Bound (N = 8)*
800	2.2 ± 0.66
400	2.8 ± 0.85
200	3.7 ± 0.51
100	8.8 ± 1.88
50	13.3 ± 3.02
25	18.3 ± 3.14
12.5	20.0 ± 4.36
6.25	19.0 ± 3.14
3.1	23.0 ± 4.86

Table II. Precision of the assay

Concentration range of hCG β-subunit (pg/ml of plasma)	*Estimated SD (s)*
50-100	±25.2 (16)
100-200	±25.4 (13)
200-500	±41.4 (19)
500-2,000	±111.6 (7)

Different samples of plasma were assayed at three convenient dilutions. The numbers of assays at three concentrations of plasma are given in parentheses. Values of s, an estimate of the standard deviation, are calculated in terms of picograms of hCG β-subunit per milliliter of plasma. The mean calculations of hCG β-subunit in the plasma samples obtained are grouped into the concentration ranges shown.

The tubes were mixed gently, capped, and incubated at 4° C for 72 hours prior to the addition of ^{125}I-labeled hCG (50 pg in 0.05 ml of diluent). Diluent refers to a solution of 0.5 mg/ml bovine gamma globulin, Fraction II (Nutritional Biochemical Corporation). Each tube was again gently mixed, capped, and returned to 4° C for a further 72 hours' incubation. Separation of bound and free hormone was carried out by a conventional double-antibody procedure. To each tube was added 0.05 ml normal rabbit serum, 1:20 dilution, in barbitone buffer, pH 8.6, 0.05M, and 0.1 ml sheep anti rabbit gamma globulin in barbitone buffer containing 370 mg/100 ml ethylenediamine tetraacetate (EDTA). The tubes were mixed gently, recapped, and replaced at 4° C for 24 hours. Separation was achieved by centrifugation in a refrigerated Sorvall RC-2 at 2,000 g, the supernatants were carefully decanted, and the precipitates were counted in a Packard Autogamma counter. Percentage bound was calculated (counts bound/counts bound + free) and plotted against amounts of standard or plasma used.

Precision and sensitivity of assay in routine use. Plasma levels varied over a wide range such that a single quality control sample was not appropriate for the calculation of interassay and intra-assay variation. We have used a log linear plot of amounts of hCG against

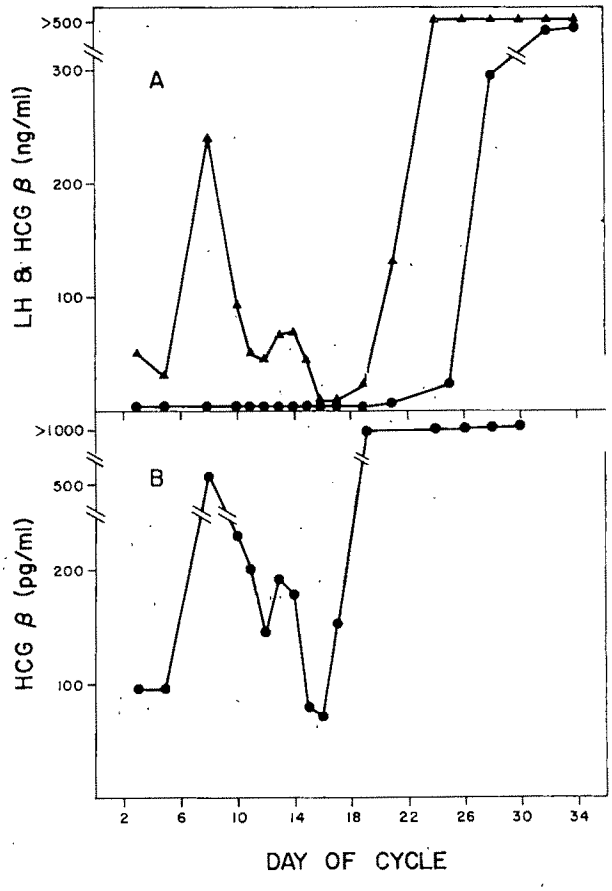

Fig. 1. Pregnancy cycle. *A:* hCG β-subunit assay data (●——●) plotted on the same scale as the LH values (▲——▲). *B:* hCG β-subunit assay data (●——●) plotted on a scale consistent with the maximal sensitivity of the assay. Note that levels after day 19 become increasingly greater than 1,000 pg/ml.

the percentage of labeled hCG bound to antibody and fitted the best straight line over the range 200 to 3.1 pg/ml hCG to give the between-assay variability of the standard curve over 4 months (Table I). In addition the precision of the assay when applied routinely to the measurements of hCG β-subunit in plasma has been calculated (Table II) as follows. Estimations were routinely carried out at six dilutions such that a minimum of three points could then be used to check parallelism between the unknown and standard. From a series of such assays at three concentrations of plasma the precision of the method in practice was calculated as shown in Table II. The quantitative sensitivity of the method was 25 pg/ml or 0.15 mIU hCG β-subunit/ml plasma as calculated from the first drop in the standard curve.

Cross-reactions. LER 907 cross reacted in the assay such that 400 pg of hCG (Serono) was equivalent to 1 μg of LER 907. These results are identical to those published by Vaitukaitis and colleagues.[3]

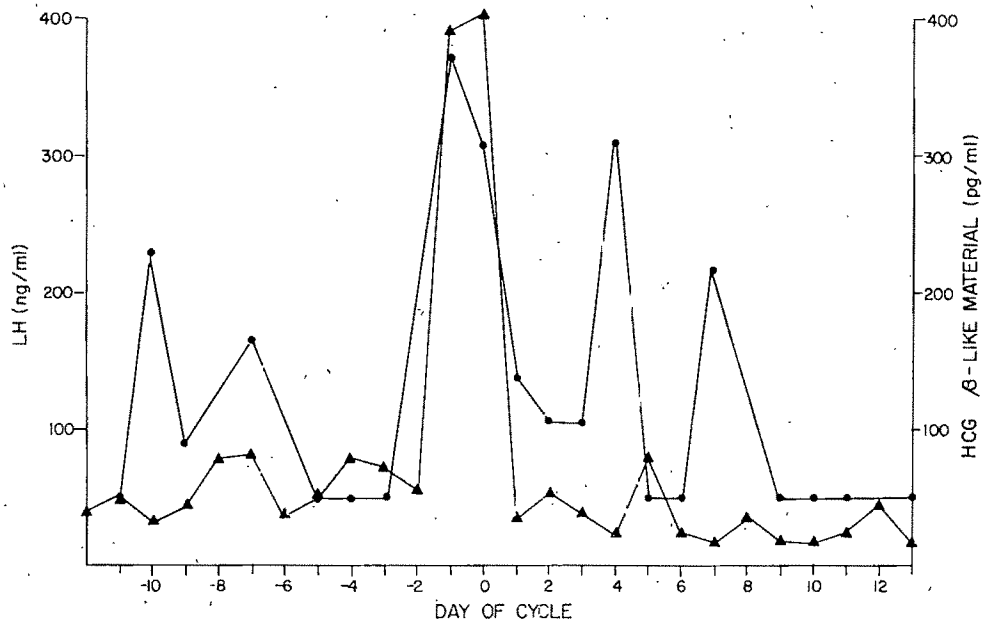

Fig. 2. LH (▲——▲) and hCGβ-like immunoactivity (●——●) in a normal woman from whom samples were taken daily for one menstrual cycle.

Radioimmunoassay for LH. Human luteinizing hormone (LH) (LER 907 for the standard and LER 960 for iodination) and antiserum No. 1 were provided by the National Pituitary Agency. The assay has been previously described by Odell and associates.[4] The sensitivity was such that 31.3 ng or 1.5 mIU LER 907/ml plasma could be differentiated from zero.

Sample collections. The samples were identical to those studied for LH, follicle-stimulating hormone (FSH), estradiol-17β, progesterone, prolactin, and relaxin immunoactivities.[2]

Nine healthy women (22 to 28 years) were selected for this study with each subject acting as her own control. None had any history of dysmenorrhea, none had received hormone therapy or oral contraceptive pills for at least 3 months prior to the study, and each had spontaneously menstruated at least once subsequent to the withdrawal of hormones. In addition blood samples from one normal healthy woman with a normal menstrual cycle were obtained daily for 36 days; these data were not included in the analysis of the control study for the women wearing the IPCS.

In the control cycles, blood samples were obtained at the start of menstruation and on days 5, 9, 11, 13, 14 to 17, 19, 21, 25, and 29 and then each day until menstruation. The IPCS was inserted between 1 and 5 days after the onset of menses. Blood samples were collected starting on the day of menstruation and on days 5, 10, 12, 14, 16, 18, 20, 22, 25, 27, and 29 and then every other day until menstruation for the first menstrual cycle (N = 9) and again at 6 to 8 months after the insertion of the IPCS (N = 8). One of the subjects left Hawaii prior to the 6 month follow-up. Blood was collected by venipuncture at 0900 hours ± 20 minutes in order to minimize any possible diurnal variation.

One subject subjectively reported a heavier than normal menstrual flow, while another subject had a milder than normal flow at the first month of the IPCS; the remaining subjects experienced no change. These two subjects reverted to their normal menstrual flow pattern by the sixth month. Seven subjects experienced intracycle spotting during the first month with the IPCS, whereas only two experienced any spotting by the sixth month.

One subject in the control cycle became overtly pregnant and was therefore a useful positive control cycle for this hCG β-subunit study.

Results

hCG β-subunit material in early pregnancy. One subject's control cycle, which was subsequently dropped from the overall study, was a pregnancy cycle. This showed an LH peak on day 8 of the cycle followed by a smaller LH peak on day 14 (Fig. 1, *A*). When the hCG β-subunit assay was plotted on the same scale as the LH values (Fig. 1, *A*) conventional results were obtained, showing a rise in hCG levels by day 28. However, when the hCG β-subunit results were plotted on a

scale consistent with the maximal sensitivity of the assay (Fig. 1, *B*) it can be seen that the hCG β-subunit assay reflects the physiologic levels of LH prior to ovulation and to day 16.

All of these plasma samples diluted out parallel to the standard as would be expected from their LH content. However, plasma samples from days 3, 5, 15, and 16 were not parallel and were toward the lower limits of sensitivity for the assay. The lack of parallelism at low levels suggests the assay is detecting material related to LH or hCG or derived therefrom. By day 17, hCG β-subunit levels were parallel to the hCG standard and thereafter rose dramatically and were greater than 1,000 pg/ml by day 19, in concert with the results of the LH assay (Fig. 1, *A*).

hCG β-subunit material in nonpregnant cycles. LH and hCGβ-like material were assayed in daily samples from a normally cycling woman (Fig. 2). It can be seen that over the midcycle LH peak the hCG β-subunit assay clearly measured LH; however, there were four peaks of immunoactivity at −10, −7, +4, and +7 days which cannot be explained simply on the basis that LH cross reacted in the hCG β-subunit radioimmunoassay (40 pg hCG ≡ 100 ng LH).

A more detailed study was therefore carried out on nine normal women from whom samples were taken on days 5, 9, 11, 13, 14 to 17, 19, 21, 25, and 29 and then each day until menstruation. The results were combined according to the day of the LH peak, thereby aligning the rest of the results. The standard error of the mean was calculated by logarithm transforms for each day of the cycle and were too small to plot (Fig. 3, *A*). Peaks of hCGβ-like material appeared again on days −10, −9, −5, −4, −3, +5, +12, and +14 which cannot be explained by cross-reactivity with endogenous LH alone. It was considered to be of interest to see whether for the entire control cycle the hCGβ-like activity would relate to LH activity; hence when the correlation coefficient for these two variables is used (r = 0.76) this is a significant correlation.

When the data for the first month after insertion of the IPCS in these women were treated in a manner identical to those of the control cycles, a very similar result was obtained (Fig. 3, *B*). However, hCGβ-like material in the follicular phase on days −10 and −6 and in the luteal phase at day +3 was again apparent but to a lesser extent. This immunoactivity throughout the cycle correlated significantly with LH values on the same samples (r = 0.92). When the 6 to 8 month samples were treated similarly and plotted, the midcycle LH peak was markedly lower than that of either the control cycles or the first month after IPCS insertion

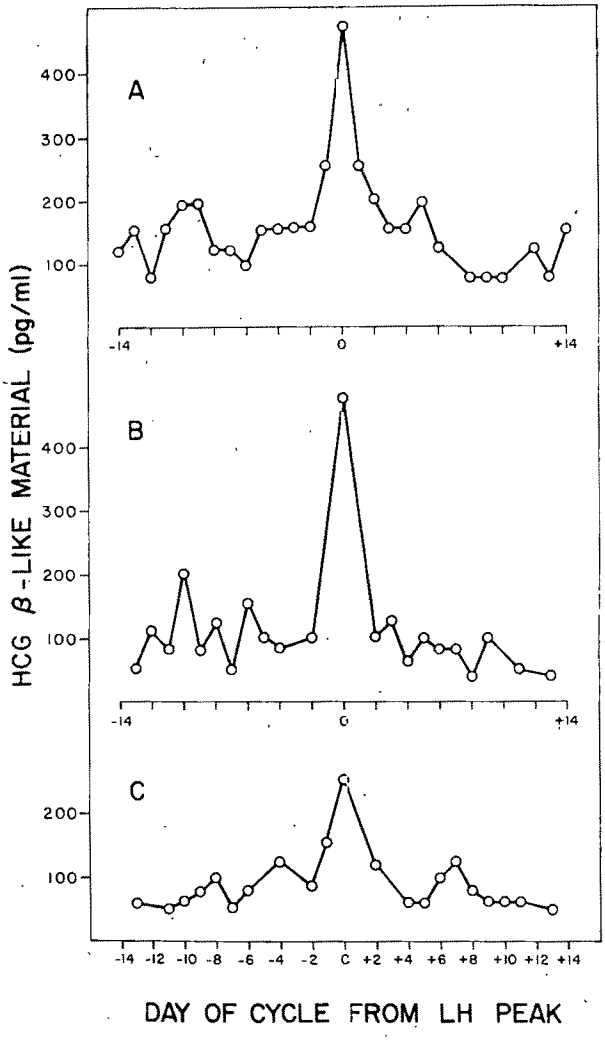

Fig. 3. hCGβ-like immunoactivity. *A:* Normal menstrual cycle (n = 9). *B:* One month after insertion of the IPCS (n = 9). *C:* six to eight months later (n = 8). Data were combined for each series according to the day of the LH peak. The standard error of the mean of logarithm transforms was calculated but was too small to be plotted.

cycles (Fig. 3, *C*).[2] Again hCGβ-like immunoactivity for the whole cycle correlated significantly with the LH levels (r = 0.62).

The overall level of hCGβ-like activity was compared in the control and first month after insertion of the IPCS cycles by Student's t test. There was significantly less hCGβ-like activity when the IUD was in use ($P < 0.01$). When the overall levels were compared between the control cycles and the 6 to 8 month follow-up there was a very highly significant reduction in hCGβ-like immunoactivity ($P < 0.001$). There was no significant decrease between the first and 6 to 8 month follow-up levels with IPCS use ($P > 0.05$).

It has been shown that in the same samples LH val-

ues did not significantly change at either 1 month or 6 to 8 months after IPCS use.[2]

Comment

This is the first systematic study of hCGβ-like immunoactivity throughout the normal menstrual cycle and on subsequent use of an IUD.

An extensive discussion on overall cycle lengths and follicular and luteal phase lengths in the cycles of the subjects studied has already been published.[2] Likewise it has already been shown that in the same samples the only significant change with use of the IPCS for 6 to 8 months that occurred was an increase in estradiol-17β levels ($P < 0.05$). No significant change in either LH or FSH levels were recorded.[2] Hence, although the hCGβ-like substance measured in this study correlated well with plasma LH values previously recorded, this correlation does not preclude an overall significant fall in hCGβ-like levels.

A similar study has been carried out using an hCG β-subunit radioimmunoassay as well as a radioreceptor assay on women wearing a copper IUD.[1] The results of this study showed 12% to 19% of IUD users with hCG in the serum during the luteal phase of the cycles. This suggests that with the copper IUD the women became covertly "pregnant" and had a fertilized ovum up to the implantation stage which was capable of secreting small amounts of hCGβ-like activity. Hence the copper probably causes interference through degeneration of the blastocyst and consequent lack of implantation.

From our study of nine women wearing the IPCS we have shown hCGβ-like immunoactivity decreased with up to 6 to 8 months of use rather than increased as was our a priori expectation. A significant fall has been recorded from the control cycles to the first month of IPCS use and an even more significant fall between the control cycles and those after 6 to 8 months of IPCS use. This suggests that the presence of intrauterine progesterone acts differently as a contraceptive agent than does copper. Indeed one study on the mechanism of action of the IPCS shows that at least part of its action is due to a direct capacitation-inhibiting effect of the uterine secretion[5]; hence fertilization would not occur and hCG β-subunit levels would not be elevated by the presence of a blastocyst. It is, however, difficult to explain why hCG β-subunit levels should actually show a decrease with IPCS use.

The immunoactive material measured here by the sensitive hCG β-subunit radioimmunoassay is of interest since we have shown its presence in normal cycles. Its presence has been reported by other workers. It has been demonstrated that such a chorionic gonadotropin, normally secreted by cytotrophoblast and syncytiotrophoblast of the placenta, can be secreted into blood by tumors developed from these cell types and by teratomas of the ovary, testis, or pineal, by hepatoblastomas, and by 6% to 13% of carcinomas of the lung, stomach, pancreas, and colon.[6-8] It has also been shown that extracts of normal human testis contained such a substance.[8] Evidence has been published for the presence of a substance in urinary extracts of normal, nonpregnant subjects of possible pituitary origin,[10] and more recently it has been shown that the liver and colon of normal subjects may elaborate a chorionic gonadotropin, akin to hCG, albeit without a carbohydrate moiety.[11] The results reported here in the blood of normal subjects are in agreement with these urine and tissue studies.

Peaks of immunoreactive hCGβ-like material have been shown to be present in both the follicular and luteal phases of the normal menstrual cycle. This cannot be explained on the basis of cross-reacting endogenous LH where cross-reactivity is calculated on the basis of purified standard LH in the hCG β-subunit radioimmunoassay. Clearly endogenous LH in plasma may not behave in the same manner since metabolic products of LH would probably also inhibit the hCG β-subunit system. Hence a spectrum of immunoreactive LH in plasma is probably measured. If this were the case one explanation of the decrease in hCGβ-like activity with IPCS use would be an altered metabolism of LH.

Irrespective of the origin of this plasma immunoactivity related to the subunit of hCG β-subunit throughout the menstrual cycle and its physiologic significance to the cycle, it may be inferred from its very ubiquity that the material gives no evidence for the presence of covert pregnancies in subjects wearing the IPCS system. Indeed the effect of the latter is to reduce the levels under the circumstances with no known physiologic sequelae.

Increased platelet aggregation and decreased high-density lipoprotein cholesterol in women on oral contraceptives

In vivo platelet function, serum total cholesterol (TC), high-density lipoprotein cholesterol (HDL), and serum triglycerides (TG) were determined in 26 women starting oral contraceptives (OCA). Studies were run prior to, and after one and two months of therapy. Platelet aggregation time decreased by 50 percent or more in eight of the 26 women from a pre-experimental mean value of 387 ± 136 seconds. TC did not vary but after the women were on medication for two months, HDL decreased from 56 ± 14.4 mg/dl to 52 ± 12.3 mg/dl ($p < 0.05$). There was a progressive increase in TG under treatment, 74 ± 23.3 mg/dl on the pre-experimental measurement to 93 ± 31.0 mg/dl after two months of therapy ($p < 0.005$). Women planning to use OCA might best be advised to have aggregation and serum lipid studies done before and early in usage. (AM. J. OBSTET. GYNECOL. 134:638, 1979.)

MANY epidemiologic studies have shown a marked relationship between use of oral contraceptives and an increased incidence of myocardial infarction, stroke, and thrombophlebitis. This was particularly marked among women who smoke. A recent report[1] suggested that a shift of cholesterol from the alpha fraction to the beta compartment might be the mechanism responsible for these conditions. Earlier workers[2] had not noted a relationship between serum cholesterol and stroke, and related phenomena. In a pilot study several years ago in this laboratory, several young women on oral contraceptives were noted to have marked platelet hyperaggregability as measured by the Filtragometer[3] technique, one shortly after initiating therapy. Since it appeared likely that platelet hyperaggregability played a major role in oral contraceptive complications, both platelet aggregation and lipids were measured in a prospective study over a period of two months in an attempt to delineate possible mechanisms.

Methods

Twenty-six women, aged 18 to 45 years, who were about to begin therapy with oral contraceptives in a large community-based obstetrics and gynecological practice, formed the cohort for the study. At the initial visit to the practice, in addition to the usual medical care, they were studied by means of the following tests.

1. Platelet aggregability as measured by the Filtragometer technique was done as follows.[3] The aggregation of platelets in flowing blood was assessed by drawing blood via an indwelling polyethylene cannula

Table I. Effect of oral contraceptives on in vivo platelet function in women

Women	*Aggregation time (sec.)*		
	Pre-experimental	*Month 1*	*Month 2*
All women on OCA (N = 26)	358.8 ± 162.9*	366.7 ± 168.4	437.6 ± 156.9
Control women not on OCA (N = 18)	267.4 ± 142.4	291.3 ± 166.9	
Women on OCA who had <50% decrease (N = 8)	386.9 ± 135.5	155.1 ± 68.9†	355.3 ± 232.8
Women who had a < 50% decrease after one month and remained on contraceptive for Month 2 (N = 5)	457.2 ± 70.9	172.4 ± 76.4†	209.8 ± 145.4
Women who had a <50% decrease and went off contraceptive on Month 2 (N = 3)	269.7 ± 145.7	126.3 ± 54.6	597.7 ± 79.5†

*Mean ± standard deviation.
†$p < 0.01$.

from an antecubital vein through a microfilter of 20 μm pore size into a motor-driven syringe, at a constant rate of 2.0 dl per minute. This filtration method is based on the use of a pore size which permits passage of red and white blood cells and platelets but is occluded by platelet aggregates. The system was maintained at 37° C. in a heating block. Heparin was infused into the system proximal to the filter at an anticoagulant concentration of 5 units per deciliter of blood. The system proximal to and including the filter was siliconized. Pressure was monitored proximal and distal to the filter, the rise in pressure difference reflecting occlusion of the filter by aggregated platelets. Macroscopic inspection and scanning electron microscopy of the filter confirmed the presence of aggregated platelets and the absence of blood clot. The procedure has been found to be reproducible. The pressure gradient across the filter was recorded for periods of up to ten minutes. The aggregation time (number of seconds taken to reach a gradient of 5 mm Hg) was noted and recorded.

2. Lipid profile to include serum cholesterol, cholesterol in the high-density lipoprotein fraction, and serum triglyceride fatty acid pattern was done.

3. Complete blood count with differential was done.

The women then were started on their assigned medication containing 1 mg norethindrone and 0.05 mg ethinyl estradiol and returned three weeks after beginning to take their medication. This was on average some three to four weeks after they were initially seen. At that time, a repeat series of studies was performed and those who developed major abnormalities of any of the parameters were advised to discontinue the medication. All subjects in the cohort were restudied a third time one month later whether they were on or off therapy to study either the cumulative effects of the contraceptives or pattern of normalization after therapy was discontinued. All subjects were advised to avoid aspirin for 10 days prior to being studied and not to smoke for at least two hours before the visit because of the confounding effects on platelet aggregation.[4, 5] They were also briefly interviewed prior to initiation of therapy by a nutritionist to obtain a brief diet history in the form of a 24 hour recall. The diet material was then tabulated and calculated for varying amounts of calories, cholesterol, saturated fat, and linoleate from the appropriate tables. The subjects were then advised to adhere to the same pattern for the ensuing two months since any radical increase in dietary linoleate might significantly alter aggregation time.[6]

Any complications were noted and all vital data was provided to the treating physicians to aid in the overall management of the subjects. Data analysis was done by the two-tailed paired Student t test.

Results

The effect of oral contraceptive agents on in vivo platelet function in the cohort studied is shown in Table I. As a group, the 26 patients showed no statistically significant change in aggregation time during the two-month period of observation. The trend was essentially the same as that noted for 18 age-matched control subjects not on oral contraceptives studied at a one-month interval. However, 8 of the 26 women on the oral contraceptive agents did show greater than a 50% drop in aggregation time during the two-month period of observation going from 387 seconds to 155 seconds at one month ($p < 0.01$) and then 355 seconds at two months largely because of the tremendous rebound toward normalcy of the three women discontinuing therapy after one month. This three-women subset changed from 270 seconds to 126 seconds at one month and then rebounded to 598 seconds ($p < 0.01$) on cessation of drug for one month. The remaining five sensitive subjects decreased from 457 seconds to 172 seconds at one month ($p < 0.01$) and stayed essentially unchanged while they were on the drug at two months.

The serum lipid changes for the entire 26 person

Table II. Effect of oral contraceptive pills on serum lipids in women

	Pre-experimental	*Month 1*	*Month 2*
Serum cholesterol (mg/dl)	170.3 ± 35.5*	160.4 ± 19.7	166.7 ± 24.1
High-density lipoprotein cholesterol (mg/dl)	56.6 ± 14.4	58.4 ± 15.5	51.8 ± 12.3†
Serum triglycerides (mg/dl)	72.9 ± 22.0	83.3 ± 29.7†	92.9 ± 31.0‡

*Mean ± standard deviation.
†$p < 0.05$.
‡$p < 0.01$.

Table III. Effect of oral contraceptives on in vivo platelet function in women

	Pre-experimental	*Month 1*	*Month 2*
Women who had a decrease in A.T. (N = 8)			
Aggregation time (sec.)	387 ± 136*	155 ± 69†	355 ± 233
	Individual values		
Women who had a decrease in A.T. and HDL (N = 2)	402	104	
Aggregation time (sec.)	460	226	
High-density lipoprotein	58	48	
Cholesterol mg/dl (N = 2)	69	45	

*Mean ± standard deviation.
†$p < 0.01$.

chohort are shown in Table II. The serum cholesterol stayed essentially unchanged mirroring the unchanged fat content of the diet consumed during the two months. However, the high-density lipoprotein cholestrol did change from 56.6 mg/dl to 51.8 mg/dl in two months and this decrease was significant ($p < 0.05$). The same was true for the serum triglycerides which increased significantly as early as one month (72.9 to 83.3 mg/dl; $p < 0.05$) and further increased to 92.9 mg/dl ($p < 0.01$) at the two-month mark.

Table III takes a closer look at the eight women who had a 50% or greater decrease in aggregation time in an attempt to delineate those who had adverse concomitant changes in aggregation and HDL cholesterol. There were two such women with observed changes altering what are considered "safe" to high-risk category levels (i.e., aggregation time <250 seconds and high-density lipoprotein cholesterol <50 mg/dl). One other subject in this group had stable but abnormally low HDL cholesterol and with her greater than 50% decrease in aggregation time she was considered to be in the high-risk category.

Comment

In late 1977 two major prospective studies on the influence of oral contraceptives on the health of users were reported.[7, 8] Both groups found an increased mortality rate from diseases of the circulatory system in oral contraceptive users, confirming the results of earlier retrospective studies. The Royal College of General Practitioners study[7] again noted the adverse effects of age and smoking but in addition noted a significant risk of cerebrovascular accident among users over nonusers. This further substantiated the reports of Horenstein[9, 10] showing a relationship of stroke and related phenomena to oral contraceptive use and raised considerable question as to the mechanisms involved in these processes.

Hennekens[11] had reported that oral contraceptive use over a 3 year period led to increased serum cholesterol and triglyceride levels and suggested that this might be the mechanism for increased risk of coronary heart disease. The report of Wallace and associates[12] substantiated these findings biochemically in ten diverse North American population groups. However, no explanation was set forth for the other complications noted such as stroke, transient ischemic attack, thrombophlebitis, or headache.

In exploring the pathogenesis of atherosclerosis, Ross and Glomset[13] cited the important role of abnormal platelet activity along with that of smooth muscle proliferation and abnormal lipid levels. A subsequent review of the entire matter[14] added the observation that abnormal serum lipids, per se, increased platelet hyperaggregability and further complicated the attempt to sort out etiologic factors. Work in this laboratory[5, 15, 16] had shown a clearcut relationship between platelet hyperaggregability, per se, and acute and chronic coronary heart disease, stroke, smoking, and stress among other factors. Interestingly, most of these factors have been found to increase risk of oral contraceptive use by the Royal College of General Practitioners study group.

The data in this study showed no significant total

serum cholesterol changes after oral contraceptives were used for two months. It did, however, show a significant drop in HDL cholesterol and rise in serum triglycerides during the interval. Since so much has been written about the importance of the serum cholesterol level over prolonged periods of time in producing atherosclerosis, some questions must be raised as to the unilateral role of this factor in producing disease in so short a time in this young cohort. More important, 8 out of the 26 (31%) subjects studied here had a 50% or greater drop in platelet aggregation time bringing them into risk factor range for vascular complications in general in the two-month period. Three of this subset also had abnormal HDL cholesterol levels providing the appropriate background for the future development of atherosclerosis. Of course, all eight were advised against use of the oral contraceptives, but should continued usage prove necessary, they serially might be monitored with the above parameters at regular intervals.

These data are still preliminary but show the value of early evaluation of platelet aggregation activity and serum lipids in those starting and continuing oral contraceptive agents. Further studies seem appropriate to confirm these findings, with a view to screening out those who can not tolerate these agents before any cardiovascular complications develop.

Human hexosaminidase isozymes

IV. Effects of oral contraceptive steroids on serum hexosaminidase activity

HAROLD M. NITOWSKY, M.D.
JOYCE DAVIS, B.A.
SACHIKO NAKAGAWA, PH.D.
DAVID FOX, B.A.
Bronx, New York

Data from a mass screening program for identification of persons who are heterozygous for Tay-Sachs disease have been analyzed for the effects of oral contraceptive steroids on the activity in serum of hexosaminidase (hex) and the various hex isozymes. Women using oral contraceptives show a significantly higher total serum hex activity, reflecting mainly an increase in the heat-stable hex isozyme (hex I), and a smaller increase in the heat-labile hex A than do women using no medications. The changes in women using oral contraceptives are qualitatively similar to those observed during pregnancy. The distribution of responses to oral contraceptives is unimodal, and some of the variations may be related to differences in amount of steroid ingested. In addition, underlying genetic variation may contribute to the observed differences in enzyme activities.
(AM. J. OBSTET. GYNECOL. 134:642, 1979.)

A DECREASE in activity of N-acetyl-β-D-hexosaminidase (hex) in serum,[1] other body fluids and secretions,[2] and tissues[3] has been utilized in the identification of the heterozygous person or carrier of the Tay-Sachs gene. In addition to problems of interpretation encountered when values for hex A activity fall in the inconclusive range between noncarriers and persons who are obligate heterozygotes, false positive results are uniformly observed with the thermal inactivation procedure for fractionation of the hex isozymes during pregnancy.[4] Similarly, tests on patients with diabetes mellitus and other disorders may give false positive results.[1]

In the original description of the carrier detection method, O'Brien and associates[1] noted that women using oral contraceptive steroids may give false positive test results. A later report by other investigators suggested no differences in hex activity between normal women and women on low-dose oral contraceptives.[5] More recently, however, an increase in activity of serum hex and β-glucuronidase was observed in women on various regimens of oral contraceptives. Moreover, there appeared to be a direct correlation between the dose of steroid ingested and the increase in hex activity.[6]

During the course of a community mass screening program for Tay-Sachs carrier detection, in which more than 8,000 persons were tested by assay of hex activity of serum samples, we had the opportunity to determine the effects of oral contraceptive steroids and other medications on activity of the enzyme. The purpose of this report is to summarize our findings and to confirm the effects of oral contraceptives in producing changes in serum hex activity that resemble qualitatively those observed during pregnancy.

Method of procedure

Subjects. The mass screening program began in 1972 and was initiated for the purpose of identifying

0002-9378/79/140642+06$00.60/0 © 1979 The C. V. Mosby Co.

Tay-Sachs heterozygous individuals among persons of childbearing age, i.e., 18 to 45, in the Jewish community residing in the New York City Metropolitan area and in several upper New York State communities. The Tay-Sachs carrier test was offered on a voluntary basis, following efforts to inform and educate the target population in accordance with procedures employed in earlier mass testing programs in other communities.[7]

At the time of the screening, persons volunteering for the test were registered and completed a questionnaire to provide identifying data, information relating to current and previous health status, use of medications according to a check list of specific types of drugs, and answers to questions bearing on knowledge or information about the screening program and attitudes relating to prevention or control of genetic disorders. At the time of registration, persons having the test were assigned one of a series of consecutive numbers, and analysis of the results and the questionnaire data were carried out by the assigned number, thereby assuring anonymity of the person tested.

For the purpose of this study, questionnaires completed during eight consecutive screenings in the community were reviewed. Noncarrier women were assigned to one of four groups, including those who were not taking any medication, women receiving medications other than oral contraceptive steroids, such as tranquilizers, antihistamines, or analgesics, women using oral contraceptive steroids only, and women using oral contraceptives in addition to other medications. The distribution of subjects in the various groups is summarized in Table I, where it can be seen that information relating to 1,129 women between the ages of 15 and 48 years was reviewed. Approximately 58% of the women were receiving no medications at the time of testing, and the remainder were on a regimen of oral contraceptives or other medications or a combination of both. Detailed analysis of the findings is restricted to two groups: (1) 652 healthy noncarrier women receiving no medications, and (2) 128 healthy noncarrier women using oral contraceptive steroids but no other medication. Women identified as carriers or who fell in the inconclusive group and were not available for additional studies to clarify their status were not included in this analysis.

The data from the questionnaire were transcribed on summary sheets that were used for key punching on IBM cards. Data storage and analysis were carried out with the aid of a Xerox Sigma 6 computer. The information utilized for this study includes age of the subject, health status, current use and type of medications employed, and results of the serum hex assay, including total activity and absolute and relative activities of the heat-labile (hex A) and the heat-stable components (hex B and I).

Fig. 1. Age distribution of women using oral contraceptive steroids and no medication.

Table I. Distribution of population sample

Group	*No. of women*	*% of sample*
No medications	652	57.8
Oral contraceptive steroids	128	11.3
Other medications	295	26.1
Oral contraceptives and other medications	54	4.8
Totals	1,129	100

Methods.

Serum hexosaminidase. For mass screening, hex A is fractionated by the thermal inactivation method.[1] Serum samples are diluted 10 times with 10 mM phosphate/6.3 mM citrate buffer (pH 4.4) and inactivated for 2 and 3 hours in a constant temperature circulating water bath at 52° C. Enzyme activities in the control and heated samples are assayed using a Technicon AutoAnalyzer II according to methods described elsewhere.[8] Activity of total hex and the heat-labile and heat-stable isozymes is expressed as nanomoles of 4-methylumbelliferone (4MU) released per 0.1 ml serum per 8 minutes. The hex components are also expressed as a proportion or percentage of total activity.

For clarification of inconclusive results or confirmation of the carrier state, alternative methods are used. These include a column chromatographic separation of the hex isozymes, using a diethylaminoethyl (DEAE) cellulose column and subsequent assay of the individual fractions using the AutoAnalyzer.[8] Alternatively, repeat blood specimens are obtained using siliconized Vacutainer tubes containing 0.2M citrate for

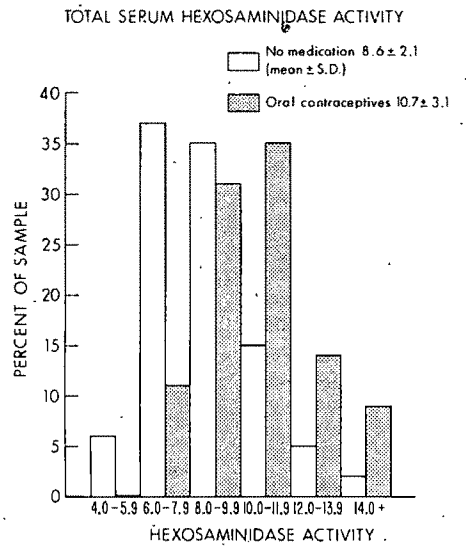

Fig. 2. Total serum hexosaminidase activity in women using oral contraceptive steroids and no medication.

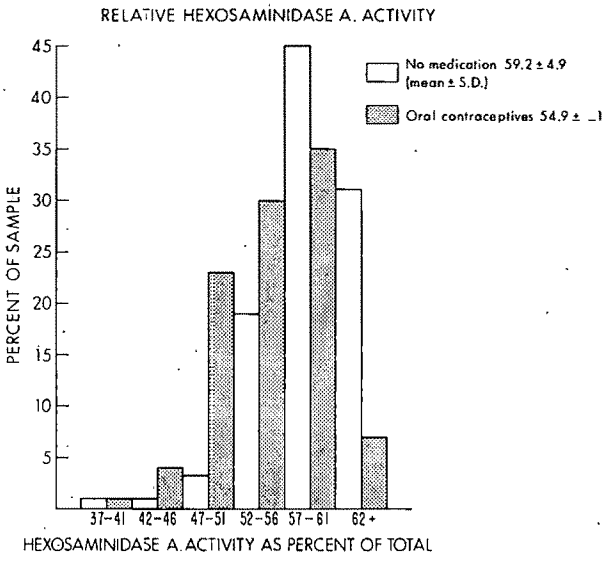

Fig. 3. Relative activity of hexosaminidase A, as a percentage of total hexosaminidase, in serum of women using oral contraceptive steroids and those receiving no medication.

separation of blood platelets. Assay of the individual hex isozymes in platelet extracts after fractionation by a DEAE-cellulose microcolumn is done with the Auto-Analyzer according to a procedure described elsewhere.[9]

Results

The age distribution of women using oral contraceptive steroids or receiving no medications is shown in Fig. 1. The distribution of ages for the oral contraceptive group is unimodal, with a mean and standard deviation of 26.4 ± 4.3 years. In contrast, there is a shift to older ages among women receiving no medication, where the mean and standard deviation are 29.2 ± 6.7 years. There is an apparent bimodality because of the grouping of women 34 years of age and older. Of the women using no medication 31% were in this age category, in contrast to only 5% of women using oral contraceptives. There is a statistically significant difference between these groups in regard to age distribution ($t = 4.548$, $p < 0.001$), which is not surprising because of recent demographic studies of patterns of oral contraceptive use.[10]

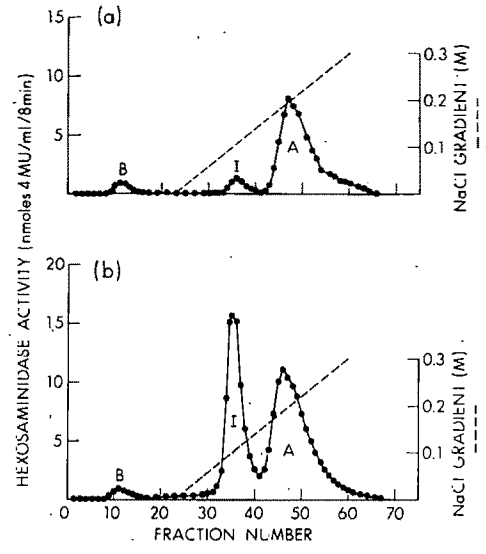

Fig. 4. Distribution of the hexosaminidase isozymes in serum from a woman receiving no medication *(a)* and from a woman using oral contraceptive steroids *(b)*. The hexosaminidase isozymes in these samples were fractionated by DEAE-cellulose chromatography as described in "Methods." Enzyme activity is expressed as nanomoles of 4MU released per milliliter of eluate per 8 minutes.

The distribution of total serum hex activity is shown in Fig. 2. There is a statistically significant difference between the mean values for women using no medication (8.6 ± 2.1, mean ± SD) and the women using oral contraceptive steroids (10.7 ± 3.1, $t = 9.367$, $p < 0.001$). The distribution of values for total serum hex of women using oral contraceptives is unimodal, with a general shift to higher activities and no indication of polymorphism in this response.

The increase in total serum hex activity of women using oral contraceptive steroids is reflected in a similar statistically significant increase in activity of both hex A and B isozymes, although the absolute magnitude of the increment is greater for hex B (Table II). As a result of the differential increase in activity of the hex isozymes, there is a significantly lower relative activity

Table II. Summary of findings in women using oral contraceptive steroids or receiving no medications

of hex A, expressed as a percentage of total activity, in women using oral contraceptives (Fig. 3).

Although the activity of serum hex has been alluded to in terms of the activities of the A and B isozymes, in fact, the thermal inactivation method for fractionation of these components in serum identifies heat-labile and heat-stable hex activity at 52° C and pH 4.4. Studies by other investigators as well as ourselves have shown that the heat-stable activity includes activity of several hex components other than the B isozyme.[8] When the hex isozymes in serum of women using oral contraceptives or receiving no medications are fractionated by chromatography on DEAE-cellulose, the differences illustrated in Fig. 4 and summarized in Table III are observed. Although there is some increase in activity of hex B in serum of women using oral contraceptives, a more important contribution to the change in activity of the heat-stable hex fraction is an increase in activity of hex I. This is a heat-stable component present in the serum of normal persons, that increases considerably in activity in patients with Tay-Sachs disease and in persons who are heterozygous for Tay-Sachs disease. A chromatographically indistinguishable component with similar thermal stability properties increases dramatically during pregnancy and has been termed hex P.[4] The terms hex P and hex I are used interchangeably since there is no method available to distinguish between these isozymes. Indeed, they may be identical in molecular structure as well as kinetic and physicochemical properties. Thus, the changes in serum hex activity of women using oral contraceptive steroids reflect mainly an increase in hex I and qualitatively resemble the alterations observed during normal pregnancy.

Comment

The results of this study confirm and extend previous reports of an effect of oral contraceptive steroids on total activity in serum of hex and the activity of the various hex isozymes.[1, 6] These changes are characterized by an increase in total serum hex activity, reflecting an increase in the heat-labile isozyme, hex A, and a more marked increment in the activity of the heat-stable form of the enzyme. In contrast to previous reports that have attributed this change to an increase in hex B, chromatographic methods for fractionation of the hex isozymes demonstrate that the change is mainly due to an increase in hex I, another heat-stable isozyme. As a result of these changes, the relative activity of hex A, expressed as a percentage of total activity, is decreased and, in some instances, may fall in the inconclusive range or suggest the carrier state for the Tay-Sachs gene.

An analysis of the basis of the variation in activity of hex and its component isozymes in serum from persons tested in the course of a mass community screening program has shown a statistically significant regression

of hex activity on age, with higher activities in older individuals.[11] Although the age distribution of women using oral contraceptive steroids showed a statistically significant trend to younger ages in comparison with women receiving no medication, the distribution of activities of hex and the heat-labile and heat-stable molecular forms of the enzyme in the group using contraceptives showed significantly higher values, contrary to the expectation from the age differences observed.

Although the data have not been presented, women receiving medications other than oral contraceptive steroids, such as tranquilizers, antihistamines, or analgesic drugs, showed no significant alterations of serum hex activity compared with the findings in women receiving no medication.

Although various types of oral contraceptives were used, information about dose or duration of use was too fragmentary to permit evaluation of a possible dose-response relation between oral contraceptive steroid intake and change in serum hex activity. However, a preliminary report indicates that the increase in activity of total serum hex as well as serum β-glucuronidase is related to total dose of estrogen and progesterone ingested.[6] This may be a major factor in the observed variation of increase in hex activity in serum of women using oral contraceptive steroids. Studies are in progress to assess this response. In addition to variations in steroid dose, it is possible that some of the differences in hex activity in response to oral contraceptives may reflect underlying genetic variation and further studies may aid in clarifying this possibility.

The changes in serum hex activity resemble qualitatively the alterations observed in women during pregnancy, when there is an increase in total serum hex, reflecting a striking increase in hex P, a heat-stable isozyme indistinguishable by currently available methods from hex I, and a less pronounced increase in hex A.[4, 8] The changes observed during pregnancy may be unique for serum, since studies of enzyme activity in peripheral blood leukocytes,[12] platelets,[9] and other tissues, including placental and fetal tissues, have not revealed similar alterations.[4, 13] Indirect evidence, related to increases of serum hex activity associated with hepatitis,[5] and observations in serum and perfused liver preparations from experimental rats with streptozotocin-induced diabetes mellitus[14] suggests that liver is a major source of various serum lysosomal hydrolases, including the hex isozymes.

Assay of serum hex activity is a convenient and practical method for Tay-Sachs carrier identification.[1] However, alterations associated with use of oral contraceptive steroids, pregnancy, or various disorders such as diabetes mellitus, may yield inconclusive or false positive results. Alternative methods may be necessary to accurately distinguish carriers from noncarriers and to confirm the carrier state ascertained by thermal inactivation of serum samples. Electrophoretic and chromatographic methods for fractionation of the hex isozymes can be employed for these purposes using serum or cell and tissue extracts. The greater complexity and longer time required for these alternative techniques may preclude their use as primary methods for carrier identification during mass screening programs. However, they may be useful and important adjuncts for more precise identification or confirmation of the Tay-Sachs carrier state, particularly during pregnancy.

We acknowledge the assistance of Dr. Robert Friis in statistical analysis of the data and express our appreciation to Irene D'Annucci for aid in preparation of the manuscript.

Hypothalamic-pituitary responses to high concentrations of gonadal steroids in a three-month-old infant with a feminizing gonadal stromal tumor

A 3-month-old female infant feminized by an ovarian stromal tumor is presented. Clinicopathologic aspects of such tumors occurring in infancy are discussed. In addition, the evaluation of hypothalamic-pituitary function preoperatively and postoperatively are presented. In the preoperative, high-steroid environment, both basal and stimulated secretion of follicle-stimulating hormone (FSH) was suppressed. Secretion of luteinizing hormone (LH) was normal. Following surgical castration, stimulated secretion of both gonadotropins clearly increased. These findings suggest an active but less sensitive negative feedback mechanism for FSH than for LH during infancy, i.e., high concentrations of gonadal steroids are necessary to maximally suppress FSH secretion while normal steroid concentrations appear to maximally suppress LH secretion. Developmental changes in hypothalamic-pituitary sensitivity to negative feedback controls are discussed in light of these findings. (AM. J. OBSTET. GYNECOL. 134:648, 1979.)

FEMINIZING OVARIAN TUMORS occur in both adults and children. Although approximately 5% of these tumors occur in children,[1] they are distinctly uncommon in infancy. Active secretion of gonadal steroids by these tumors may cause precocious sexual development. Maturational changes of the hypothalamic-pituitary-ovarian (HPO) axis, however, are absent. The increased steroid concentration in such cases presents an unusual opportunity to examine functional aspects of the HPO axis. Such investigations might be expected to add to the limited information now available on function of the HPO axis in infancy. This study of a 3-month-old infant with a feminizing ovarian tumor examines hypothalamic-pituitary function in both a high- and low-steroid environment.

Case study

The patient, a female infant, was delivered at term following an uncomplicated prenatal course. The neonatal course was normal; however, the infant was hospitalized at 3 months of age with lobar pneumonia. Bilateral breast tissue was palpable at this time and the abdomen was slightly protuberant. The pneumonia resolved with standard therapy. At 3½ months of age, bleeding through the vagina occurred. Both the breast tissue and abdominal distention were more prominent and an evaluation was initiated.

On admission the pulse was 164 beats per minute and respirations were 70 per minute. Blood pressure and temperature were normal. The weight was 7.33 kg (ninetieth percentile) and the length was 61 cm (fiftieth

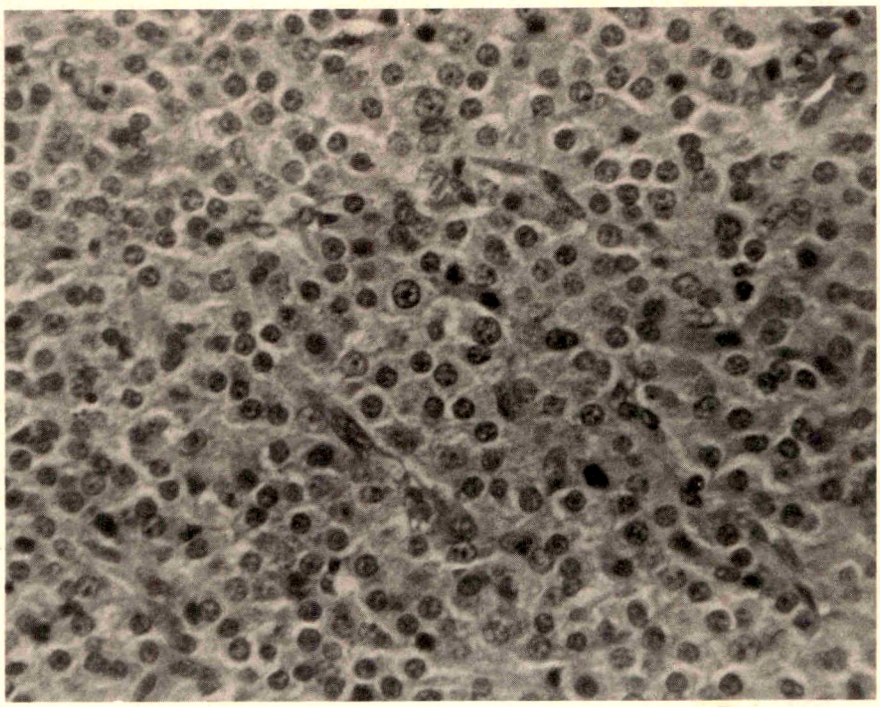

Fig. 1. Marked luteinization of the tumor is present. Call-Exner bodies are absent. (Hematoxylin and eosin. ×250.)

percentile). The abdomen was distended with a girth of 51 cm. Breast tissue was palpable, approximately 5 cm in diameter bilaterally, and the areolae were darkened. The remainder of the examination, including rectopelvic and cardiovascular parameters, was normal. Increasing respiratory distress over the next 2 days was relieved by abdominal paracentesis.

Laboratory values obtained on admission were as follows: hematocrit, 39%; white blood cell count, 19,000/mm^3; blood urea nitrogen, 30 mg/100 ml; total protein, 5.5 g/100 ml; albumin, 3.1 g/100 ml; creatinine, 0.8 mg/100 ml; total bilirubin, 0.4 mg/100 ml; lactic dehydrogenase, 190 mU/ml; and serum glutamic oxalacetic transaminase, 35 mU/ml. Urinalysis, including a pregnancy test, was normal. Ascitic fluid was yellow and clear, with a specific gravity of 1.024 and a total protein of 3.2 g/100 ml. No malignant cells were noted on cytologic examination, and bacterial cultures were negative. Both intravenous pyelography and liver-spleen scan, except for ascites, were normal.

Examination during anesthesia revealed a pelvic mass and laparotomy was undertaken. Clear ascitic fluid, 1,500 ml, was evacuated and the abdomen was inspected. An encapsulated, yellow, 5 cm, solid tumor replaced the left ovary and was removed. The remainder of the pelvis appeared normal. The right ovary was less than 1 cm in length and no irregularities were palpated. No lymph nodes were palpable and the liver and peritoneal surfaces were normal. Postoperatively the patient did well. The serum 17β-estradiol fell rapidly from a preoperative level of 4,980 to 59 pg/ml by the third postoperative day.

Two months following operation the serum 17β-estradiol concentration rose to 898 pg/ml and bleeding through the vagina again occurred. On examination the breat tissue was unchanged and the areolae were more pigmented. An enlarged cervix and uterine corpus were palpable on rectoabdominal examination. Both the height and weight were greater than the ninetieth percentile for the patient's age. Routine laboratory studies were normal and the chest x-ray film and abdominal ultrasonography were unremarkable. Intravenous pyelography indicated a mass displacing the bladder. The liver-spleen scan was normal. Examination during anesthesia revealed a 3 cm mass palpable in the area of the right adnexa. A second laparotomy revealed a 3 cm, solid, yellow tumor of the remaining right ovary. Total hysterectomy and right salpingo-oophorectomy were performed without difficulty. Thorough inspection of the abdomen and liver failed to reveal further evidence of tumor. Postoperatively the patient did well and is clinically free of recurrence at one year. The 17β-estradiol concentration has remained less than 50 pg/ml.

Material and methods

All blood samples were obtained by single venipuncture or by indwelling intravenous needle. The serum was separated and stored at −20° C until ana-

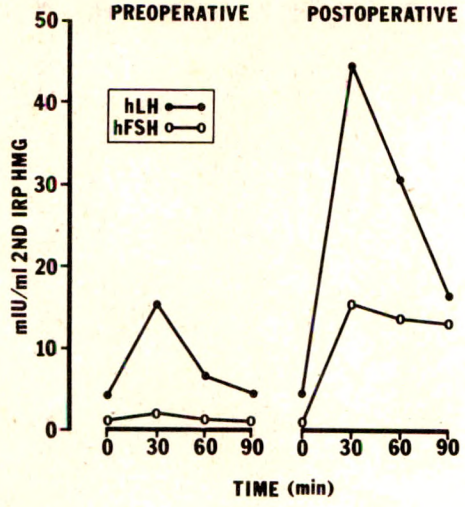

Fig. 2. LH-RH, 50 μg, was injected intravenously at time 0 on both occasions. The responses of both gonadotropins were increased postoperatively, i.e., following surgical castration ($p < 0.05$). *2nd IRP HMG* = Second International Reference Preparation of human menopausal gonadotropins.

Table I. Preoperative and postoperative concentrations of gonadal steroids

	Steroid		
Time	*Progesterone (ng/ml)*	*Estrone (pg/ml)*	*Estradiol (pg/ml)*
Preoperative:	13.1	1,328	4,979
Serum	13.1	1,328	4,979
Ascites	11.6	1,167	3,475
Postoperative:			
Day 3	0.2	47	59
Day 7	0.3	34	70

lyzed. Ascitic fluid was also frozen for subsequent analysis. The poor status of the infant prior to the original operation precluded extensive endocrine studies. However, dynamic studies of the hypothalamic-pituitary axis were performed immediately prior to the second operation and again one month postoperatively. Luteinizing hormone–releasing hormone (LH-RH), 50 μg, and thyrotropin-releasing hormone (TRH), 50 μg, were administered by intravenous bolus. Venous blood samples were obtained at 0, +30, +60, and +90 minutes.

The concentrations of estrone, 17β-estradiol, and progesterone were determined in duplicate by radioimmunoassay. Extraction of samples with ethyl acetate was followed by collection of appropriate fractions by chromatographic separation on LH-20 columns. After this separation and preparation of the internal standards for recovery counts, antisera and tritiated tracer were added. Incubation overnight at 4° C was followed by separation with dextran charcoal. The intra-assay and interassay coefficients of variation for estrone and estradiol were less than 5%. Progesterone coefficients of variation were 4.6% and 12%, respectively.

The serum gonadotropin and prolactin concentrations were determined by double-antibody radioimmunoassay. The standards and antisera were supplied by the National Institutes of Health. All samples were determined in triplicate. In these assays, 0.7 ml of phosphasaline buffer, pH 7.8, with 1% bovine serum albumin was added to 0.1 ml of sample. Antisera, 0.1 ml, was added in concentrations necessary to achieve approximately 30% binding and the samples were incubated at 4° C for 2 days. Iodination of the respective hormones with I^{125} was catalyzed with chloramine-T and the purified tracer was isolated by column chromatography. In all assays the appropriate tracer was added on the third day—0.1 ml adjusted to 5,000 counts per minute (cpm) for the gonadotropins and 10,000 cpm for prolactin (PRL). Two days later the second antiserum was added. After equilibrium was achieved the bound and free fractions were separated and counted. The respective intra-assay and interassay coefficients of variation were 3.6% and 7.5% for luteinizing hormone (LH), 9.5% and 10.7% for follicle-stimulating hormone (FSH), and 7.4% and 11% for PRL. To avoid inter-assay variation, samples from preoperative and postoperative pituitary testing were included in the same appropriate assay. Statistical comparisons were performed with the t test for comparison of paired samples.

Results

Histology. The histologic features of the ovarian tumors were the same on both specimens (Fig. 1). There were large, solid areas of cells and areas of cystic change. The predominant cell type was polygonal with scant, slightly granular, eosinophilic cytoplasm. The nuclei were large and oval and demonstrated diffuse clumping of chromatin. Mitoses were numerous. Clusters of lipid-containing cells were also present. Neither Call-Exner bodies nor crystals of Reinke were identified. The predominant ultrastructural characteristics were those common to steroid-producing cells, e.g., complex swirls of tubular smooth membranes and membrane-bound lipid in the cytoplasm.[2]

Endocrine. The steroid concentrations before and following the initial operation are shown in Table I. By the third postoperative day basal levels for estrone, 17β-estradiol, and progesterone were achieved. Two months following operation steroid concentrations increased. Progesterone increased to 4.3 ng/ml. Estrone and 17β-estradiol increased to 239 and 898 pg/ml, re-

spectively. Following the second operation steroid concentrations again fell to basal levels, and all subsequent values have been normal. The 17β-estradiol concentration has not exceeded 50 pg/ml.

Pituitary function was investigated with LH-RH on two occasions (Fig. 2). Initial testing was performed prior to the second operation when circulating concentrations of gonadal steroids were markedly elevated. LH concentrations increased from 4.3 to 15.5 mIU/ml at +30 minutes, approximately a fourfold rise. The concentration then decreased to basal levels by +90 minutes. FSH concentrations demonstrated little change, rising from 1 to 2 mIU/ml at +30 minutes and returning to basal levels at +90 minutes. LH-RH testing was again performed one month following removal of the remaining ovary, i.e., in a low-steroid environment. Although the basal concentration of LH, 4.6 mIU/ml, was similar to the preoperative basal concentration, the rise to 44.8 mIU/ml at +30 minutes was much greater than the response preoperatively. In a similar fashion, the increase of FSH from 0.8 to 15.4 mIU/ml at +30 minutes was considerably greater than encountered preoperatively. Both responses were significantly different ($p < 0.05$).

The PRL response to TRH was also determined before and after the second operation (Fig. 3). Preoperative and postoperative basal concentrations were 39 and 34 ng/ml, respectively. Although the pattern of response differed slightly, the overall responses were not significantly different ($p > 0.10$).

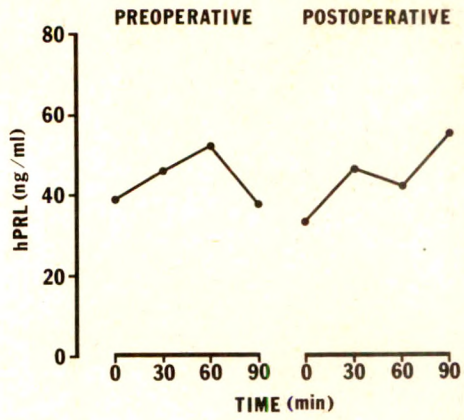

Fig. 3. TRH, 50 μg, was injected intravenously at time 0 on both occasions. The quantitative responses preoperatively and postoperatively were not significantly different although the patterns appear different.

Comment

Ovarian neoplasms in children are generally benign cystic lesions, stromal tumors, or germ cell tumors.[3–5] Approximately 20% to 30% are malignant,[5] and 10% are hormonally active.[6] In the case reported above, marked feminization occurred as a result of steroid secretion by a gonadal stromal tumor. Such tumors are distinctly uncommon in infancy.

Feminizing gonadal stromal tumors generally have been reported as granulosa-theca cell tumors in the past. Reports of these tumors in children are numerous but the number of cases is small. In a recent report from the Ovarian Tumor Registry 307 cases of granulosa-theca cell tumors were presented. Only seven were in children less than 9 years of age.[7] In a review of the literature, records of 52 children under 10 years of age with granulosa-theca cell tumors were collected.[8] Of note, 41 of these 52 children were clinically feminized. Prior to 1941, the youngest child reported with a granulosa-theca cell tumor was 4 years old. Since then several infants with feminizing granulosa-theca cell tumors have been reported.[9–14]

Clinical findings in infants with these tumors are similar to the findings in older children and adults, e.g., abdominal pain, palpable mass, ascites, and feminization. None of these findings, however, are consistently present. Feminization, although common, is not uniformly present,[8, 9] and a mass may be palpable only during anesthesia as in this case. Ascites occurs in 10% to 15% of cases over all and also occurs in children.[4, 15]

Stromal tumors may be less malignant in children, 5% versus 25%,[16] although in one report two of five children died with recurrence.[17] It is difficult in this case to differentiate recurrence from persistence. Since such tumors occur bilaterally in 5% of cases[16, 18] and because the second tumor in this patient developed so rapidly, it would seem likely that the tumor was initially present in both ovaries but not clinically detected.

The luteinization present in this tumor was extensive, resembling closely a luteoma of pregnancy. Luteinization occurs to some degree in 13% of granulosa-theca cell tumors, most commonly in tumors removed during pregnancy.[12] Luteinization, however, may be more common in tumors occuring in childhood. In four children with feminizing tumors all tumors demonstrated marked luteinization.[12] Luteinization was also noted in the tumor of a 9-month-old infant.[13] Whether luteinization is truly more common in children, especially infants, remains to be proved. Regardless, it does seem clear that the presence of luteinized cells is closely associated with steroid secretion.[2]

The abnormal steroid concentrations in this case offer a unique opportunity to examine the HPO axis of infancy. When the preoperative basal gonadotropin concentrations are compared to levels reported for normal infants,[19] LH appears unchanged while FSH is slightly suppressed. This finding suggests increasing

the steroid concentrations above normal does not proportionally increase the negative feedback on tonic LH secretion but does increase the negative feedback on tonic FSH secretion. Two possible explanations for a normal basal LH level in an abnormally high-steroid environment are: (1) LH secretion may be extremely insensitive to negative feedback regulation by gonadal steroids in infancy; (2) normal concentrations of gonadal steroids exert maximal suppression and additional steroids would have no further effect.

Pituitary stimulation with LH-RH was performed preoperatively and postoperatively in an effort to further examine the gonadotropin secretion patterns. The same pattern for stimulated secretion of the gonadotropins was found during preoperative testing, i.e., the LH response was unaffected by the abnormally high steroid concentration while FSH secretion was suppressed. The 3.5-fold rise in LH during preoperative testing with LH-RH, 50 μg, is similar to the threefold rise reported for normal female infants in response to LH-RH, 100 μg.[20] The twofold rise in FSH, however, is less than the eightfold rise reported for the same normal infants. The difference in response is not explainable by the difference in the dosage of LH-RH.[21] A study of nine normal female infants,[22] using a dose of 0.1 mg/M² LH-RH, similar to the dose in this study, confirmed a threefold rise in LH (5.5 to 15.7 mIU/ml). The rise in FSH (6.1 to 24.4 mIU/ml), although somewhat less than previously reported for normal infants, still exceeded the response in this infant preoperatively. Comparison with such published studies, therefore, suggests that high concentrations of steroids further suppress FSH secretion, both basal and stimulated, but have little effect on LH secretion.

These findings, at least in part, are consistent with present concepts of HPO axis development. As recently reviewed,[23] gonadotropin concentrations in fetal serum rise from late in the first trimester to midgestation. Serum levels of both LH (β-subunit) and FSH then decrease progressively to term. The low concentrations at term are associated with high concentrations of gonadal steroids[24] which presumably effect a negative feedback on gonadotropin secretion. Following delivery, steroid concentrations rapidly fall and gonadotropin concentrations later increase, presumably escaping from the negative feedback.[25] The escape of FSH appears to be more pronounced, with concentrations reaching adult levels on occasion. As infancy progresses the gonadotropins again decrease to low concentrations which are maintained until a prepubertal increase.[19, 26–28] These patterns can be explained in part by a gradual increase in hypothalamic-pituitary sensitivity to steroid feedback through fetal life and childhood. The high steroid concentrations in late pregnancy may be necessary to suppress gonadotropin secretion if the hypothalamic-pituitary axis is relatively insensitive at this time. During the neonatal period and infancy, low levels of steroids do not completely suppress gonadotropin secretion, but similar steroid levels become more effective in later childhood. With the onset of puberty a decrease in the sensitivity of the hypothalamic-pituitary axis to the negative feedback of steroids occurs. Gonadotropin and steroid concentrations increase and eventually a positive feedback is acquired.[29, 30]

An increased FSH : LH ratio and a greater FSH response to LH-RH appears characteristic of the infantile HPO axis. This suggests that FSH secretion is less sensitive than LH to the negative feedback of steroids. If normal steroid concentrations effect a maximum negative feedback on LH in infancy, no further decrease in LH secretion would be expected with increased steroid concentrations. Incompletely suppressed FSH secretion, however, would decrease further in response to high concentrations of steroids. This was indeed the finding in this case. The other explanations suggested above for these findings, i.e., the LH secretion is not sensitive to steroid feedback control while FSH secretion is sensitive, seem unlikely. Both LH and FSH secretion increased postoperatively (Fig. 2), providing clear evidence that LH secretion was actively suppressed preoperatively by the gonadal steroids. That steroids exert a negative feedback on both gonadotropins, in children at least, is now accepted.[21, 31]

In contrast to the gonadotropins, basal and stimulated PRL concentrations following TRH, 50 μg, were the same preoperatively and postoperatively. With the exception of the first 6 weeks of life, during which PRL concentrations are increased, the mean PRL concentration for infants is variably reported from 10 to 30 ng/ml.[32, 33] In this case, the basal PRL concentrations preoperatively and postoperatively were both elevated. A stimulatory effect of the gonadal steroids on PRL secretion might explain the preoperative but not the postoperative elevation. Since a progressive decrease in PRL occurs following delivery in both term and premature infants, it appears that infants can metabolize PRL at a rate sufficient to return PRL to normal concentrations within 4 weeks.[32] Thus, the elevated postoperative basal PRL is difficult to explain. Likewise, the similar PRL responses to TRH on both occasions are difficult to interpret. PRL responses in children to both TRH and L-dopa are quantitatively and qualitatively similar to adult responses, but PRL secretion in response to hypoglycemia does not occur in children.[32] It appears that the control of PRL secretion in children is

complex and somewhat different from that in adults, making interpretation of the PRL responses difficult.

The interpretations presented above presume a normal HPO axis acted upon by changing steroid concentrations. The age at onset of the ovarian tumor, its rapid recurrence, and the histologic character of the tumor suggest another, albeit remote, possibility. Hyperstimulation of the ovary by autonomously secreted LH might explain both the ovarian tumor formation and the findings of "normal" LH secretion in an abnormally high-steroid environment. Although there was no evidence of a pituitary tumor in this subject, a functional derangement of the hypothalamic-pituitary axis is possible. The increased LH secretion in response to LH-RH postoperatively, however, demonstrates some functional integrity of the LH control mechanisms. It seems more likely that the abnormalities described simply represent the difference in feedback mechanisms of gonadal steroids on the two gonadotropins, LH and FSH. The differences in control of these two gonadotropins are increasingly apparent and appear to be related to a number of factors, e.g., stage of development, age, sex, and status of gonadal function. This study is an attempt to further define these differences in a unique situation—a feminized infant.

We wish to thank Drs. Jean Rivier and R. Guillemin for supplying the LH-RH and TRH used during this investigation.

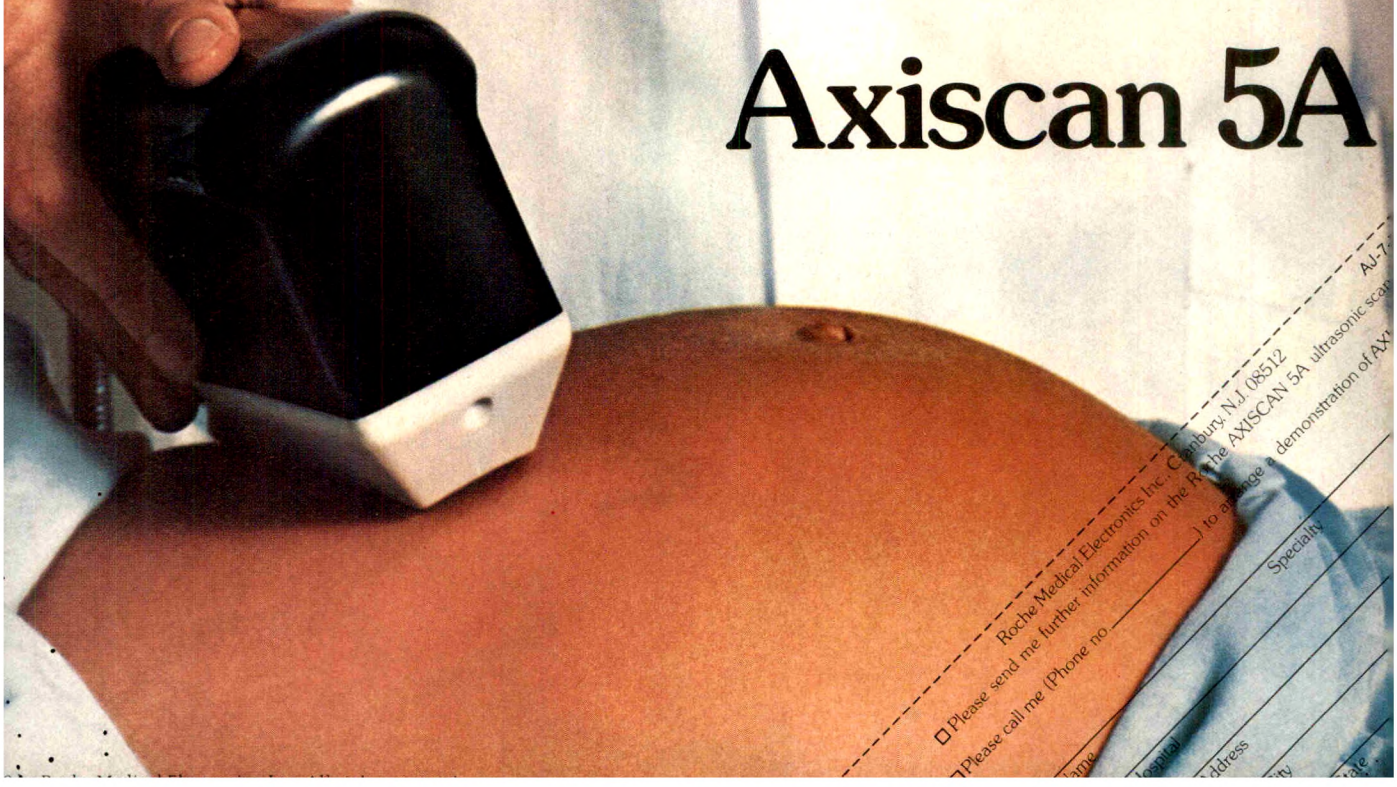
Tune into tomorrow

with Axiscan 5A portable ultrasound scanner from Roche Medical Electronics

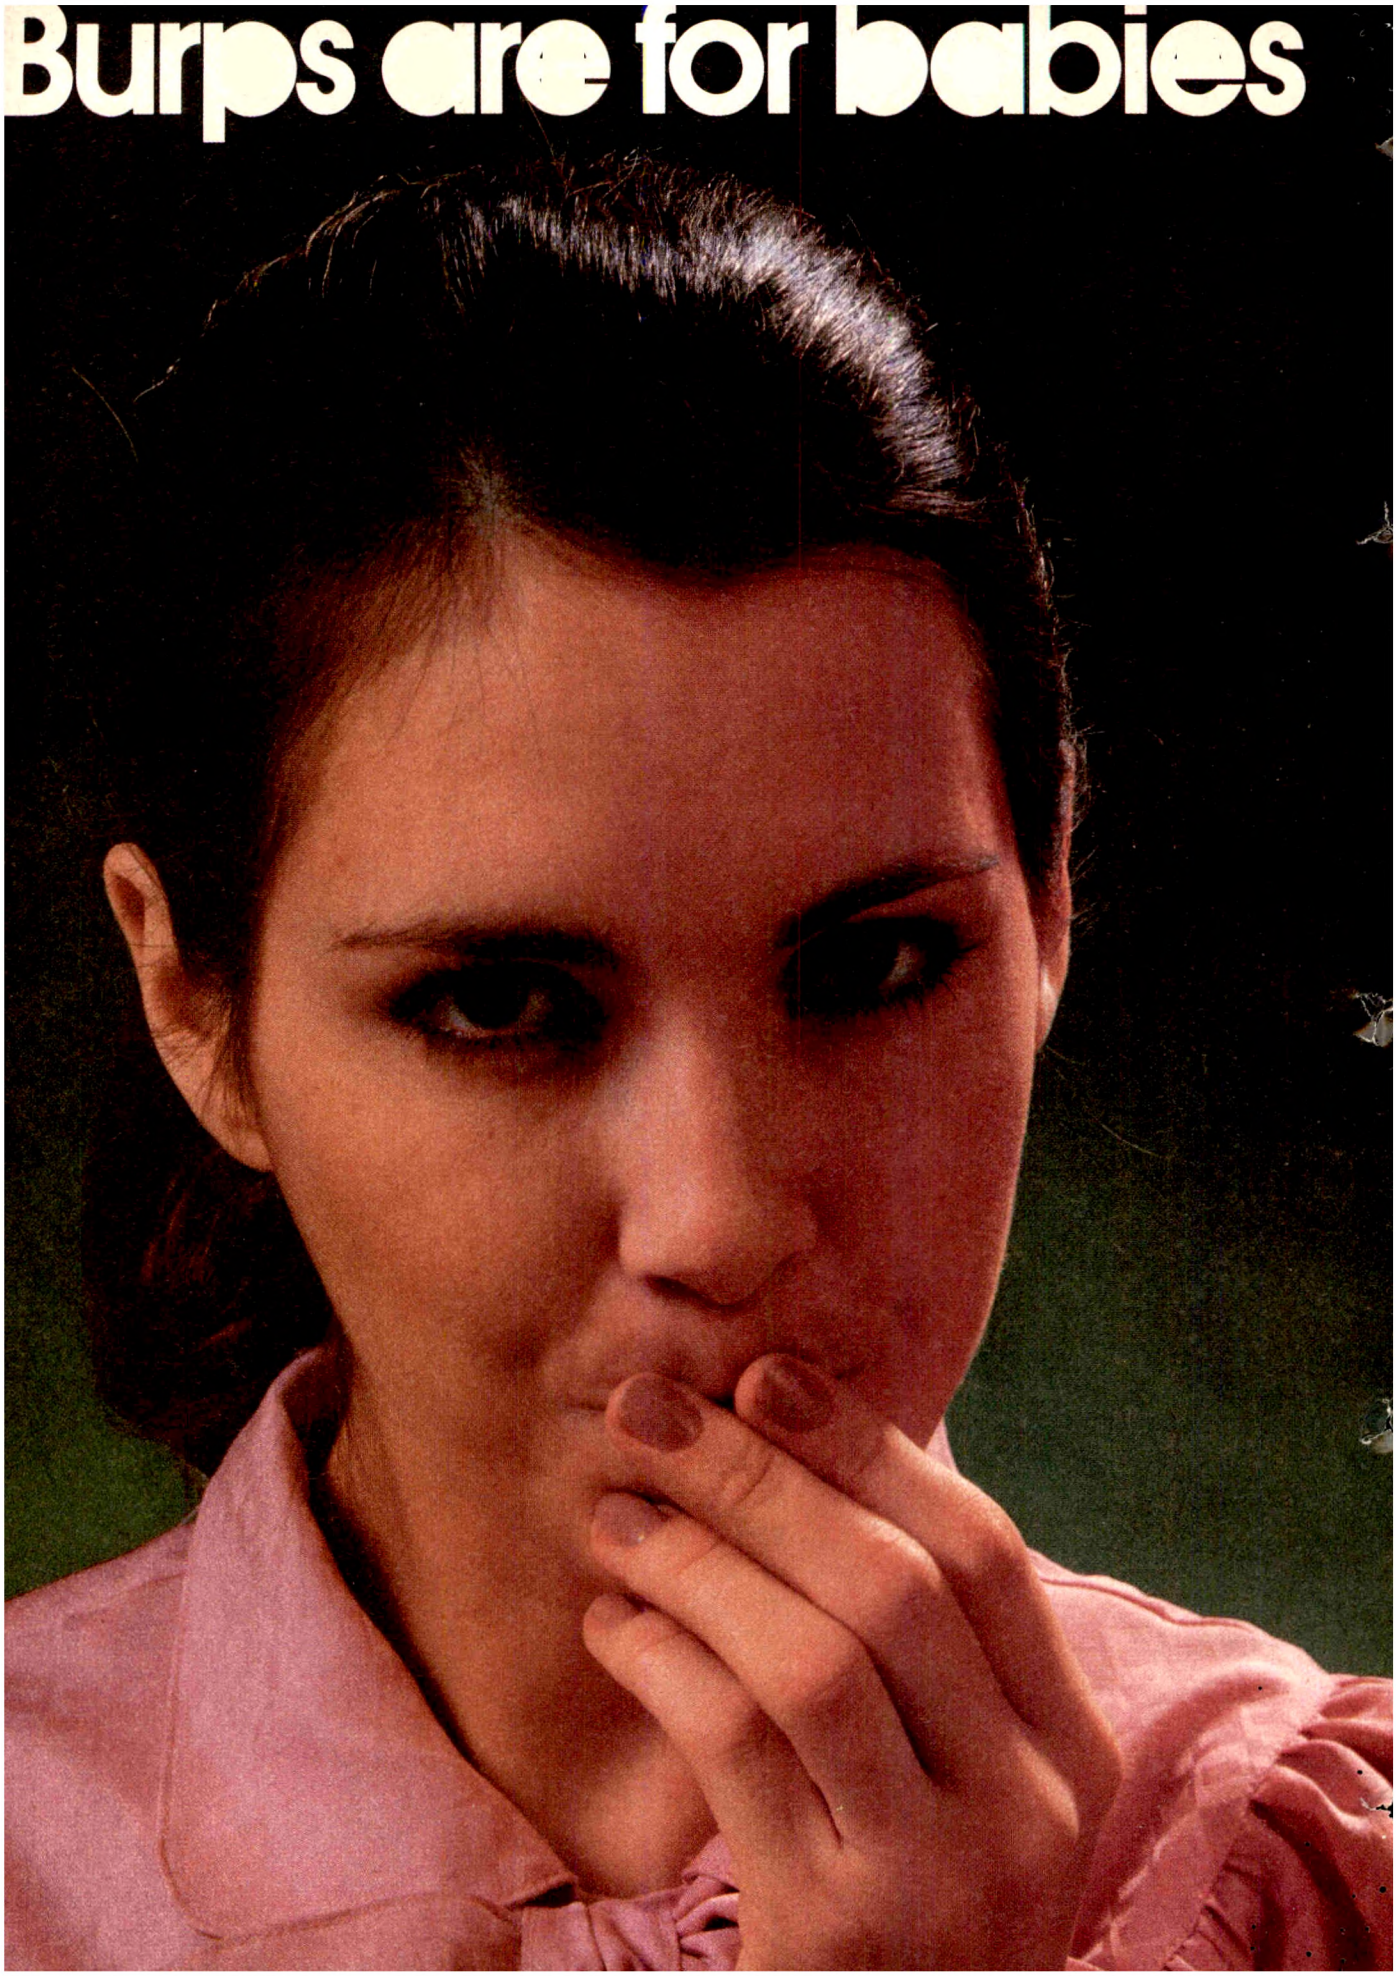
essment of the fetus *in utero*, ulation of gestational age delivery date, and detection ıture complications such as enta previa, cephalo-pelvic roportion and others, are ng the advantages of visual enatal surveillance with SCAN 5A. This portable rument, with its dramatic e" picture, makes routine alization of the fetus possible out the cost, inconvenience possible radiation risks of ntgenology.

Axiscan 5A
The portable ultrasonic scanner that has it all



All the qualities you expect
Real-time electronic scanning.
Flickerless images.
Well-defined grey scale.

All the extra features you want
Full-screen utilization ▫ Freeze-frame capability ▫ Electronic calipers ▫ Digital, on-screen presentation of measurements ▫ Automatic contrast/intensity compensation for photography ▫ A single transducer optimized for two ranges ▫ 180-degree image reversing switch.



he Roche AXISCAN 5A ovides a safe, noninvasive method for:
enta localization ▫ detecting fetal anomalies easuring fetal biparietal diameter, with built-in tronic calipers ▫ facilitating amniocentesis ▫ luating pelvic masses.

You get it all with Axiscan 5A
These aren't "options" or "add-ons," but built-in features of the finest portable real-time ultrasonic scanner available — an instrument that combines the achievements of modern technology with the requirements of clinical practice.

Axiscan 5A

Burps are for babies

Only Abbott hematinics offer the Gradumet®... and minimal gastric upset

NO IRON-TASTING "BURPS" because the controlled-release Gradumet deposits most of the iron beyond the stomach... in the small intestine. BETTER ABSORPTION because the small intestine is the site of *best* absorption. With just one tablet daily, patients receive iron therapeutically equivalent to ordinary $FeSO_4$ tablets 300 mg t.i.d. SUPERIOR COMPLIANCE because without apprehension about "burps"... without the confusion of a multi-dose regimen... you can count on your patient *getting* the iron you prescribe.

This isn't a moonscape. It's the Gradumet, our inert, porous plastic matrix, magnified 120 times. There are thousands of these minute channels in the Gradumet... the ferrous sulfate is stored here. Most of the iron is not diffused or dissolved until the Gradumet has passed through the stomach and entered the small intestine.

Both of these Abbott hematinics feature the Gradumet®

Fero-Folic-500® ℞

525 mg of Ferrous Sulfate
(equivalent to 105 mg of elemental iron)
Vitamin C
Folic Acid

Iberet-Folic-500® ℞

525 mg of Ferrous Sulfate
(equivalent to 105 mg of elemental iron)
Vitamin C
Folic Acid
B-Complex Vitamins

ABBOTT

Fero-Folic-500 ℞

Controlled-Release Iron
525 mg. of Ferrous Sulfate
(equivalent to 105 mg. elemental iron)

Plus Enhanced Iron Absorption
500 mg. Ascorbic Acid (as sodium ascorbate)

Plus 800 mcg. of Folic Acid

Indications: For the treatment of iron deficiency and prevention of concomitant folic acid deficiency in non-pregnant adults. Also indicated in pregnancy for the prevention and treatment of iron deficiency and to supply a maintenance dosage of folic acid. **Contraindication:** Pernicious anemia. **Warning:** Folic acid alone is improper therapy in the treatment of pernicious anemia and other megaloblastic anemias where vitamin B_{12} is deficient. **Precautions:** Where anemia exists, its nature should be established and underlying causes determined. Fero-Folic-500 contains 800 mcg. of folic acid per tablet. Folic acid especially in doses above 1.0 mg. daily may obscure pernicious anemia, in that hematologic remission may occur while neurological manifestations remain progressive. **Adverse Reactions:** The likelihood of gastric intolerance is remote. If such should occur the tablet may be taken after a meal. Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

Iberet-Folic-500 ℞

Controlled-Release Iron
525 mg. of Ferrous Sulfate
(equivalent to 105 mg. elemental iron)

Plus Enhanced Iron Absorption
500 mg. Ascorbic Acid
(as sodium ascorbate)

Plus the B-Complex
Niacinamide, 30 mg.; Calcium Pantothenate, 10 mg.; Vitamin B_1 (Thiamine Mononitrate), 6 mg.; Vitamin B_2 (Riboflavin), 6 mg.; Vitamin B_6 (Pyridoxine Hydrochloride), 5 mg.; Vitamin B_{12} (Cyanocobalamin), 25 mcg.

Plus 800 mcg. of Folic Acid

Indications: In non-pregnant adults, for the treatment of iron deficiency and prevention of concomitant folic acid deficiency where there is an associated deficient intake or increased need for the B-complex vitamins. Also indicated in pregnancy for the prevention and treatment of iron deficiency where there is a concomitant deficient intake or increased need for B-complex vitamins (including folic acid). **Contraindication:** Pernicious anemia. **Warning:** Folic acid alone is improper therapy in the treatment of pernicious anemia and other megaloblastic anemias where vitamin B_{12} is deficient. **Precautions:** Where anemia exists, its nature should be established and underlying causes determined. Iberet-Folic-500 contains 800 mcg. of folic acid per tablet. Folic acid especially in doses above 1.0 mg. daily may obscure pernicious anemia, in that hematologic remission may occur while neurological manifestations remain progressive. **Adverse Reactions:** The likelihood of gastric intolerance is remote. If such should occur, the tablet may be taken after a meal. Allergic sensitization has been reported following both oral and parenteral administration of folic acid. 9023303R

EDITORS! REVIEWERS! AUTHORS!

For you . . . a new book that contains virtually everything you want to know about

THE SCIENTIFIC JOURNAL: EDITORIAL POLICIES AND PRACTICES

Guidelines for Editors, Reviewers, and Authors

In 1665 the first scholarly journal was published in France. Since that time, there has been no one source of editorial guidelines for journal editors. This new book now provides you with such a source.

YOU DECIDE YOUR OWN APPROACH!

Presenting the advantages and disadvantages of each specific decision, eminent editors offer you various recommendations, discussions, and opinions concerning the problems you may encounter:

"Because we are aware that there is no 'right' policy on most editorial matters, we have tried not to prescribe rules, but have, instead, explored various facets of the problems that confront the editor in his daily work."

The book is divided into two general sections: editorial policies, which usually require major decisions; and editorial practices, which involve minor decisions, often about format or mechanical style. You'll find essays exploring: the manuscript reviewing system; special types of manuscripts (abstracts, transactions, solicited manuscripts, book reviews). You'll value chapters which cover: information for authors; copyright; errata; references cited; copy-editing; journal cover; etc.

From "the purpose of scientific journals" to "binding practices," this new book contains virtually everything you want to know as editor, reviewer, or author. See for yourself!

By Lois DeBakey, Ph.D. In collaboration with: Paul F. Cranefield, M.D., Ph.D.; Ayodhya P. Gupta, M.D.; Franz J. Ingelfinger, M.D.; Robert J. Levine, M.D.; Robert H. Moser, M.D.; J. Roger Porter, Ph.D.; and F. Peter Woodford, Ph.D. August, 1976. 128 pages, 6″ × 9″. Price, $12.50.

Tablets
PERCODAN®
oxycodone with APC C II

Tablets
PERCODAN®-Demi
oxycodone with APC C II

Brief Summary of Prescribing Information

INDICATIONS For the relief of moderate to moderately severe pain.

CONTRAINDICATIONS Hypersensitivity to oxycodone, aspirin, phenacetin or caffeine.

WARNINGS Drug Dependence Oxycodone can produce drug dependence of the morphine type and, therefore, has the potential for being abused. Psychic dependence, physical dependence and tolerance may develop upon repeated administration of PERCODAN® and PERCODAN®-Demi, and it should be prescribed and administered with the same degree of caution appropriate to the use of other oral narcotic-containing medications. Like other narcotic-containing medications, PERCODAN® and PERCODAN® Demi are subject to the Federal Controlled Substances Act.

Usage in ambulatory patients Oxycodone may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery. The patient using PERCODAN® and PERCODAN®-Demi should be cautioned accordingly.

Interaction with other central nervous system depressants Patients receiving other narcotic analgesics, general anesthetics, phenothiazines, other tranquilizers, sedative-hypnotics or other CNS depressants (including alcohol) concomitantly with PERCODAN® and PERCODAN®-Demi may exhibit an additive CNS depression. When such combined therapy is contemplated, the dose of one or both agents should be reduced.

Usage in pregnancy Safe use in pregnancy has not been established relative to possible adverse effects on fetal development. Therefore, PERCODAN® and PERCODAN®-Demi should not be used in pregnant women unless, in the judgment of the physician, the potential benefits outweigh the possible hazards.

Usage in children PERCODAN® should not be administered to children. PERCODAN®-Demi, containing half the amount of oxycodone, can be considered.

Salicylates should be used with caution in the presence of peptic ulcer or coagulation abnormalities.

PRECAUTIONS Head injury and increased intracranial pressure The respiratory depressant effects of narcotics and their capacity to elevate cerebrospinal fluid pressure may be markedly exaggerated in the presence of head injury, other intracranial lesions or a pre-existing increase in intracranial pressure. Furthermore, narcotics produce adverse reactions which may obscure the clinical course of patients with head injuries.

Acute abdominal conditions The administration of PERCODAN® and PERCODAN®-Demi or other narcotics may obscure the diagnosis or clinical course in patients with acute abdominal conditions.

Special risk patients PERCODAN® and PERCODAN®-Demi should be given with caution to certain patients such as the elderly or debilitated, and those with severe impairment of hepatic or renal function, hypothyroidism, Addison's disease, and prostatic hypertrophy or urethral stricture.

Phenacetin has been reported to damage the kidneys when taken in excessive amounts for a long time.

ADVERSE REACTIONS The most frequently observed adverse reactions include light-headedness, dizziness, sedation, nausea and vomiting. These effects seem to be more prominent in ambulatory than in nonambulatory patients, and some of these adverse reactions may be alleviated if the patient lies down.

Other adverse reactions include euphoria, dysphoria, constipation and pruritus.

DOSAGE AND ADMINISTRATION Dosage should be adjusted according to the severity of the pain and the response of the patient. It may occasionally be necessary to exceed the usual dosage recommended below in cases of more severe pain or in those patients who have become tolerant to the analgesic effect of narcotics. PERCODAN® and PERCODAN®-Demi are given orally.

PERCODAN® The usual adult dose is one tablet every 6 hours as needed for pain.

PERCODAN®-Demi Adults—One or two tablets every six hours. Children 12 years and older—One-half tablet every six hours. Children 6 to 12 years—One-quarter tablet every six hours. PERCODAN®-Demi is not indicated for children under 6 years of age.

DRUG INTERACTIONS The CNS depressant effects of PERCODAN® and PERCODAN®-Demi may be additive with that of other CNS depressants. See WARNINGS.

Aspirin may enhance the effect of anticoagulants and inhibit the uricosuric effect of uricosuric agents.

Between an episiotomy and a hysterectomy, there's a lot of room for pain...

that's where

PERCODAN® TABLETS C II

Each tablet contains 4.50 mg oxycodone HCl (WARNING: May be habit forming), 0.38 mg oxycodone terephthalate (WARNING: May be habit forming), 224 mg aspirin, 160 mg phenacetin and 32 mg caffeine.

comes in

When the pain following an obstetrical procedure ranges from moderate to moderately severe, it's no time for inadequate analgesia. Consider PERCODAN.

Reliable—provides effective relief of moderate to moderately severe pain.

Acts rapidly—starts relieving pain usually within 15 to 30 minutes after administration.

Long-lasting—convenient q6h dosage provides up to 6 hours of comforting pain relief.

Economical—average day's dosage can cost less than most other leading oral narcotic analgesics.

and when less narcotic is needed PERCODAN®-Demi Tablets C II

Each tablet contains 2.25 mg oxycodone HCl (WARNING: May be habit forming), 0.19 mg oxycodone terephthalate (WARNING: May be habit forming), 224 mg aspirin, 160 mg phenacetin and 32 mg caffeine.

Please see opposite page for brief summary of prescribing information.

ODAY'S PREGNANT WOMAN

SHE'S GOT A LOT OF LIVING TO DO

MATERNA™ 1•60

Prenatal Tablets

WE EVEN NAMED IT AFTER HER

Each tablet contains:	MATERNA™ 1•60 Prenatal Tablets (Film Coated)	For Pregnant or Lactating Women—% of U.S. RDA
Vitamin A Acetate	8,000 I.U.	(100%)
Vitamin D	400 I.U.	(100%)
Vitamin E (as dl-Alpha Tocopheryl Acetate)	30 I.U.	(100%)
Vitamin C (Ascorbic Acid)	120 mg.	(200%)
Folic Acid (Folacin)	1mg.	(125%)
Thiamine (as Thiamine Mononitrate Vitamin B_1)	3 mg.	(176%)
Riboflavin (Vitamin B_2)	3.4 mg.	(170%)
Vitamin B_6 (as Pyridoxine Hydrochloride)	4 mg.	(160%)
Niacinamide	20 mg.	(100%)
Vitamin B_{12} (Cyanocobalamin)	12 mcgm.	(150%)
Calcium (as Calcium Carbonate)	350 mg.	(26%)
Iodine (as Potassium Iodide)	0.3 mg.	(200%)
Elemental Iron (as Ferrous Fumarate)	60 mg.	(333%)
Magnesium (as Magnesium Oxide)	100 mg.	(22%)
Copper (as Cupric Oxide)	2 mg.	(100%)
Zinc (as Zinc Oxide)	15 mg.	(100%)
Dioctyl Sodium Sulfosuccinate USP	50 mg.	

A phosphorus-free vitamin and mineral dietary supplement with surfactant, for use during pregnancy and lactation. Recommended intake: 1 daily or as prescribed by physician.

PRECAUTION: Folic acid may obscure pernicious anemia in that the peripheral blood picture may revert to normal while neurological manifestations remain progressive. Allergic sensitization has been reported following both oral and parenteral administration of Folic Acid. Supplied: Bottles of 100.

Saf-T-Coil®— in use for over 10 years

Saf-T-Coil is an IUD found comparable to the "pill" in use effectiveness.[1-2]

Five-year study[2]—27,712 insertions—541,248 women/months of use:

- a low 0.8% *in situ* pregnancy rate
- high 80% continuation rate
- 11.9% expulsion rate
- 8.0% removal rate

Subsequently, the investigators made Saf-T-Coil their "device of first choice."

1. Caraway, A.F.: Florida's Experience with an Intrauterine Device for the Nulliparous Patient. Presented at the International Family Planning Research Association Meeting, Palm Springs, California, October 21, 1974.
2. Caraway, A.F. and Vaughn, B.J.: J. Reprod. Med. *10*:170, April 1973.

Life table data—46,721 women/months

Clinical trials were conducted with Saf-T-Coil in which use effectiveness was determined as follows for parous women, as tabulated by the life table method.[3-7] This experience is based on 46,721 women/months of use including 4,231 women who completed 12 months of use and 1,842 women who completed 24 months of use. Rates are expressed as events per 100 women through 12 and 24 months of use.

	12 Months	24 Months
Pregnancy	2.4 (0.42-2.8)	3.1 (0.42-3.8)
Expulsion	18.3 (7.8-29.0)	18.8 (9.0-21.5)
Medical Removal	15.6 (4.8-18.7)	23.2 (9.0-27.0)
Continuation Rate	70.4 (55.2-88.0)	59.8 (57.0-81.5)

7. Tietze, C.: Report of a New IUD: The Double Coil. Advances in Planned Parenthood, III:85, 1967.

Three Saf-T-Coil sizes ensure contraceptive effectiveness throughout her reproductive years: Saf-T-Coil Nullip 25-S for the nulliparous and young woman, Saf-T-Coil 32-S for the primiparous woman and Saf-T-Coil 33-S for the multiparous woman.

Every Saf-T-Coil is made of inert plastic with no copper additives. And with every Saf-T-Coil—Saf-T-Sound®—the sterile, disposable intrauterine probe that helps make fitting easier and more accurate.

Caution: Federal law restricts this product to sale by or on the order of a physician.
Contraindications: Should not be used in: pregnancy or suspicion of pregnancy; abnormalities of the uterus resulting in distortion of the uterine cavity; acute pelvic inflammatory disease or a history of repeated pelvic inflammatory disease; postpartum endometritis or infected abortion in the past three months; known or suspected uterine or cervical malignancy including unresolved, abnormal "Pap" smear; genital bleeding of unknown etiology; untreated acute cervicitis until infection is controlled.

Premature rupture of the membranes: A conservative approach

KENNETH A. KAPPY, M.D.

CHARLES J. INGARDIA, M.D.
ANTHONY J. SBARRA, PH.D
JOSE C. SCERBO, M.D.
GEORGE W. MITCHELL, M.D.
Boston, Massachusetts

A conservative approach was followed in 188 patients with premature rupture of the membranes (PROM) over a 2 year period. There were no neonatal deaths from sepsis, and only one infant showed a positive central bacteriologic culture. Fifty-seven percent of all patients less than 37 weeks' gestation had a latent period of 24 hours and 19% went beyond 7 days before labor began. Patients less than 34 weeks' gestation who received antepartum steroids for lung maturation showed no increased infectious morbidity or mortality. A conservative approach to patients with PROM seems reasonable when either prematurity and/or a cervix unfavorable for induction further complicates the pregnancy. (AM. J. OBSTET. GYNECOL. 134:655, 1979.)

PREMATURE rupture of the membranes (PROM) is a major obstetric complication. It is associated with a high perinatal mortality rate, which is attributed primarily to delivery of premature, low-birth weight infants.[1-6]

The clinical management of patients with PROM is controversial. Infection and prematurity are two major complications. Two main management approaches are being used: (1) aggressive and (2) expectant or conservative.

The aggressive approach consists of delivery within 24 to 48 hours of ruptured membranes.[2, 7-9]

The expectant or conservative approach consists of a "watchful waiting" period with close attention to either spontaneous labor or signs of infection.[4, 6, 10, 11]

Gunn and associates[2] demonstrated an increased perinatal mortality rate after 48 hours of PROM and advocated early delivery. Because of maternal deaths from infection occurring after PROM, Russell and Anderson[12] advocated an aggressive approach.

Recently, Meade and Clapp[8] administered steroids to mothers with PROM in an attempt to accelerate fetal lung maturation[13] in preterm pregnancies. In this study, 27 patients received antepartum steroids and

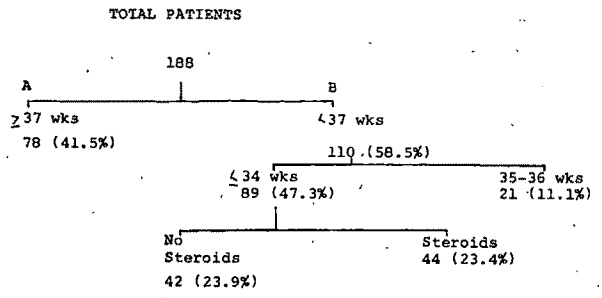

Fig. 1. Distribution of patients with PROM by weeks of gestation at delivery.

were delivered in 24 to 28 hours with a lower rate of respiratory distress syndrome (RDS) and a decreased neonatal mortality rate. They also showed that a conservative approach was not significantly beneficial in prolonging intrauterine development.

On the other hand, Taylor and associates[4] contended that the perinatal mortality rate from PROM is mainly due to prematurity and rarely to infection. He showed a corrected perinatal mortality rate of only 3.5% due to infection in PROM patients. From this he advocated a conservative approach.

In this study we report our results over a two-year period using a conservative approach.

Materials and methods

All patients admitted to St. Margaret's Hospital for Women between July, 1975, and June, 1977, with a diagnosis of PROM and an intrauterine pregnancy greater than 24 weeks were included. St. Margaret's Hospital for Women is a regional perinatal care center in the Greater Boston area receiving high-risk transfers from outlying hospitals. The participants in this study consisted of high-risk referral, clinic, and private patients. Upon arrival at the hospital, a thorough history was taken. Leakage of fluid was documented by a sterile speculum examination. No attempt was made to do a digital examination of the cervix except in cases where patients were thought to be in labor. If no fluid was seen on the speculum examination, fundal pressure was exerted and the patient was asked to perform a Valsalva maneuver to demonstrate any leakage of fluid. Vaginal fluid was tested with Nitrazine paper for pH and swabbed on a slide for ferning or aborization. Vaginal pooling confirmed ruptured membranes, but both a positive Nitrazine test and positive ferning were needed to confirm rupture of the membranes in the absence of pooling. In cases where the history was suggestive of PROM but no confirmation was possible by speculum examination, amniocentesis with instillation of indigo carmine into the amniotic sac was considered. Leakage of the dye into the vagina indicated a slow or minimal leak.

Patients with documentation of PROM were admitted to the hospital and a general physical examination was done. Appropriate laboratory studies were carried out. All patients had fetal heart rate monitoring to observe for signs of occult cord prolapse (variable decelerations) and/or signs of infection (fetal tachycardia).

An ultrasound examination was done on most patients for gestational age and placental localization. In those patients where a clear window of amniotic fluid was found by ultrasound, an amniocentesis was attempted. However, if large amounts of amniotic fluid were lost or if no appropriate window was found, amniocentesis was not carried out. All fluids obtained at amniocentesis were cultured. Lecithin/sphingomyelin (L/S) ratios and optical density 650 measurements[14] were also done. No tocolytic agents or prophylactic antibiotics were used.

If any signs of infection existed, an aggressive approach was instituted, by means of high doses of antibiotics and labor augmentation or induction with intravenous oxytocin. With uninfected patients a conservative approach was begun.

The conservative management consisted of daily complete blood counts, vital signs with temperature every four hours while the patient was awake, daily evaluation of uterine tenderness, and weekly antepartum fetal heart rate evaluations. If signs of infection were not noted, the patients were allowed to go into spontaneous labor. If infection developed, the conservative approach was abandoned, antibiotics were given, and the patients were induced.

All patients less than 37 weeks were managed in the manner described above. However, patients who were 28 to 34 weeks at the time of PROM were also offered antepartum steroids. Betamethasone was given in a dose of 12 mg intramuscularly initially with a repeat dose 24 hours later.

Patients greater than 37 weeks gestation at the time of rupture of membranes were managed somewhat differently. The initial evaluation of these patients was similar to those less than 37 weeks; however, if the speculum examination showed evidence of a favorable cervix for labor induction by the Bishop score,[15] labor was induced. If the cervix was unfavorable, the conservative approach was used. An occasional private patient was induced at this point because the attending physician did not wish to follow a conservative approach.

A pediatrician was in attendance at all deliveries. Most infants were placed in the intensive care nursery for at least 24 hours. The infants were evaluated with a

gram stain of the gastric aspirate and by surface, (ear, nose, cord) blood, and cerebral spinal fluid cultures if indicated. Infants felt to be clinically infected were started on antibiotics at delivery. If the cultures were negative and the infant was clinically free of infection, antibiotics were discontinued. Infants who did have clinical or laboratory evidence of infection were treated with antibiotics for at least a 7 to 10 day course. Placentas from these deliveries were cultured for both aerobic and anaerobic bacteria and were sent to the pathology department for study.

Results

In this study, PROM was defined as rupture of the membranes with at least a two-hour latent period before active labor. One hundred eighty-eight patients were admitted to St. Margaret's Hospital with a diagnosis of PROM between July, 1975, and June, 1977. These patients were subdivided by weeks of gestation at the time of delivery into two main groups (Fig. 1): (A) Patients beyond 37 weeks' gestation, and (B) Patients less than 37 weeks' gestation. For purposes of analysis, Group B was further separated into: (1) patients who were 35 to 36 weeks' gestation, and (2) those who were less than or equal to 34 weeks. Patients less than 34 weeks who received steroids for lung maturation were analyzed separately from those who did not.

The patients in Group A (greater than 37 weeks) had shorter latent periods than those with rupture of the membranes less than 37 weeks. In the group with gestational age less than 37 weeks, 63 patients (57%) went more than 24 hours before labor commenced, and 21 patients (19%) went beyond 7 days. The longest latent periods in this group were 58, 44, 39, 33, and 19 days. In the group of patients with gestational ages beyond 37 weeks only 12 (15%) went greater than 24 hours before the onset of labor, and 3 (4%) went beyond 7 days. The longest latent periods in this group were 14, 12, 9, 7, and 3 days.

There was only one positive blood culture in these 188 patients and their offspring. One infant had a Group B beta hemolytic streptococcal septicemia and survived. No infant died of sepsis. Since infectious morbidity as measured by positive central cultures was so low, analysis was made of infectious potential as measured by clinical maternal infection at delivery, chorioamnionitis by placental examination, bacterial colonization, and antibiotic use. These results may be seen in Table I.

The mode of delivery in the two main groups was similar with approximately 65 to 70% of the patients being delivered vaginally and 30 to 35% having cesarean births.

A comparison of the patients less than 34 weeks is

Induced	15 (19%)	7 (47%)	7/7	100	<0.05
Spontaneous	63 (81%)	21 (33%)	9/21	43	

*Lack of progress.

seen in Table II. In both the steroid and nonsteroid groups, the latent periods were similar. When the factors used to monitor the potenital for infections were compared there was no statistically significant difference except in bacterial colonizations of the infant and antibiotic use in the infants (p = >0.05).

When the bacterial colonizations were analyzed, the most common organisms isolated in all the groups of patients were similar. The organisms isolated were *Escherichia coli, Staphylococcus epidermidis* coagulase negative, *Enterococci* Group D, and Group B beta hemolytic *streptococci.* Multiple isolations were obtained from some patients.

The incidence of respiratory distress in all of the infants was 6% (11 patients), and all of these occurred in patients less than 37 weeks' gestation. These patients had x-ray and clinical evidence of RDS and needed mechanical ventillation assistance to maintain an adequate Po_2. Since staff opinion varied on the value of antepartum steroids, 45 patients who were 28 to 34 weeks' gestation did not receive antepartum steroids at rupture of the membranes, and 44 patients received steroids in the same gestational age group. There were no deaths due to hyaline membrane disease (HMD) in any infant greater than 28 weeks' gestation at delivery, with or without the use of steroids. There were four patients (8%) who developed RDS in the control group and six patients (14%) who developed RDS in the steroid group (p = N.S.) Table II. The two groups were also compared for Type II RDS which included such diagnoses as wet lung, apnea of the newborn infant, transient tachypnea of the newborn infant, aspiration, etc. There were 15 patients (33%) who developed Type II RDS in the control group and 23 patients (52%) in the steroid-treated group.

A comparison of the cesarean section rates for lack of progress in patients beyond 37 weeks with induced and spontaneous labors was made. Fifteen patients (19%) of the 78 patients beyond 37 weeks at rupture of the membranes were electively induced. The remaining 63 (81%) went into spontaneous labor. Of the patients induced, there were seven patients who had cesarean sections, and all of these were done for lack of progress. Of the patients who went into spontaneous labor, there were 21 patients who had cesarean sections, and of these nine (43%) were done for lack of progress (p = <0.05). These results are summarized in Table III.

There were no maternal deaths in this study. There were, however, 12 perinatal deaths (6.4%), 2 fetal deaths (antepartum stillborns), and 10 neonatal deaths. All of these were in infants weighing less than 1,000

grams except for two infants weighing more than 1,000 grams with congenital anomalies. There were a total of four patients who had congenital anomalies incompatible with sustained life (Cases 1, 8, 9, and 12). There were no neonatal deaths attributable to neonatal sepsis in an infant who by birth weight and gestational age was considered viable (greater than 1,000 grams or greater than 28 weeks' gestation). Every infant that was considered viable survived, if no congenital anomalies existed leading to the infant's death. Examinations of the deaths by gestational age and birth weight at delivery were carried out (Table IV). All infants with a birth weight less than 700 grams and less than 24 weeks' gestation died. Those infants between 800 and 1,000 grams had a 50% mortality rate (3/6). Likewise, the infants between 25 and 28 weeks' gestation showed less than a 50% mortality rate (4/12). Infants with congenital anomalies incompatible with sustained life were excluded from these analyses.

Comment

The greatest fear or contraindication to a conservative approach in patients with ruptured membranes is the risk of infection. In this study no babies died from infection, either sepsis or neonatal pneumonia, and only one patient (infant) had a positive blood culture. Perhaps our avoidance of bimanual examinations minimized the risk of ascending infection in our population. There was no significant maternal morbidity and no maternal deaths despite a higher potential for infection at delivery as indicated by such parameters as clinical infection at the time of delivery, chorioamnionitis on placental examination, and bacterial colonization. It would appear that the conventional parameters

of temperature, uterine tenderness, and white blood cell count generally used to assess maternal clinical infection at delivery are not suitable indicators for actual infectious morbidity. In fact approximately 50% of those thought to be infected at delivery did not show infection by placental examination for chorioamnionitis or bacterial colonization. Similarly, approximately 50% of those not thought to be infected did show chorioamnionitis or had positive bacterial colonizations. The work of Townsend and colleagues[6] would support this belief. The parameters of pathologic examination of the placenta and bacterial colonization can also be erroneous, since they can be influenced by factors such as length of rupture of the membranes and route of delivery, without indicating true infection.

Since prematurity is accompanied by complications such as RDS, necrotizing enterocolitis, intracranial hemorrhage, and aspiration, any prolongation of intrauterine existence would be expected to reduce the risk of death. One hundred ten patients in this study were less than 37 weeks at the time of rupture of the membranes and were therefore at risk for these complications. Approximately 60% had a latent period greater than 24 hours and almost 20% had a latent period greater than 7 days. The longest latent period was 58 days. A continued in utero existence of these infants would appear to be the major contributing factor responsible for their successful outcome.

Eighty-nine patients in this study were less than 34 weeks and were as a result, candidates for antepartum steroid therapy to accelerate fetal lung maturation.[13] A decreased incidence of RDS could not be demonstrated, however, in the infants of the steroid-treated mothers, probably because of the small number of infants in this study who actually developed RDS. Interestingly, neither was there an increased potential for infection in steroid-treated mothers or their infants (Table II). The only parameters that were significantly different in the steroid versus nonsteroid patients were infant bacterial colonizations and infant antibiotic use. The first may be explained by the significantly increased rate of vaginal deliveries in the steroid-treated group with resultant bacterial contamination of the infant on its passage through the vagina. The increased use of antibiotics is explainable by the aggressiveness of the pediatric service to use prophylactic antibiotics.

The availability of an intensive care nursery certainly contributed to the low morbidity and mortality rates observed in this study. From our results it would appear that all patients with PROM who are less than 37 weeks' gestation should be referred to a perinatal center where an intensive care nursery awaits the premature infant.

Seventy-eight patients in this study were beyond 37 weeks and the majority of these were managed conservatively. Interestingly, 100% of the cesarean sections on induced patients in this group were done for lack of progress in labor. This compares to a 43% cesarean section rate for lack of progress in patients who had spontaneous labor (Table III). In the electively induced patients who had cesarean sections, it was also observed that some of the patients had delivered larger babies vaginally in previous pregnancies. Because infection was a minor problem in this study, the indiscriminate use of labor inductions in patients with PROM at term seems unwarranted. Only 12 patients (15%) of those beyond 37 weeks gestation at the time of rupture of the membranes went more than 24 hours before labor commenced, and only three patients (4%) went beyond one week. This suggests that careful observation of these patients within the hospital is reasonable and practical, and that such a scheme may decrease the morbidity and mortality rate from an increased cesarean section rate.

Summary

From this study we may conclude the following: (1) The conservative approach in the management of patients with PROM is safe and beneficial. Morbidity and mortality rates in both mother and infant are low as in utero development continues. (2) The use of steroids to accelerate fetal lung maturation does not seem to increase the risk of infection. (3) A conservative approach in a term pregnancy with PROM and an uninducible cervix seems to decrease the incidence of cesarean sections without an appropriate increase in the infectious morbidity. (4) Patients with premature ruptured membranes prior to 37 weeks should be treated at a perinatal care center where an intensive care nursery is available. (5) The lack of digital examinations in this study may account for the low incidence of infectious morbidity.

Thalassemia and pregnancy: Results of an antenatal screening program

LINDSAY STAUBUS ALGER, M.D.
MITCHELL S. GOLBUS, M.D.
RUSSELL K. LAROS, JR., M.D.
San Francisco, California

A thalassemia screening program was implemented at our institution using the finding of a mean corpuscular volume < 80 fl as the index of abnormality. Further evaluation using hemoglobin (Hb) electrophoresis and serum iron studies was carried out according to the scheme detailed below. A diagnosis of thalassemia was made in 33 women (42 pregnancies). Eight patients had α-thalassemia trait, 23 β-thalassemia trait, and two Hb H disease. Thalassemia trait did not have any adverse effect on pregnancy outcome. In two couples the fetuses were at risk for homozygous disease and in one couple the fetus was at risk for sickle cell β-thalassemia. The screening program described is an effective and inexpensive means of detecting thalassemia in an antenatal population and is applicable to most every clinic or office setting. (AM. J. OBSTET. GYNECOL. 134:662, 1979.)

THE THALASSEMIAS are a genetically determined, heterogenous group of disorders characterized by reduced production of one or more of the globin chains in human hemoglobin. Consequently, hemoglobin synthesis is impaired. Moreover, the partner chains which are produced at a normal rate, but in relative excess, accumulate. Precipitation of these excess unpaired globin chains results in ineffective erythropoesis, red cell sequestration and destruction, and hypochromic anemia.[1] The most severe forms of this disorder may cause intrauterine or childhood death. A person who is heterozygous, or a carrier, for a thalassemia trait may be asymptomatic and, therefore, unaware of his/her condition until a mating with another carrier produces a severely affected child.

During the past decade substantial progress has been made in our understanding of the molecular defects in thalassemia; however, there is still no cure for the disease. At present we must rely on prevention: either preventing the conception of an affected fetus or, once conceived, preventing its birth. The first alternative would require a degree of social engineering unacceptable to most people. Fortunately, remarkable advances in the field of prenatal diagnosis now make it possible to detect a thalassemic fetus in utero and, hence, in combination with selective abortion, to avoid the birth of a child doomed to illhealth and an early death.

This paper will discuss: (1) the molecular basis and pathophysiology of thalassemia, (2) the methods for screening and detection in adults, in particular during pregnancy, and (3) the methods of prenatal diagnosis. We will conclude by presenting a suggested protocol for antenatal screening of thalassemia and the results of implementing this program at our institution during the years 1975 to 1978. These results lead us to recommend widespread antenatal screening.

Background

Hemoglobin is a tetrameric protein consisting of four globin chains. In humans there are six structurally different types of globin chains, designated α, β, γ, δ, ϵ, and ζ.[2] Most pertinent to the thalassemias are the α-, β-, γ-, and δ-chains. The early embryonic globins ϵ and ζ are rapidly replaced as the fetus develops.[3] Two α-chains and two non-α-chains combine to form each of the different hemoglobins found in adults. Normally Hb A ($\alpha_2\beta_2$) constitutes 96% of adult hemoglobin while Hb A_2 ($\alpha_2\delta_2$) contributes an additional 2 to 3%. The predominant hemoglobin during fetal life, Hb F ($\alpha_2\gamma_2$)

0002-9378/79/140662+12$01.20/0 © 1979 The C. V. Mosby Co.

comprises less than 2% in the adult, except when certain conditions, including pregnancy, supervene.[4]

The messenger ribonucleic acid (RNA) for each globin chain is transcribed from a varying number of genes which may differ among populations. It appears that there are four genes controlling α-chain synthesis in Oriental and Caucasian people[5] but an inconstant number, from two to four, in black populations.[6] There are two genes each for β- and δ-chains and at least four for γ-chains.[7] The β-, δ-, and γ-genes are closely linked on the same chromosome, while the α-genes are thought to reside on another chromosome.[8]

The thalassemia syndromes are named and classified by the type of chain which is inadequately represented. The two major groups are the α- and β-thalassemias, both of which affect the synthesis of Hb A. Reduced synthesis of γ- and δ-chains, and even combinations in which two or more globin chains are affected (e.g., δβ-, γβ-, hereditary persistence of fetal hemoglobin [HPFH]) have been reported, but these are rarer.[9–11] In each instance the thalassemia is a quantitative disorder of globin synthesis; structurally the chains are entirely normal. There is no single etiology of the disease. On the molecular level, a variety of defects have been demonstrated, each involving a different step along the pathway of transcription of gene deoxyribonucleic acid (DNA) into messenger RNA (m-RNA) and translation of m-RNA into globin chains.

In the most common form of α-thalassemia one or more structural genes are physically absent, permanently deleted from the genome.[12] In the homozygous condition, when all four genes are deleted, no α-chains are produced and the fetus is unable to synthesize Hb F or any of the adult hemoglobins.[13] The predominant hemoglobin is Hb Barts (γ_4) which releases inadequate amounts of oxygen to tissues because of its high oxygen affinity. The result is high-output heart failure, hydrops fetalis, and a stillborn fetus.

The most severe form of α-thalassemia compatible with extrauterine life is Hb H disease which results from the deletion of three genes.[14] In patients with this disease abnormal quantities of both Hb H (β_4) and Hb Barts accumulate. β_4-Tetramers precipitate during the life of the red cell to form inclusion bodies. The "pitting out" of these bodies by the reticuloendothelial system causes moderately severe hemolytic anemia. In α-thalassemia minor (α-thalassemia-1) two genes are deleted, causing a mild hypochromic, microcytic anemia which must be differentiated from iron deficiency.[6] A single gene deletion (α-thalassemia-2) is clinically undetectable or the "silent carrier" state.

α-Thalassemia may also result from a nondeletion defect.[15] All genes are present, yet the phenotype is that of α-thalassemia 1. Apparently only a small amount of globin can be synthesized from these genes. Still another group of defects is exemplified by mutant hemoglobins such as Hb Constant Spring where an elongated α gene product is incorporated into the Hb molecule.[16] A greatly reduced amount of this mutant product is produced.

The etiology of α-thalassemia in black people is less clear than for those who are Oriental and Caucasian. They do not demonstrate an imbalance as marked or consistent in globin synthesis. Hgb H disease is seen very rarely and thalassemia minor is clinically very mild, apparently because the α-thalassemia in this population involves both deletion and nondeletion mutations or a variable number of genes influencing m-RNA concentration in reticulocytes.

Unlike α-thalassemia, a gene deletion has not been demonstrated in β-thalassemia. There are two forms of β-thalassemia, designated β^+ and β^0, depending on whether β-chain production is reduced or entirely absent. In β^+ thalassemia, m-RNA for β-globin chains is present but is quantitatively reduced.[17] This might be due to a particularly unstable m-RNA or to a decreased rate of transcription of m-RNA.

In some cases of β^0-thalassemia m-RNA is present, but there is defect in its translation which might be explained by an abnormal m-RNA.[18] In the Ferrara type of β^0-thalassemia the translation may be corrected in vitro by the addition of ribosome-free supernates from normal reticulocyte lysates,[19] and it has been postulated that a necessary translation control factor, perhaps acting at globin chain initiation, is missing while the m-RNA itself is normal.[20] In other cases the β-globin gene is present but no detectable m-RNA is found in the reticulocyte.[21, 22] Possible explanations include a mutation in the initiation region for transcription, preventing the synthesis of m-RNA, rapid breakdown of transcribed m-RNA before it can be translated, or failure of m-RNA to be processed from the nucleus to the cytoplasm.[22] Reduced β-chain synthesis may also be seen with Hb Lepore, a product of δ-and β-gene crossover, HPFH, and in δβ-thalassemia. HPFH and δβ-thalassemia differ from β-thalassemia in that they both involve β-gene deletions.[23]

In the homozygous β-thalassemia condition, α-chain production is unimpeded and these highly unstable chains accumulate and eventually precipitate. Markedly ineffective erythropoiesis and severe hemolysis result in a condition known as thalassemia major or Cooley's anemia.[24] The affected infant is anemic by 3 months of age, has hepatomegaly, requires blood transfusions every 3 to 4 weeks, and dies by the third decade, usually of myocardial hemosiderosis. Those

female patients surviving until puberty are usually amenorrheic with severely impaired fertility.[25] In the heterozygous state (thalassemia minor) the normal β-globin gene allows developing red cells to accumulate up to 75% of the normal complement of Hb A.[6] The remaining deficit is partially corrected by production of an increased number of smaller than normal cells. This results in the hypochromic microcytosis of β-thalassemia trait, but the individual may not be clinically anemic. Because δ-chain synthesis is increased relative to β-chain synthesis, the Hb A_2 level is also increased.

The clinical severity of β-thalassemia is influenced by the extent to which γ-chain production can compensate for deficient β-chain synthesis. Approximately 50% of patients with β-thalassemia trait have elevated Hb F levels, and in δβ-thalassemia there is a marked increase in Hb F, which acts to ameliorate this condition. The rare instances of pregnancy in patients reported to have thalassemia major most likely occurred in individuals actually heterozygous for two different β-thalassemia genes, at least one of which is a "high F" form.[25, 26]

Due to the marked heterogeneity of the thalassemia syndromes there is no single diagnostic method applicable to all cases. Except for genetically obligate heterozygous persons, the β/α globin synthetic ratio provides the most accurate method of identifying thalassemia trait.[27] It is the only means of detecting α-thalassemia-2. However, it is generally unavailable and too elaborate for routine clinical use. (It also may not detect cases of combined α-and β-thalassemia.) Currently, an elevated Hb A_2 level (>3.5) is considered sufficient evidence to substantiate a diagnosis of β-thalassemia trait. Hb A_2 levels are normal in α-thalassemia and, hence, this is a diagnosis of exclusion made only after iron deficiency has been ruled out. In δβ-thalassemia, Hb A_2 levels will also be normal but Hb F levels will be increased.[2] Red blood cell morphology and osmotic fragility measurements provide additional evidence of the thalassemic state.

Thalassemia is found throughout the world but is concentrated in the Mediterranean coastal areas, central Africa, and parts of Asia. In these regions it is believed that the high incidence represents a balanced polymorphism due to heterozygous advantage.[1] Persons who are heterozygous are protected against malaria when compared to the homozygous normal.

All forms of thalassemia are inherited as an autosomal recessive trait. The lethal homozygous state results only when all of an individual's genes for the α- or β-chain are affected. If a couple, each of whom is heterozygous for the same condition (carriers), chooses to have children they have a 25% chance of conceiving an affected fetus and a 50% chance that the fetus will be heterozygous.

Antenatal diagnosis

Until very recently, the obstetrician has had little to offer patients who were α- or β-thalassemia carriers. They usually had uncomplicated pregnancies and the obstetrician's role was limited to genetic counseling and performing abortions for those couples fearful of delivering an affected child. The development of methods to diagnose thalassemia in utero now allows the obstetrician to give parents definite answers rather than statistical probabilities. Couples at risk can avoid having affected children without remaining childless and are spared months of anxiety awaiting the outcome of a pregnancy.

Since the homozygous state is invariably fatal, α-thalassemia does not produce the major medical and social problems associated with β-thalassemia. Even so, early diagnosis is desirable to minimize the emotional trauma of an unsuccessful pregnancy and to prevent the development of third trimester pre-eclampsia which frequently accompanies this disease.[28]

The method for prenatal diagnosis of α-thalassemia involves measuring the number of intact α-globin structural genes present in the cellular genome using the technique of molecular hybridization.[29] Since any nucleated cell, including amniotic fluid fibroblasts, contains the full complement of globin genes, amniocentesis provides fetal cells which can be cultured and then analyzed. Using reverse transcriptase, a viral enzyme which transcribes DNA from RNA, complementary α-DNA (c-DNA) can be transcribed from α-globin m-RNA. This complementary DNA is also complementary to and capable of binding to α-globin structural genes in cells. The rapidity with which the c-DNA binds to DNA from amniotic fibroblasts is proportional to the number of copies of α-globin structural genes present in the cells. This technique clearly distinguishes the homozygous state from carrier or normal states.

Since the known molecular defects in the β-thalassemias do not involve gene deletions, antenatal diagnosis depends upon actually quantitating the fetal production of Hb A. A number of investigators have demonstrated the presence of Hb A during the first trimester, with β-chain synthesis increasing as the pregnancy progresses.[30, 31] By measuring the synthesis of globin chains, the normal ratio of β- to γ-chain synthesis has been determined for varying gestational ages.[32, 33] By comparing the β/γ synthetic ratio of a sampled fetus to that of normal fetuses of the same

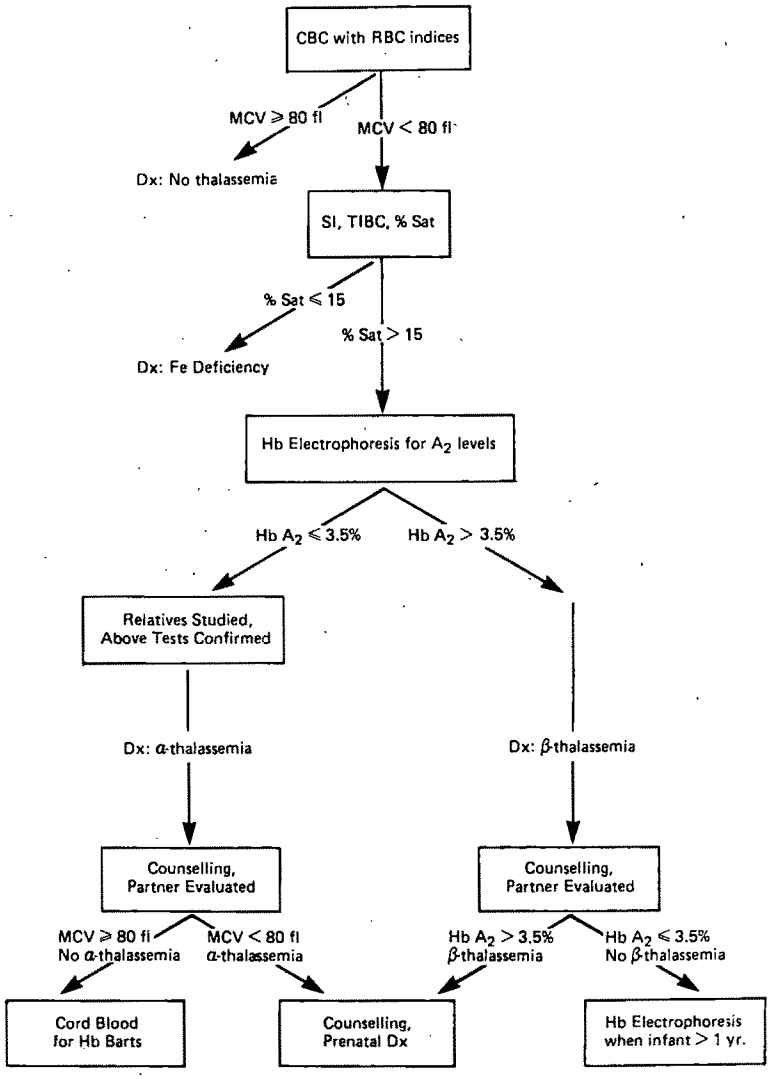

Fig. 1. Scheme for antenatal thalassemia program.

gestational age, the presence of β-thalassemia can be detected. However, such synthetic studies require fetal erythrocytes.

Fetal blood may be aspirated under direct visualization using a modified cannula through which both a fetoscope and a 26 gauge blood drawing needle can be inserted transabdominally.[34] The rigid fetoscope renders this technique unsuitable for some anterior placentas. Using fetoscopy, it has been possible to obtain sufficient fetal red blood cells for hemoglobin synthesis studies from approximately 90% of patients.[35] A second technique for obtaining fetal blood is by sonographically directed placental aspiration through a 20 gauge needle.[36] In our hands this technique has been successful in obtaining samples from 86.4% of anterior placentas and from 94.4% of posterior placentas. Over 40 pregnancies have been evaluated.[35] Regardless of technique, sampling should be performed at approximately 18 to 20 weeks gestation. As pregnancy progresses any given amount of blood loss represents a smaller proportion of the total fetal blood volume and yet this is sufficiently early to terminate a pregnancy, if required. At 18 to 20 weeks' gestation the normal β/γ ratio is >0.07 with a mean of 0.11, the ratio for the heterozygous state is 0.058 ± 0.020 ($\pm$2SD) and the ratio for the homozygous state in all reported cases has been <0.03.[37]

Both blood sampling procedures result in a mixture of fetal and maternal blood. Since fetal erythrocytes synthesize globin chains at rates greater than 500 times that of maternal cells, the maternal contribution to the sample's β-chain synthesis is small.[38] If the sample con-

tains less than 50% fetal cells, these can be separated from the mixture by agglutination with anti-i, an antibody which binds only to fetal cells.[39] This method has been successful in analyzing samples containing as little as 7% fetal red cells and eliminates the need to suppress maternal erythropoiesis by transfusions.

Antenatal diagnosis of β-thalassemia is not without hazard. The risk of fetal loss is approximately 10%.[40, 41] The two reports of inaccurate diagnoses were early in one center's experience and with the additional expertise now gained are unlikely to recur.

Antenatal screening

The availability of prenatal diagnosis provides strong impetus for the creation of mass maternal screening programs. Since the primary aim of screening is the detection of individuals who already carry the gene and the prevention of homozygous individuals in the future, the ideal population for evaluation is women of reproductive age. A good screening method should have no false negative and few false positive results. It should be inexpensive, simple to perform, and acceptable to patients. Protocols which center upon the determination of red blood cell indices are particularly appealing, since they presently afford the greatest potential for meeting the above criteria.

Several proposals may be found in the literature. Healy suggests that all individuals in whom the function (0.23 × mean corpuscular volume[MCV]) − (0.22 × red blood cells) − (0.93 × Hg) − 3 is less than zero have thalassemia.[42] England and Fraser[42] simplified the formula to MCV − red blood cells − 5 × Hg − 3.4 < 0. Mentzer[43] advocates using the ratio of MCV/red blood cells, values less than 13 corresponding to patients with thalassemia. Recently, Shine and Lal[44] have developed a heuristic method which they claim yields the lowest false negative rate and an acceptable number of false positive results: $MCV^2 \times$ mean corpuscular hemoglobin (MCH) < 1,530.

At our institution we have implemented a thalassemia screening program specifically designed to evaluate obstetric patients. We believe this protocol provides the information most pertinent to the pregnant patient while retaining the virtues of simplicity and low cost. Each patient registering for prenatal care at our clinic has a complete blood count with red blood cell indices performed at the time of the first prenatal visit. This includes measurement of the MCV by a Coulter electronic counter. If the MCV is less than 80 fl (similar to Pearson's[45] threshold of 79 fl), the patient is further evaluated following the scheme outlined in Fig. 1. In addition to thalassemia, microcytic, hypochromic anemia may be due to iron deficiency, chronic illness, or sideroblastic anemia. To differentiate between these disorders serum iron studies are performed (serum iron, iron binding capacity, percent saturation). If iron studies are normal (serum iron greater than 50 μg/dl, saturation greater than 15%) the Hb A_2 level is determined. A level greater than 3.5 is considered diagnostic of β-thalassemia trait. If the Hb A_2 is less than 3.5 all studies are repeated and the patient's relatives are evaluated if possible. A diagnosis of α-thalassemia is made only when microcytosis, normal serum iron studies, and a normal level of Hb A_2 are confirmed. A diagnosis of Hb H disease is made if, in addition, hemoglobin electrophoresis demonstrates β_4.

Serum iron studies were chosen as the second diagnostic step for several reasons. By far the largest number of false positive results using Pearson's threshold will be due to iron deficiency. Indeed, pregnant patients, including those with thalassemia trait, are at particular risk for this condition. However, patients with thalassemia are often misdiagnosed and treated with iron for years without response. This may lead to iron overloading, particularly if parenteral iron is used.[46] Since it is desirable to treat all iron-deficient patients but inappropriate to do so without first verifying the diagnosis, determination of iron status would properly follow even if the obstetrician were uninterested in thalassemia. By eliminating microcytosis secondary to iron deficiency fewer hemoglobin electrophoreses are required. Finally, in cases of coexistant β-thalassemia and iron deficiency, Hb A_2 levels may be depressed below 3.5 and the diagnosis missed. In this event A_2 levels may become elevated only after iron replacement.[46] If after appropriate iron therapy microcytosis persists, a repeat Hb A_2 level is performed.

Once a diagnosis of thalassemia has been made the patient is informed as to its possible significance and her partner is evaluated by means of a complete blood count and hemoglobin electrophoresis. If he is found to be a carrier of a like thalassemia trait, or is heterozygous for a hemoglobinopathy that in the double heterozygous state with thalassemia trait causes clinical disability, the couple receives genetic counseling and is offered prenatal diagnosis as described above.

Antenatal thalassemia screening was begun at our institution in the fall of 1975. We have examined the

results of this program along with our previous data on thalassemic patients in order to assess: (1) conflicting reports on the effect of thalassemia on pregnancy and vice versa, and (2) the impact of the thalassemia screening program.

Subjects and methods

Between July, 1970, and February, 1978, approximately 10,000 pregnancies were observed at our prenatal clinic. Using the criteria described above, a diagnosis of thalassemia was noted in 42 pregnancies in 33 women. Patients were ascertained by several means. In some cases the diagnosis was discovered in the course of evaluating a persistent anemia of pregnancy. In others, the diagnosis was known prior to presentation at the clinic and one patient was specifically referred for prenatal (fetal) diagnosis. Subsequent to implementing the screening program the majority of patients were detected by screening. Several patients discovered by our screening program were found to have had previous pregnancies during which the diagnosis had remained unrecognized. For the purposes of analysis these earlier pregnancies were examined in retrospect.

All patients received routine obstetric care without consideration of the diagnosis. Data concerning the maternal hematologic status, prior obstetric history, and obstetric and fetal outcome were abstracted, key punched, and analyzed by an IBM 370 computer. Statistical analyses using chi-square and Student's t tests were performed with the Statistical Package for the Social Sciences (SPSS). The total obstetric population registered at our clinic between January, 1976, and March, 1978, (4,574 pregnancies) served as control subjects. Only p values < 0.05 were considered significant.

ophenanthroline sulfonate. Hemoglobin electrophoreses were determined using a cellulose acetate membrane and quantitated by densitometer. Hg A_2 levels were run against both normal and abnormal controls. After obtaining informed consent, antenatal diagnosis was performed as described by Kan and associates.[30, 47] Neonatal cord blood specimens were analyzed for Hb Barts and quantitated by densitometer.

Results and comment

The maternal diagnoses in 42 pregnancies were distributed as shown in Table I. Four patients had additional hematologic diagnoses possibly influencing their results. One patient with α-thalassemia had sickle trait. Among β-thalassemic patients there were single incidences of iron deficiency, aplastic anemia, and the carrier state for combined immune deficiency disease.

Hematologic variables. First-trimester hematologic parameters for each type of thalassemia are displayed in Table II. As expected, Hb A_2 levels were significantly increased in β-thalassemia ($p = 0.003$). None of the group differences among the remaining parameters is significant. Although the mean values for each group were in the anemic range, there were individual patients who had a normal hematocrit and hemoglobin level. Anemia is not a prerequisite of thalassemia. The range of values was hematocrit 31.7 to 37.5 and hemoglobin 9.8 to 12.2 in α-thalassemia and hematocrit 28.0 to 37.7 and hemoglobin 8.9 to 12.3 in β-thalassemia. There was a trend for α-thalassemic patients to be less anemic than those with β-thalassemia but this was significant only during the second trimester (Table III). It is apparent that a complete blood count with red blood cell indices cannot differentiate between α- and β-thalassemia during pregnancy.

Contrary to the findings of Pakes and co-workers,[48] our pregnant thalassemic patients had higher red blood cell counts than their hematologically normal counterparts. The expected physiologic hemodilution of pregnancy was observed as a tendency for the hematocrit, hemoglobin, and red blood cell counts to fall after the first trimester; however, this trend did not achieve statistical significance. No such decline was noted for red blood cell indices; the MCV and MCH actually increased between the first and third trimesters. For patients with α-thalassemia trait the first-trimester and third-trimester MCV's and MCH's were 68.1 versus 69.8 fl ($p = 0.013$) and 21.9 versus 22.8 gm/dl of red blood cells ($p = 0.003$), respectively. For β-thalassemic patients the values were 67.8 versus 70.8

fl ($p = 0.068$) and 21.6 versus 23.4 gm/dl of red blood cells ($p = 0.10$). This may be attributable to increased release of immature cells into the circulation as the total red blood cell volume expands during pregnancy. Pakes and associates[48] found that reticulocyte counts were higher in thalassemic patients throughout pregnancy.

In agreement with other investigators, we found no evidence to support Hocking and Ibbotson's[49] supposition that pregnancy presented an overwhelming hematologic stress to the thalassemic patient's defective erythropoietic system. While 36% of their patients received blood products, none of our patients required transfusions, including those undergoing cesarean section. Although megaloblastosis secondary to folate deficiency may complicate β-thalassemia major, it is rarely associated with thalassemia minor.[46] All of our clinic patients routinely receive prenatal vitamins with folate, thus avoiding the possibility of this deficiency. Fleming and Lynch[46] have suggested that increasingly ineffective erythropoiesis and/or hypersplenism might contribute to the decline in hemoglobin levels seen between the first and second trimesters in thalassemic patients. Since the mean decrease in hemoglobin level (0.52 grams) was less than that reported for normal pregnancies (1.6 grams between the twelfth and twenty-sixth weeks[50]), we find no reason to invoke mechanisms in addition to the normal hemodilution of pregnancy.

Pregnancy variables. Maternal age, parity, gravidity, and the number of previous spontaneous abortions, therapeutic abortions, stillbirths, and neonatal deaths did not differ between α- and β-thalassemic patients. Furthermore, these values were comparable to those of the control population. The number of previous stillbirths (three) was greater than normally expected; however, two of these occurred in one woman who also had had three spontaneous abortions. Our results agree with those of Pakes and colleagues[48] who found no impairment of fertility in patients with thalassemia.

The influence of thalassemia on pregnancy was examined and the outcome of 38 pregnancies is shown in Table IV. Four patients remain undelivered. Comparisons between α- and β-thalassemia and between thalassemic and control populations revealed no differences in method of delivery, birth weight, placental weight, fetal/placental ratio, gestational age, or fetal size for age (using Lubchenko's criteria).

When defined as a gestational age ≤37 weeks, six infants (15.4%) were premature. However, only three of these infants weighed under 2,500 grams. The largest infant weighed 3,960 grams with a 700 gram placenta. Unlike previous studies[51, 52] we did not find an increase in placental size.

Fetal outcome. With the exception of one unexplained 300 gram stillborn infant, there were no deaths. Fetal distress was assessed by Apgar scores. Scores were comparable to those of control subjects: 12.8% of 1 minute and 5.1% of 5 minute Apgar scores were less than 7 (control values 15.0% and 4.6%). Thirty-four of the 38 newborn infants were entirely healthy. There were three complications: an imperforate anus, a mild case of idiopathic respiratory distress syndrome at 35 weeks' gestation, and one episode of mild intrapartum asphyxia. It appears that maternal thalassemia does not adversely affect the fetus.

Five neonates at risk for α-thalassemia had cord blood hemoglobin electrophoreses and two had elevated Hb Barts levels. One additional infant, not initially sampled, was later shown to have the α-thalassemia trait. We did not test for the presence of β-thalassemia at birth since this would require synthesis studies but two infants were evaluated when they were over 1 year of age and were found to have β-thalassemia trait. All five thalassemic heterozygous fetuses were healthy newborn infants. There was no instance of a fetus homozygous for thalassemia.

Early investigations concerning the effect of thalassemia on pregnancy indicated that there was a higher incidence of fetal distress and perinatal death. Women with hemoglobin levels less than 10 gm were reported to have a 25% incidence of subnormal estriol excretion[53] and a 5.4% greater incidence of low-birth-weight infants.[54] These adverse effects were attributed to fetal hypoxia secondary to maternal anemia, which in turn resulted in placental hypertrophy.[52] Beischer and associates[51] found approximately twice the normal incidence of placentas weighing over 700 grams.

Our findings agree with more recent observations which demonstrate no increase in prematurity, fetal distress, or perinatal deaths.[48] We did not encounter the prolonged labor and excess blood loss noted by Beaven and coworkers.[55] Although in our experience placentas were of normal size with a normal fetus/placenta ratio, our inability to correlate placental and fetal weight in 22 pregnancies might support Fleming and Lynchs'[46, 52] view that the balance between fetal and placental growth is disturbed by thalassemia. Our patients had hemoglobin levels slightly higher than those in earlier series, perhaps partially accounting for the difference in neonatal results.

Screening results. There has been a substantial increase in the number of thalassemic patients delivered in our hospital. This increase is almost entirely due to detection of patients by the screening program. Of the 33 patients observed during the past 8 years, 21 cases were diagnosed by screening. Over the 5½ years pre-

ceding the program only seven cases (nine pregnancies) were detected. This represents a sixfold increase in the rate of detection. In addition, four heterozygous patients delivered before the institution of screening were identified only when a subsequent screened pregnancy was evaluated. Two thirds of the cases diagnosed by screening were β-thalassemia; one third was α-thalassemia. Prior to implementing our program we had not recognized a single case of α-thalassemia.

Paternal screening. In 50% of the pregnancies the father was also evaluated for thalassemia. Only four of 33 fathers refused screening, but an additional 10 were not assessed due to either physician or paternal inaction. In the years preceding the program only a single father was evaluated.

Fetal risk. Two couples were found in which both parents were heterozygous for thalassemia, thus putting the fetus at risk for homozygous disease. One couple was at risk for a fetus with α-thalassemia, and a prenatal diagnosis of α-thalassemia trait was made and confirmed at delivery. The second couple, heterozygous for β-thalassemia, had two deliveries. The paternal status was unknown during the first pregnancy, which resulted in a 300 gram stillborn infant. The father was not screened until late in the second trimester of the second pregnancy, making it impossible to offer antenatal diagnosis. Fortuitiously, the offspring was found to have only β-thalassemia trait. A third couple was found to have a fetus at risk for sickle-thalassemia disease. The patient declined antenatal diagnosis and is as yet undelivered. Since the status of both partners was known in only 57.5% (19/33) of couples, these three pairs comprised 15.8% (3/19) of examined couples. Over all there was a 0.5% incidence of thalassemia in our prenatal clinic. The percentage of pregnancies at risk for the homozygous state is much less, but 10% of the fathers screened were carriers for the same trait as their spouses.

Ethnic background. Although generally considered a disease affecting peoples of the eastern hemisphere, there is a significant incidence of thalassemia in the United States. A previous study of Greek Americans revealed a 5.0% incidence of β-thalassemia trait and a 2.4% incidence of α-thalassemia trait.[45] In a Canadian prenatal clinic 10.5% of Greek patients were found to have β-thalassemia trait.[48] Thalassemia is one of the most frequent hematologic abnormalities in black Americans with a reported incidence of 1.4% and 5.7% for β- and α-thalassemia traits, respectively.[56] In our experience no ethnic group is exempt from the risk of thalassemia, including those of northern European ancestry.

Comparison of screening methods. It is insufficient to evaluate only patients found to be anemic. Many of our patients with thalassemia trait (α or β) were only mildly anemic and some had normal hematocrit and hemoglobin levels. Therefore, our program uses the simple discriminant MCV < 80 as the initial screening index. In order to evaluate alternative discriminants we applied the Healy, England-Fraser, Mentzer, and Shine-Lal formulas to our thalassemia population.

During the first trimester the Healy and England-Fraser indices each detected 10 of 25 patients (40%) when values less than 1 were considered. During the second trimester the Healy index identified only three patients while the England-Fraser–derived function detected a single patient. The Mentzer index selected nine and three patients during the first and second trimesters, respectively. The Shine-Lal formula was superior to all others. It failed to detect only two cases during the first trimester. The sole case missed by this formula during the second trimester had a MCV > 80 and thus would have escaped detection by our screening program as well. Although previously microcytic, this patient's red blood cell indices had become normal after she developed systemic lupus erythematosus and began releasing immature cells into the peripheral blood. All patients detected had Shine-Lal values < 1,390 (means 1,065 first trimester and 1,118 second trimester). We do not know whether there were cases not recognized by our program which might have been noted by the Shine and Lal function. There were no significant differences in values or rates of detection between α- and β-thalassemic patients using any of the methods.

None of the proposals for screening found in the literature are recommended by their authors for use during pregnancy; our results support this. The Healy, England-Fraser, and Mentzer discriminants failed to detect the majority of thalassemic patients. All are affected by the hemodilution that occurs physiologically during pregnancy. In the presence of concomitant iron deficiency the diagnosis of thalassemia is frequently missed. However, the more recent proposal by Shine and Lal does appear to be useful during pregnancy.

Summary

While in the past the specific diagnosis of thalassemia trait has satisfied the intellectual curiosity of the physician, prevented the useless prescription of iron, and allowed genetic counseling for future pregnancies, a correct prenatal diagnosis was of no urgency. The advent of prenatal diagnosis of thalassemia makes such a casual attitude inappropriate. Homozygous thalas-

semia is a lethal condition. Each year 100,000 children die of β-thalassemia worldwide.[57] The fetus who is homozygous for α-thalassemia is inevitably stillborn. To continue a pregnancy destined to a tragic outcome is unacceptable to most couples when the alternative of prenatal diagnosis and selective abortion is available.

We have instituted a screening program (Fig. 1) which requires little additional cost, but rather an increased awareness of the implication of routine laboratory test results. Since implementing the program we have had a sixfold increase in the number of thalassemic patients detected. This does not appear to be due to an increase in the frequency of the disorder but rather to detection and appropriate evaluation of each patient with microcytosis. Indeed, prior to our program we had not recognized a single case of α-thalassemia trait. During the past 2½ years we have discovered eight such patients who previously would have gone unnoticed or would have been incorrectly diagnosed as iron deficient. In addition, we have encountered four β-thalassemic patients observed at our clinic for previous pregnancies during which time the diagnosis was unsuspected, further supporting our contention that the increased detection rate is attributable to screening.

Our findings indicate that thalassemia occurs more frequently than was previously suspected, but it is still an uncommon disease. Although most clinics will be able to detect couples at risk for having thalassemic infants, it is unlikely that all will generate sufficient volume to provide the experience necessary for accurate and safe prenatal diagnosis. We recommend that such couples be referred to centers which have the necessary expertise in in utero diagnosis.

At our institution we have established such a referral center. Over a period of less than 3 years we have had the opportunity to evaluate 36 pregnancies at risk for β-thalassemia. Eighteen of these couples had requested antenatal diagnosis because they already had had one or more children affected by homozygous disease. We believe that a thalassemia screening program could have prevented most, if not all, of these unfortunate births. Although in the present study we did not encounter a known instance of homozygous disease in our screened population, in those patients referred for prenatal diagnosis we found six fetuses with homozygous thalassemia among the 34 cases where adequate fetal blood was obtained for study. All six pregnancies were terminated at parental request and the diagnosis confirmed by the absence of β-chains and Hb A in the cord blood. Similarly, one instance of homozygous α-thalassemia was found among five sampled pregnancies and terminated.

Thus far, there has been a single factor limiting the effectiveness of our program—inadequate patient education. We are unable to offer fetal prenatal diagnosis to patients if they do not seek prenatal care sufficiently early to terminate the pregnancy, should this be indicated. Similarly, a diagnosis of thalassemia in the mother is of little value unless her partner also understands its implications and agrees to an evaluation. Paternal participation may be facilitated by providing diagnostic evaluation at times other than usual working hours. Of course those patients who find selective abortion unacceptable may not wish to participate in the program. However, we find most patients are interested in the diagnosis and anxious to participate.

Thalassemia is one of the few nongynecologic diseases for which the obstetrician will most likely be the first to make the diagnosis. Over 85% of our cases were diagnosed by the obstetrician. Unlike the rest of the medical community who can attempt only to minimize the suffering which accompanies the homozygous state, the obstetrician-gynecologist can now prevent its occurrence. For both humanitarian and economic reasons, antenatal thalassemia screening is recommended.

We wish to acknowledge the invaluable assistance of Linda Ataide, R.N., B.S., Lyn Doherty, R.N., Jacquilline Morrill, R.N., B.S., and Bobbie J. Herron (Medical Records Department).

Maternal and amniotic fluid steroids throughout human pregnancy

MANUBAI NAGAMANI, M.D.*
PAUL G. McDONOUGH, M.D.
JAMES O. ELLEGOOD, M.S.

Augusta, Georgia

Concentrations of testosterone, dihydrotestosterone, androstenedione, progesterone, 17α-hydroxyprogesterone, and estradiol were measured by radioimmunoassay in the amniotic fluid and maternal peripheral blood obtained from normal pregnancies between 14 and 40 weeks of gestation. There was a sex difference in the levels of all the androgenic steroids in the amniotic fluid before 20 weeks with higher levels in pregnancies with male fetuses. Amniotic fluid 17α-hydroxyprogesterone levels were significantly elevated in a pregnancy with the fetus affected with congenital adrenal hyperplasia. The levels of all the steroids in the amniotic fluid were significantly elevated in the pregnancy with molar degeneration of the placenta. There was a sex difference in the levels of dihydrotestosterone in the maternal peripheral blood before 20 weeks with higher levels in pregnancies with male fetuses. There was no correlation between the steroid levels in the maternal serum and amniotic fluid even though most of the samples of maternal serum were drawn at the same time as amniocentesis. (AM. J. OBSTET. GYNECOL. 134:674, 1979.)

PREVIOUS studies on the endocrine function of fetal gonads show that human fetal testis in contrast to ovary secretes significant amounts of testosterone at the period of sexual differentiation in utero.[1, 2] Jost,[3] by his experiments on fetal rabbits, had shown that the development of the male phenotype, except for regression of the müllerian system, depends on the secretion of testosterone by the fetal testis at this critical period. It is also clear from the work of Wilson and Lasnitzki[4, 5] that testosterone itself is responsible for the differentiation of wolffian duct into epididymis, vas differens, and seminal vesicle, and dihydrotestosterone is probably the intracellular mediator in the differentiation of urogenital sinus and urogenital tubercle to prostate and external genitalia. Estradiol does not seem to play a significant role in the process of sexual differentiation and no significant amounts of this steroid had been detected in the fetal testis or ovaries at this stage of pregnancy.[6]

The fetus plays a considerable role in the formation of amniotic fluid in all stages of pregnancy. Before 20 weeks, amniotic fluid possibly bears a closer relationship to fetal plasma in its concentration of the steroids because of the free diffusion occurring through the fetal skin which had been shown by electron microscopy to be a meshlike structure with numerous microvilli.[7] After 20 weeks, fetal urine becomes an important source.[8] The present study was designed to measure various steroids in the amniotic fluid to see whether this approach could be utilized to study the hormonal events occurring in the fetus during different stages of pregnancy. Steroids were also measured in maternal peripheral blood for comparison.

Material and methods

One hundred one samples of amniotic fluid were obtained between 14 and 40 weeks of pregnancy when amniocentesis was done for cytogenetic studies in early pregnancy and for fetal maturity in late pregnancy. All the pregnancies were normal without any complica-

tions. Fifty-one samples were from pregnancies with male fetuses and 50 samples were from pregnancies with female fetuses. The sex of each fetus was determined at the time of delivery or by karyotype of amniotic fluid cells if undelivered. Seventy-six samples were between 14 and 20 weeks of pregnancy and 25 samples were between 26 and 40 weeks of pregnancy. Additionally, one sample of fluid was obtained from a pregnancy (17 weeks) which ended in an abortion, and the abortus contained a fetus whose karyotype showed triploidy (69, XXX) and extensive molar degeneration of the placenta. There were also four samples of amniotic fluid obtained from different stages of pregnancy in a patient who subsequently delivered a male fetus affected with congenital adrenal hyperplasia (21-hydroxylase deficiency). Sixty samples of maternal peripheral vein blood were obtained from different stages of normal pregnancies. The serum and amniotic fluid samples were stored at −20° C until assayed. Each sample was assayed for testosterone, androstenedione, dihydrotestosterone, estradiol, progesterone, and 17α-hydroxyprogesterone. Fetal age was obtained by subtracting two weeks from the time since the last menstrual period. If the last menstrual period was not known, the length of gestation was determined by ultrasonic measurement of fetal biparietal diameter. Student's t test and Duncan's multirange analysis were used for statistical analysis.

Hormone assays. All the steroids were measured by radioimmunoassay after fractionation of the steroids by Celite microcolumn chromatography as reported earlier.[9] Three milliliters of amniotic fluid or 3 ml of serum was extracted twice with three volumes of ether after adding ^{3}H tracers of progesterone, androstenedione, dehydroepiandrosterone, testosterone, and estradiol for recovery calculations. The extracts were dried under nitrogen and subjected to chromatography on microcelite column with ethylene and propylene glycol as stationary phase. The chromatographic separation was effective in removal of steroids that would interfere in the assay due to cross-reactivity. For example, progesterone and 17α-hydroxyprogesterone; androstenedione, dihydrotestosterone, and testosterone; and estrone and estradiol appeared in separate fractions and estriol was not eluted from the column.[9] The various fractions were collected and dried, and the residue was redissolved in 2 ml of assay buffer. Duplicate aliquots of different volumes of this were used in the assay and 0.1 ml was used for recovery calculations. Blank and control sera (pooled male serum to serve as internal control between assays) were run with each assay. The coefficient of variation between assays had been 5.4% for progesterone, 4.3% for androstenedione, 5.6% for testosterone, 5.8% for dihydrotestosterone, 8.5% for 17α-hydroxyprogesterone, and 8.9% for estradiol. The precision, specificity, and sensitivity for the assay system had been reported previously.[9] ^{3}H-progesterone, ^{3}H-testosterone, and ^{3}H-estradiol were added to amniotic fluid. After extraction, Celite microcolumn chromatography was carried out as previously described with the exception that 1 ml aliquots of the column eluate were collected.

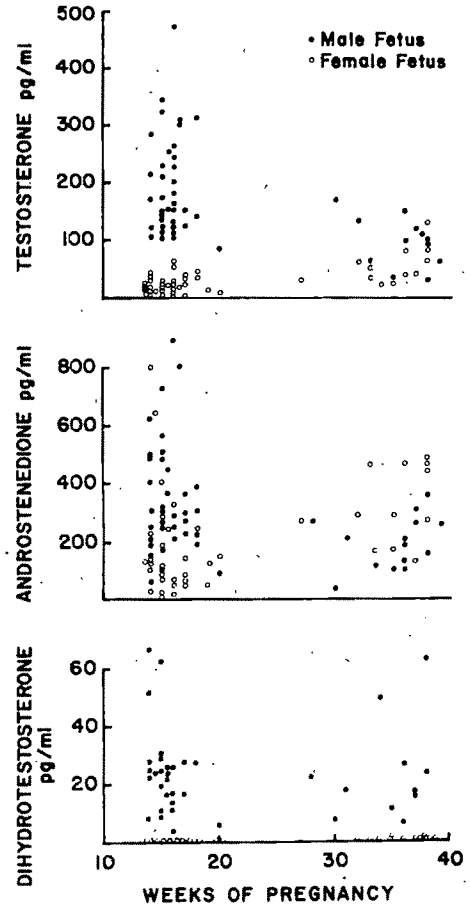

Fig. 1. Concentrations of testosterone, androstenedione, and dihydrotestosterone in amniotic fluid.

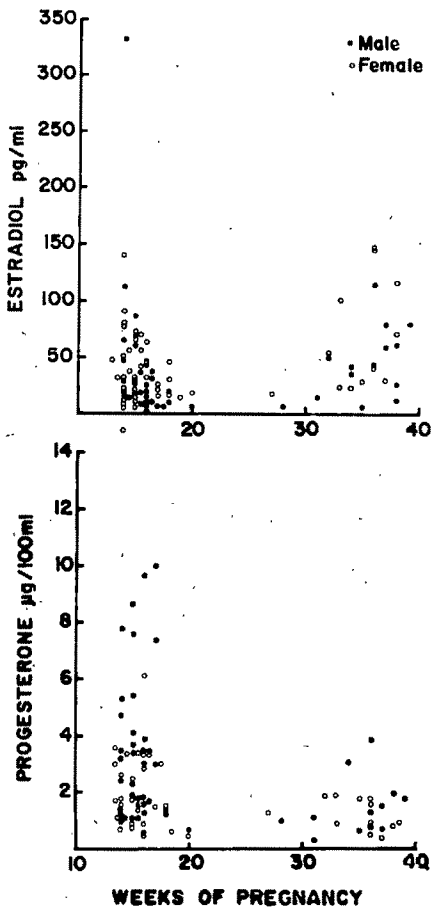

Fig. 2. Concentrations of estradiol and progesterone in amniotic fluid.

There was an excellent correlation between the pattern of radioactivity and immunoassayable material in the fractions in which the above steroids were eluted. Thus, the validation of the method for amniotic fluid was demonstrable.

Results

Amniotic fluid. The mean testosterone concentrations in 101 samples of amniotic fluid are shown in Table I. At all stages of pregnancy, the levels of testosterone were significantly higher when the fetus was male and the difference was significant both in mid-pregnancy and in late pregnancy ($p < 0.001$). Highest levels were noted in the cases of a male fetus at 16 weeks. Between 14 and 20 weeks, the levels of testosterone in pregnancies with male fetuses varied from 0.086 to 0.477 ng/ml (mean 0.188 ± 0.014) and the levels with female fetuses varied from 0.006 to 0.064 ng/ml (mean 0.022 ± 0.002) with no overlap of values (Fig. 1). Toward term, the difference in mean testosterone levels depending on the sex of the fetus persisted, but there was considerable overlap in values (Fig. 1).

The androstenedione levels in the amniotic fluid are also shown in Table I. Between 14 and 20 weeks the levels were significantly higher when the fetus was male than when it was female ($p < 0.001$). Toward term, higher concentrations of androstenedione were present in pregnancies with female fetuses ($p < 0.01$). Although there was a sex difference in the mean levels, there was nevertheless considerable overlap of values between the sexes in all stages of pregnancy (Fig. 1).

Amniotic fluid dihydrotestosterone levels in pregnancies with male fetuses varied from 0.008 to 0.067 ng/ml (mean 0.024 ± 0.003). The levels found between 14 and 20 weeks were not significantly different from those seen close to term. The samples from pregnancies with female fetuses did not have any detectable amounts of dihydrotestosterone (Fig. 1, Table I).

The levels of estradiol in the amniotic fluid are shown in Table I. In all stages of pregnancy, the mean levels were slightly higher in pregnancies with female fetuses than in pregnancies with male fetuses, but the difference was not statistically significant ($p > 0.05$). There was considerable overlap in levels in pregnancies with male fetuses and female fetuses (Fig. 2).

Table II. Amniotic fluid steroids in a pregnancy with a male fetus having congenital adrenal hyperplasia

Weeks of pregnancy	*T (ng/ml)*	*A (ng/ml)*	*DHT (ng/ml)*	*E_2 (ng/ml)*	*P (ng/ml)*	*17α-OHP (ng/ml)*
14	0.22	0.345	0.026	0.106	15	8.23
22	0.606	1.224	—	0.067	15	20.68
28	0.251	0.826	0.040	0.046	20	2.93
34	0.200	—	—	—	—	3.67

Abbreviations: T = testosterone, A = androstenedione, DHT = dihydrotestosterone, E_2 = estradiol, P = progesterone, 17α-OHP = 17α-hydroxyprogesterone.

Table III. Amniotic fluid steroids in a pregnancy with hydatidiform degeneration of placenta

	T (ng/ml)	*A (ng/ml)*	*DHT (ng/ml)*	*E_2 (ng/ml)*	*P (ng/ml)*	*17α-OHP (ng/ml)*
Affected pregnancy	0.129	0.482	0.050	0.466	160.0	6.24
Control	0.022 ± 0.002	0.156 ± 0.029	Undetectable	0.048 ± 0.009	30.1 ± 0.4	1.51 ± 0.1

See Table II for abbreviations.

Progesterone levels in amniotic fluid are shown in Fig. 2 and Table I. The levels were significantly higher ($p < 0.05$) between 14 and 20 weeks than toward term. There was no difference in the levels depending on the sex of the fetus. The 17α-hydroxyprogesterone levels in the amniotic fluid also showed a similar trend with a higher level in early pregnancy ($p < 0.01$; Table I) with no sex difference in the levels.

In the samples of fluid obtained from a patient who subsequently delivered a male fetus affected with congenital adrenal hyperplasia, the concentration of testosterone and androstenedione was higher than the control levels in one sample obtained at 22 weeks, but the levels in other samples were not significantly different from the control levels (Table II). The levels of progesterone, dihydrotestosterone, and estradiol in these samples were within the range of the control samples. However, 17α-hydroxyprogesterone levels were elevated above the control levels in all stages of pregnancy (Table II). The maximum elevation was at 22 weeks of pregnancy.

In the sample of amniotic fluid obtained from a pregnancy in which there was extensive hydatidiform degeneration of the placenta, the level of progesterone, 17α-hydroxyprogesterone, testosterone, dihydrotestosterone, and estradiol were significantly higher than in control samples (Table III). Among the control pregnancies one fetus was found to be mongoloid (trisomy 21) by karyotype of amniotic fluid cells and this pregnancy was subsequently aborted. The steroid levels in the fluid obtained from this pregnancy were within the normal range.

Maternal serum. All the steroids in maternal serum showed progressive increase with increasing duration of gestation. The levels of estradiol varied from 0.6 to 22.6 ng/ml and the levels of progesterone varied from 8.6 to 288.8 ng/ml. Testosterone levels ranged from 0.2 to 3.2 ng/ml with a mean level of 1.01 ± 0.1 ng/ml. Androstenedione levels varied from 1.7 to 21.2 ng/ml with a mean level of 3.29 ± 0.51 ng/ml. The mean levels in pregnancies with male and female fetuses are given in Table IV. We did not find any difference in the levels of these steroids depending on the sex of the fetus. The levels of dihydrotestosterone ranged from 0.04 to 2.02 ng/ml with the mean value of 0.35 ± 0.05 ng/ml. The mean level of dihydrotestosterone in the maternal serum in the pregnancies with male fetuses before 20 weeks was 0.22 ± 0.01 ng/ml which was significantly higher than the mean level of 0.14 ± 0.02 ng noted in pregnancies with female fetuses before 20

Table IV. Levels of steroids in maternal serum

Steroids	*14-20 wk.*	*26-40 wk.*
Testosterone (ng/ml):		
M	0.744 ± 0.08*	0.87 ± 0.2
F	0.935 ± 0.2	1.38 ± 0.3
Androstenedione (ng/ml):		
M	1.87 ± 0.18	3.05 ± 0.9
F	1.6 ± 0.35	6.37 ± 1.8
Dihydrotestosterone (ng/ml):		
M	0.22 ± 0.01	0.42 ± 0.14
F	0.14 ± 0.02†	0.67 ± 0.17
Estradiol (ng/ml):		
M	5.29 ± 0.5	8.26 ± 2
F	4.6 ± 0.6	8.32 ± 2.2
Progesterone (ng/ml):		
M	60.16 ± 9.3	76.73 ± 20
F	51.00 ± 2.4	84.4 ± 24
17-Hydroxyprogesterone (ng/ml):		
M	2.2 ± 0.2	5.2 ± 1.0
F	2.5 ± 0.4	5.6 ± 1.0

M = Pregnancies with male fetus; F = pregnancies with female fetus.

*Mean ± S.E.

†Significantly different from pregnancies with male fetus.

weeks of gestation ($p < 0.02$). There was, however, considerable overlap of values. The concentration of 17α-hydroxyprogesterone in maternal serum before 34 weeks ranged from 0.78 to 4.07 ng/ml with a mean level of 2.6 ± 0.2 ng/ml. There was a twofold increase after 34 weeks with a mean level of 5.4 ± 0.6 ng/ml. The 17α-hydroxyprogesterone level in maternal serum in the pregnancy with the fetus affected with congenital adrenal hyperplasia was significantly higher than the control levels after 34 weeks of pregnancy. The 17α-hydroxyprogesterone levels during pregnancy have been reported by us previously.[25]

Comment

This study compares six steroids in the amniotic fluid of pregnancies with male and female fetuses along with a comparison with steroids circulating in maternal blood. Higher testosterone concentrations in pregnancies with male fetus as compared to female fetus were found with no overlap of values between 14 and 20 weeks of pregnancy. This sex difference persisted in late pregnancy but with considerable overlap of values.

Reyes and associates[10] found significantly higher testosterone levels in the fetal serum when the fetus was male than when it was female. Abramovich and Row[11] found a similar difference in the testosterone concentrations of serum of male and female fetuses between 12 and 18 weeks, but at term there was no significant difference. Our results on amniotic fluid testosterone levels seem to follow the same pattern as that reported for fetal serum. Similar results have been reported recently by Warne and colleagues.[12] Judd and co-workers[13] also found significantly higher levels of testosterone in the amniotic fluid from pregnancies with male fetuses at midterm.

The source of amniotic fluid androstenedione is not very clear. The presence of sex difference in the levels suggests that at least part of this steroid comes from the fetal gonads. In pregnancies with male fetuses we found significantly higher levels of androstenedione between 14 to 20 weeks at which time the fetal testis has been shown to be the site of active steroidogenesis. Robinson and associates[14] have reported similar observations on the sex difference in the levels of androstenedione in midpregnancy. The levels reported by them were three to four times higher than our values. The antiserum for androstenedione used by them was a different one, and no explanation for this difference is available. Close to term, we found significantly higher levels in pregnancies with female fetuses. We are not aware of any report on amniotic androstenedione levels in late pregnancies. Riverola and co-workers[15] did not find any sex difference in the androstenedione levels in the umbilical vein sera of term infants. Payne and Jaffe,[16] by in vitro incubation studies of fetal ovaries with ^{3}H-pregnenolone sulfate, found androstenedione as one of the major C19 metabolite formed by the ovaries, although they failed to detect any estradiol. Fetal adrenals also had been shown to be capable of producing androstenedione.[6]

The third androgen we measured in the amniotic fluid was dihydrotestosterone. Dihydrotestosterone has been shown to be the steroid involved in the differentiation of urogenital sinus to prostate and external genitals. The rate of conversion of testosterone to dihydrotestosterone has been shown to be most rapid in the tissues of urogenital sinus and urogenital tubercle.[1] Significant amounts of dihydrotestosterone were present in the amniotic fluid of pregnancies with male fetuses and it was below the limit of detectability of the assay in the pregnancies with female fetuses. Dawood and Saxena[17] were not able to find any dihydrotestosterone amniotic fluid.

Robinson and colleagues[14] found significantly higher amniotic fluid estradiol concentration in pregnancies with female fetuses at midterm. In addition, the levels of estradiol reported by them were higher than ours. We did not find any significant sex difference in the levels of this steroid and the reason for the discrepancy is not clear at this time. The source of estradiol in the amniotic fluid is still speculative. Payne and Jaffe,[16] by in vitro incubation studies with radioactive precursors, failed to detect any estradiol in the fetal ovaries. Reyes and associates[6] found little or no estradiol in the fetal testis, ovaries, or adrenals. Fetal granulosa cells lacked ultrastructural features associated with steroidogenic activity,[18] and theca interna, a principal source of steroid hormones in the mature ovary, does not differentiate until the follicle development is well established. It seems likely that placenta is probably the principal source of the estradiol in the amniotic fluid.

Progesterone levels in amniotic fluid were higher between 14 and 20 weeks of pregnancy than toward term, with no sex difference in the levels. Our results are comparable to those of Warne and associates[12] with the exception that the decrease in progesterone at term observed by them in pregnancies with male fetuses was not observed by us. Hageman and Kittinger[19] reported that the progesterone concentrations in the umbilical vein were always higher than in the umbilical artery. Billair and co-workers[20] injected ^{3}H-pregnenolone sulfate during midgestation and reported 50% extraction of progesterone by the fetus. Placenta via the fetus is probably the principal source of progesterone in the amniotic fluid. Hageman and Kittinger[19] found that the progesterone concentrations in the umbilical vein at term did not show any sex difference but the umbilical arteriovenous difference at term was higher for fe-

male fetuses than for male fetuses. These authors speculated that the female fetuses seem to metabolize progesterone to a greater extent than male fetuses.

Attempts had been made to diagnose congenital adrenal hyperplasia in utero by measuring different steroids like 17-ketosteroids and pregnanetriol in the amniotic fluid but the results have not been uniform.[21, 22] Frasier and associates[23] have reported that testosterone concentrations in the amniotic fluid from a pregnancy in which the fetus was affected with congenital adrenal hyperplasia were within the range found in control pregnancies. This is in agreement with our results of normal testosterone levels in the affected pregnancy with the exception of the sample at 22 weeks of pregnancy. Measurement of 17α-hydroxyprogesterone levels in the amniotic fluid had been shown to be more promising in the prenatal diagnosis of this disorder.[24, 25]

Previous reports on steroidogenic function of trophoblastic tissue in molar pregnancy are limited. Toeh and co-workers[26] found very high concentrations of progesterone in the mole vesicular fluid. Dawood and co-workers[27, 28] have reported elevated levels of progesterone and estradiol in maternal peripheral blood. Presently we do not have any data available on the levels of androgenic steroids in molar tissue. We found elevated levels of progesterone, estradiol, testosterone 17α-hydroxyprogesterone, and dihydrotestosterone in the amniotic fluid from the pregnancy which ended in an abortion and showed extensive hydatiform degeneration of the placenta (Table III).

The mean level of testosterone in the maternal serum is comparable to the levels reported by other investigations during pregnancy.[29] This increase could be explained by the increased steroid-binding globulin levels during pregnancy and increased binding. The production rate of testosterone during pregnancy had been shown to be not significantly different from the rate seen in nonpregnant state while the metabolic clearance rate is significantly reduced because of increased binding.[30] The level of androstenedione was also higher in the pregnant serum compared to the levels noted in cycling females.[9] Gandy[31] found similar increased levels of androstenedione during pregnancy, while Rivarola and associates[15] did not find any significant increase.

Dihydrotestosterone was also found in higher concentrations during pregnancy than in the nonpregnant state.[9] The production rate of dihydrotestosterone had been reported to be similar in pregnant and cycling women.[31] It is interesting to find increased levels of dihydrotestosterone in the maternal peripheral blood in pregnancies with male fetus than in pregnancies with female fetuses. This raises the possibility that the fetus might be contributing to some of this steroid in the maternal serum. It is hard to explain why this difference did not persist throughout the late stages of pregnancy.

Another steroid in the maternal serum to which the fetus seems to contribute significantly is 17α-hydroxyprogesterone in later stages of pregnancy. This is shown by the fact that increased levels were found in our patient with congenital adrenal hyperplasia and marked fall in levels were noted by Tulchinsky and Simmer[32] in anencephaly and intrauterine death of the fetus.

Our results on the levels of progesterone in the maternal serum are comparable to the levels reported by other investigators.[33, 34] It is fairly well established that placenta is the main site of progesterone production in mid- and late pregnancy.[35, 36] Estradiol is mainly produced by the placenta by way of aromatization of androgenic steroids. Tulchinsky and Korenman[37] found that maternal dehydroepiandrosterone sulfate contributed to 60% of estradiol that is formed during pregnancy. Lindberg and associates[38] measured the estradiol and estriol levels in ten healthy pregnant women and the levels reported by these authors are close to our results.

In conclusion, the maternal compartment does not seem to contribute significantly to the steroids in amniotic fluid since we did not find any correlation between the levels in the maternal serum and amniotic fluid. Several steroids in the amniotic fluid were found in higher concentration in early pregnancy (taking into account the sex of the fetus) while the levels in the maternal serum showed increasing levels with increasing duration of gestation. Since the concentration of steroids found in the amniotic fluid does not correlate with the levels in maternal serum, it leads to the speculation that the fetus is probably the major source of various steroids in the amniotic fluid. There are two possible explanations for the observations of higher concentration of steroids in the amniotic fluid in midpregnancy than in late pregnancy. First, the increased concentrations may indicate increased production of these steroids by the fetus at the critical period of sexual differentiation in midpregnancy. Second, it may be due to the difference in the sources of the amniotic fluid in different stages of pregnancy. In early pregnancy, the steroids possibly enter the amniotic fluid by way of passive diffusion through the fetal skin at which time the steroid levels in the amniotic fluid may closely reflect the levels in the fetal serum. After 20 weeks, the fetal skin gradually becomes thick and cornified and fetal urine becomes an important source. Studies are now underway to correlate the steroid levels in umbilical cord blood and amniotic fluid.

Effect of stress during labor on the concentration of cortisol and estriol in maternal plasma

J. M. MALTAU, M.D.
O. V. EIELSEN, M.D.
K. T. STOKKE, M.D.
Oslo, Norway

The effect of stress during labor on the plasma concentration of cortisol, unconjugated estriol, and human chorionic somatomammotropin was studied in 15 healthy primiparous women. According to the method of pain relief the parturients were divided into two groups. One group was given continuous epidural analgesia and the other group received pethidine, diazepam, and nitrous oxide/oxygen in response to pain. In the most stressed nonepidural group there was a significant rise in the cortisol level during labor and the estriol concentration fell significantly. In the epidural group no significant changes were observed with respect to the concentration of either cortisol or estriol. These results give further support to the hypothesis that severe maternal stress may lead to a reduced concentration of estriol in maternal plasma. (AM. J. OBSTET. GYNECOL. 134:681, 1979.)

DETERMINATION of unconjugated estriol in maternal plasma has gained wide acceptance as a fetoplacental function test.[1] Fetoplacental insufficiency, however, is not the only factor influencing the estriol production. For instance, it has been shown that administration of corticosteroids to the mother leads to a marked suppression of the synthesis of estriol precursors.[2]

Stress during labor is known to stimulate the maternal hypothalamic-pituitary-adrenal axis.[3] This leads to an increased concentration of cortisol in maternal plasma. The present study was undertaken to see if pain-induced stress during labor is of importance for estriol production. The cortisol-estriol levels were determined during pain-free labor with the use of continuous epidural analgesic drugs as well as during labor with partial relief of pain by conventional central-acting analgesic drugs.

Material and methods

Fifteen healthy primiparous patients (21 to 37 years old) were studied during spontaneous labor. The gestational ages varied from 37 to 42 weeks. All pregnancies were uncomplicated and the study was restricted to labors starting in the morning. Oxytocin was not given. Informed consent was obtained before patients entered the study. Due to ethical reasons strict randomization was omitted. All patients knew and had chosen the method of analgesia to be utilized. The eight patients in the nonepidural group (conventional analgesia) received pethidine, 100 mg intramuscularly, as a single agent or in combination with diazepam, 10 mg orally. A 50/50 mixture of nitrous oxide and oxygen was available for self-administration. A transvaginal pudendal block was given during the second stage of labor. One of the patients did not accept central-acting analgesic or sedative drugs.

The seven parturients in the epidural group received a continuous epidural analgesic drug according to our standard technique[4] early in the first stage of labor. Bupivacaine without adrenaline (Marcain, A/B Astra), 0.25%, was injected into the epidural space through an indwelling catheter. The initial dose of bupivacaine was 25 mg. Top-up doses varying from 12 to 25 mg were administered according to the need of each patient. Other analgesics or sedatives were not given.

The mean duration of labor (from admittance to delivery) was about 14 hours in both groups (range 8 to 19 hours). All neonates were healthy with Apgar scores of 9 or 10 at 5 minutes. Birth weight and placental weight were within normal ranges.

Blood samples for determination of estriol, cortisol,

‡Significance of difference from the initial level: $p < 0.05$

and human chorionic somatomammotropin (hCS) were drawn from an antecubital vein into heparinized tubes at the following stages: (1) at a cervical dilatation of 1 to 5 cm, (2) at a cervical dilatation of 6 to 8 cm, (3) at a cervical dilatation of 10 cm, and (4) 30 minutes after delivery.

The first sample in the epidural group was taken before the analgesic drug was administered. Plasma was immediately separated from the corpuscles and stored at −20° C until analyzed.

Hormone analyses. All samples were run in duplicate, and the complete series of samples from one patient was analyzed in the same run. The concentration of unconjugated estriol in plasma was determined by radioimmunoassay principally according to the method of Goebelsmann and associates.[5] Own antiserum directed against 6-keto-estriol 6-carboxy-methoxime: bovine serum albumin was used. No chromatographic purification of the diethyl ether extract was performed since cross-reaction with other steroids was insignificant. The coefficient of variation (CV) (between assays) for estriol analysis was 10%. Cortisol in plasma was determined by double-antibody radioimmunoassay technique with reagents purchased from Diagnostic Products Corporation. The CV of the analysis was 8%. The plasma concentration of hCS was determined by the HPL immunoassay kit supplied by The Radiochemical Centre, Amersham, England; the CV was 7%.

Statistical method. The Wilcoxon two-sample test was used.

Results

Cortisol. The concentration of cortisol in each patient at the different stages of labor is shown in Fig. 1. Table I gives the statistical data. In the "stressed" nonepidural group there was a significant increase in plasma cortisol level from the initial value early in labor to the second stage ($p < 0.05$). Two of the patients in this group had suffered some pain before the first blood sample was obtained. This is reflected in a high initial concentration of cortisol, especially in one of these patients.

In the epidural group there was a slight and insignificant increase in cortisol. In two of the parturients there was an actual fall in cortisol concentration during labor. None of the parturients who received the epidural analgesic drug had been noticeably stressed before entering the study.

Estriol. Fig. 2 shows the concentration of unconjugated estriol in maternal plasma at the different stages. The statistical data are given in Table I.

During labor there was a significant fall in estriol

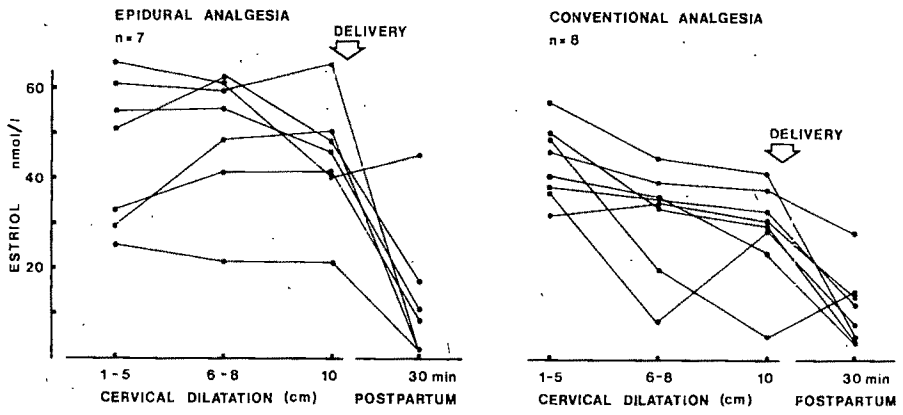

Fig. 2. Plasma concentration of unconjugated estriol at different stages of labor. Left: Patients receiving continuous epidural analgesic drug. Right: Patients receiving conventional analgesic drug.

($p < 0.01$) in the nonepidural group. In the "unstressed" group the range was wider and the changes less consistent. The mean values at the different stages of labor were, however, almost constant. Statistical analysis revealed no significant influence on the estriol concentration in the epidural group.

Determination of hCS was introduced as a parameter of the placental function. The plasma concentration was within the normal range and there was no significant difference between the two groups.

Comment

During labor and delivery a considerable rise in the production of cortisol may occur, usually more marked in primiparous than in multiparous patients.[6] Pain is one of the several stimuli known to initiate such a rise.[7] In a recent study[8] we have shown that the intramuscular administration of a single dose of a synthetic corticosteroid (betamethasone, 12 mg) leads to a more than 50% reduction in the estriol concentration in maternal plasma within 4 hours. This effect may be due to cortisol inhibition of the synthesis of fetal adrenocorticotropic hormone (ACTH), subsequently reducing the production of estriol precursors, mainly 16α-hydroxydehydroepiandrosterone in the fetal adrenal cortex.[9]

In the present study the two groups of patients differed from each other only with respect to the type and efficiency of pain relief. In other respects the groups were very similar, including the placental function as judged by the concentration of hCS.

A considerable difference in the cortisol response during labor and delivery was observed. In the "stressed" nonepidural group there was a marked and significant rise in the cortisol level. In the epidural group, however, only a slight and nonsignificant rise was observed. This is in concert with the results presented by Thornton and associates[7] who found that continuous epidural analgesia was able to block the adrenocortical response to stress only to a certain extent.

A fall in the concentration of unconjugated estriol was observed in every patient in the nonepidural group. In fact, the patient with the highest cortisol value also displayed the lowest estriol level. In the epidural group no significant change was observed in the estriol concentration. In a similar study Okada and colleagues[10] also found a significant increase in cortisol during labor, whereas the decreases in the plasma concentration of estriol was not significant ($p > 0.05$). In our study, however, a significant fall in estriol was observed in the stressed group ($p < 0.01$). The difference between these two studies may be due to differences in parity, in the duration of labor, and in the type of analgesia.

Simmer and associates[2] found that administration of 150 mg cortisol intravenously in three divided doses led to a sixfold increase in the plasma concentration of cortisol. This increase was followed by a reduction in maternal plasma concentration of estriol. In our study the parturients being most stressed (the nonepidural group) showed a threefold increase in cortisol as compared to the level seen in normal third-trimester pregnancies.[8] Thus labor may induce a rise in the concentration of cortisol high enough to suppress fetal ACTH production and thereby also estriol synthesis. When pain is relieved by means of epidural analgesia, this effect is less pronounced. The present investigation, therefore, supports the hypothesis that an increased maternal cortisol concentration may suppress the production of estriol. This mechanism has also been suggested as an explanation of diurnal variations of estriol.[11]

The study indicates that severe maternal stress in pregnancy may have to be considered when estriol is used as a fetoplacental function test.

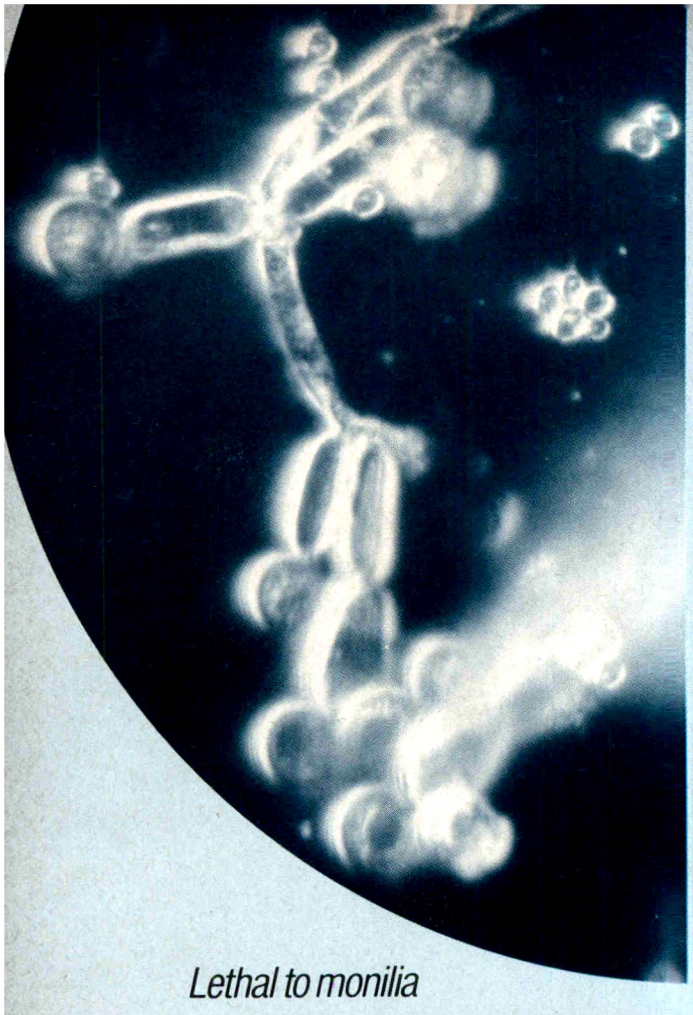
Natafort®

In each reformulated Natafort Filmseal Tablet:

Vitamin A (acetate) (1.8 mg)	6,000 IU*
Vitamin D (ergocalciferol) (10 mcg)	400 IU*
Vitamin C (ascorbic acid)	120 mg
Vitamin B_1 (thiamine mononitrate)	3 mg
Vitamin B_2 (riboflavin)	2 mg
Vitamin B_6 (pyridoxine hydrochloride)	15 mg
Vitamin B_{12} (cyanocobalamin), crystalline	6 mcg
Folic Acid†	1 mg
Nicotinamide (niacinamide)	20 mg
Vitamin E (*dl*-alpha tocopheryl acetate) (30 mg)	30 IU*
Calcium (as calcium carbonate)	350 mg
Iodine (as potassium iodide)	0.15 mg
Iron (as ferrous fumarate)	65 mg
Magnesium (as magnesium oxide)	100 mg
Zinc (as zinc oxide)	25 mg
Dioctyl sodium sulfosuccinate	50 mg



*IU = International Units

†CAUTION—Folic acid may obscure pernicious anemia; the peripheral blood picture may revert to normal while neurological manifestations remain progressive.

USUAL DOSE: One tablet daily.

CAUTION—Federal law prohibits dispensing without prescription.

BETTER THAN EVER... NATAFORT

Lethal to monilia

Gentle to patients

IN MONILIASIS

BETADINE® Microbicides Vaginitis Regimen

High cure rate... rapid symptomatic relief

High cure rate is achieved in monilial vaginitis with the topical regimen employing BETADINE Microbicides:

BETADINE® SOLUTION
BETADINE® VAGINAL GEL*
(povidone-iodine)
BETADINE® DOUCHE

Easy-to-follow regimen

In the office, swab the cervix and vulvovaginal area with BETADINE Solution which is promptly and decisively microbicidal. Prescribe BETADINE Vaginal Gel (povidone-iodine), one applicatorful of which is to be inserted each night, followed the next morning by BETADINE Douche in therapeutic concentration.

After 2 weeks

The patient returns for an office visit after two weeks of therapy. In more resistant cases, the regimen may have to be continued through 1 or 2 cycles. BETADINE Microbicides are virtually nonirritating to vaginal mucosa and do not stain skin and natural fabrics.

Lethal to other vaginal pathogens too

The broad-spectrum microbicidal action of BETADINE Microbicides kills not only monilia, but also *Trichomonas* and *Hemophilus vaginalis*. Unlike exclusively antimonilial agents, the BETADINE MICROBICIDES VAGINITIS REGIMEN is not contraindicated when *Trichomonas* or *H. vaginalis* is present.

BETADINE Microbicides kill both gram-positive and gram-negative bacteria (including antibiotic-resistant strains), fungi, viruses, protozoa and yeasts. Their microbicidal action is maintained in the presence of blood, serum, and vaginal secretions.

*BETADINE Vaginal Gel (povidone-iodine) has been evaluated as possibly effective for use in the management of *Trichomonas vaginalis* vaginitis, monilial vaginitis and nonspecific vaginitis.

Purdue Frederick

See adjoining page for brief summary.

Now availab e...
BETADINE® Douche Kit

For douching in the BETADINE Microbicides Vaginitis Regimen, you can now prescribe BETADINE Douche Kit for a complete douching system, or BETADINE Douche 8 oz. for use with a gravity-flow douche bag o bulb syringe.

BETADINE Douche Kit contains:

(1) BETADINE Douche concentrate for making the douche solution
(2) Comfortable-to-use, squeezable, plastic syringe bottle
(3) Anatomically-correct cannula
(4) Instruction booklet
— Complete, ultra-modern, convenient douching system
— Provides the benefits of microbicidal BETADINE Douche

For a therapeutic concentration using BETADINE Douche Kit, instruct the patient to: Pour one (1) tablespoonful of BETADINE Douche concentrate into the syringe bottle provided in the kit. Add lukewarm water up *to the top of the syringe bottle.* Attach nozzle and shake gently to mix. Douche, *then repeat the procedure.*

For a therapeutic concentration using BETADINE Douche 8 oz., instruct the patient to: Add two (2) tablespoonfuls to a quart of lukewarm water, for use with a gravity-flow douche bag or bulb syringe.

BETADINE® Vaginal Gel (povidone-iodine) Brief Summary

For use in the treatment of Trichomonas vaginalis vaginitis, monilial vaginitis and nonspecific vaginitis.

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows: possibly effective for use in the management of trichomonas vaginalis vaginitis, monilial vaginitis and nonspecific vaginitis. Final classification of the less-than-effective indications requires further investigation.

Precaution

If irritation, redness or swelling develops, discontinue use. The rare individual with history of iodine sensitization should not use this product, pending further investigation.

FACULTY POSITIONS

There are currently openings for full-time faculty in Obstetrics and Gynecology who have Board certification or eligibility. Teaching, research and patient care interests important. Special training and expertise in maternal and fetal medicine, reproductive endocrinology, gynecologic oncology or ambulatory care is desired. Academic rank and salary are dependent on qualifications. If interested, please send curriculum vitae and bibliography to:

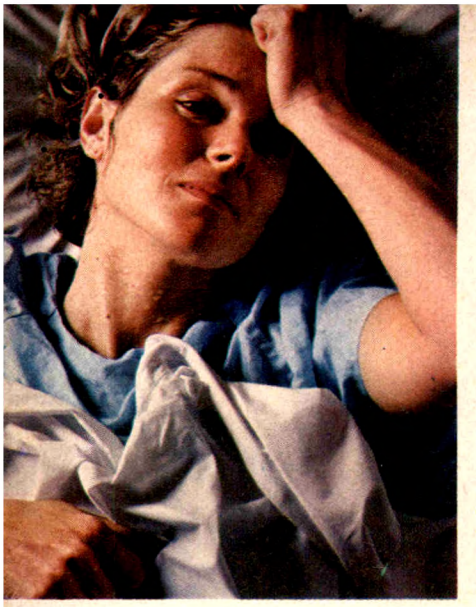
William N. Spellacy, M.D.
Professor and Head
Department of Obstetrics & Gynecology
Abraham Lincoln School of Medicine
University of Illinois Medical Center
840 South Wood Street
Chicago, Illinois 60612

(Affirmative Action/Equal Opportunity Employer)

GROUP PRACTICE OPPORTUNITIES PACIFIC NORTHWEST

Rapid growth in the metropolitan area of Portland, Oregon has created immediate openings in the Department of Obstetrics and Gynecology. We are seeking obstetrician/gynecologists and/or perinatologists to join an active service with over 3,700 deliveries per year, a high risk intensive care nursery and complete fetal monitoring equipment.

Northwest Permanente, P.C. is a professional medical corporation which provides health care services to the 220,000 members of the Kaiser Foundation Health Plan of Oregon. Through its association with Kaiser Foundation Health Plan, a federally qualified HMO, Northwest permanente, P.C. operates nine outpatient clinics and two full service hospitals.



The medical practice is varied and professionally stimulating offering the physician a pure practice free of business and administrative concerns. A comprehensive salary and benefits package including a sabbatical program, malpractice coverage, three weeks vacation and one week educational leave to start, life, medical/dental and disability insurance along with two excellent retirement programs is provided. The physician is eligible for ownership participation after two years of service.

Portland, Oregon, on the Columbia and Willamette Rivers, is a city with a moderate climate located in a stable, prosperous economic region of the beautiful Northwest. Outdoor recreational facilities are superb and include excellent skiing, backpacking, fishing and boating opportunities. The Environmental Protection Agency, in a recent study, selected Portland as the "most livable city" in the United States.

Please send a curriculum vitae with your initial response to Marvin P. Goldberg, M.D., President, Northwest Permanente, P.C., 1500 S. W. 1st Avenue, 11th Floor, Portland, Oregon, 97201.

NORTHWEST PERMANENTE, P.C.-
PHYSICIANS & SURGEONS

An Equal Opportunity Employer

IN THE SURGICAL MENOPAUSE:

Possibly the most convincing reasons for using Premarin®

...are the years after surgery.

Severe vasomotor symptoms following surgical menopause: in the patient without contraindications, estrogen replacement is clearly indicated now...and to prevent the progressive debilitating effects of prolonged estrogen deficiency.

For the younger, oophorectomized woman, the deferred symptoms of postmenopausal bone loss* and its painful sequelae may appear at a needlessly early age. PREMARIN may retard this loss and avert the accompanying pain, muscle contracture, and kyphosis.

Although endometrial stimulation is not a concern in the hysterectomized patient, PREMARIN should still be administered cyclically at the lowest effective dose.

PREMARIN. Frequently indicated after surgery...a growing part of the routine.

PREMARIN®
(CONJUGATED ESTROGENS TABLETS, U.S.P.)
0.3 mg/0.625 mg/1.25 mg/2.5 mg

FOR THE SHORT- AND LONG-TERM CONSEQUENCES OF SURGICAL MENOPAUSE

*Conjugated Estrogens Tablets have been evaluated as probably effective for postmenopausal osteoporosis.

See last page of this advertisement for prescribing information.

TERIOR FLA
PAINT

BRIEF SUMMARY
(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULAR)

PREMARIN® Brand of Conjugated Estrogens Tablets, U.S.P.

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.

Three independent case control studies have reported an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for more than one year.[1-3] This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade.[4] The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment[1] and on estrogen dose.[3] In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration;[3] it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.

The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a non-steroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare.[5,6] This risk has been estimated as not greater than 4 per 1000 exposures.[7] Furthermore, a high percentage of such exposed women (from 30 to 90 percent) have been found to have vaginal adenosis,[8-12] epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb reduction defects.[13-16] One case control study[16] estimated a 4.7-fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 per 1000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well controlled studies that progestogens are effective for these uses. If PREMARIN is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the advisability of pregnancy continuation.

DESCRIPTION: PREMARIN (Conjugated Estrogens Tablets, U.S.P.) for oral administration contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters.

INDICATIONS: Based on a review of PREMARIN Tablets by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications for use as follows:

Effective:

1. Moderate to severe *vasomotor* symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression without associated vasomotor symptoms, and they should not be used to treat such conditions.)
2. Atrophic vaginitis.
3. Kraurosis vulvae.
4. Female hypogonadism.
5. Female castration.
6. Primary ovarian failure.
7. Breast cancer (for palliation only) in appropriately selected women and men with metastatic disease.
8. Prostatic carcinoma—palliative therapy of advanced disease.
9. Postpartum breast engorgement—Although estrogens have been widely used for the prevention of postpartum breast engorgement, controlled studies have demonstrated that the incidence of significant painful engorgement in patients not receiving such hormonal therapy is low and usually responsive to appropriate analgesic or other supportive therapy. Consequently, the benefit to be derived from estrogen therapy for this indication must be carefully weighed against the potential increased risk of puerperal thromboembolism associated with the use of large doses of estrogens.[19]

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

"Probably" effective: For estrogen deficiency-induced osteoporosis, and only when used in conjunction with other important therapeutic measures such as diet, calcium, physiotherapy, and good general health-promoting measures. Final classification of this indication requires further investigation.

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 2. Known or suspected estrogen-dependent neoplasia. 3. Known or suspected pregnancy (See Boxed Warning). 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. A past history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

WARNINGS: At the present time there is no satisfactory evidence that estrogens given to postmenopausal women increase the risk of cancer of the breast,[17] although a recent study has raised this possibility.[18] There is a need for caution in prescribing estrogens for women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease, or abnormal mammograms. A recent study has reported a 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease in women receiving postmenopausal estrogens.[17]

Adverse effects of oral contraceptives may be expected at the larger doses of estrogen used to treat prostatic or breast cancer or postpartum breast engorgement; it has been shown that there is an increased risk of thrombosis in men receiving estrogens for prostatic cancer and women for postpartum breast engorgement.[19-22] Users of oral contraceptives have an increased risk of diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction.[23-30] Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users.[31,32] An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives.[33,34] If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization. Estrogens should not be used in persons with active thrombophlebitis, thromboembolic disorders, or in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease. Large doses (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown[35] to increase the risk of nonfatal myocardial infarction, pulmonary embolism and thrombophlebitis. When doses of this size are used, any of the thromboembolic and thrombotic adverse effects should be considered a clear risk.

Benign hepatic adenomas should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Hepatocellular carcinoma has been reported in women taking estrogen-containing oral contraceptives.[36] Increased blood pressure may occur with use of estrogens in the menopause[37] and blood pressure should be monitored with estrogen use. A worsening of glucose tolerance has been observed in patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolau smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc. Oral contraceptives appear to be associated with an increased incidence of mental depression.[23a] Patients with a history of depression should be carefully observed. Preexisting uterine leiomyomata may increase in size during estrogen use. The pathologist should be advised of estrogen therapy when relevant specimens are submitted. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, metabolic bone diseases associated with hypercalcemia, or in young patients in whom bone growth is not complete.

The following changes may be expected with larger doses of estrogen:

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered.

d. Impaired glucose tolerance.

e. Decreased pregnanediol excretion.

f. Reduced response to metyrapone test.

g. Reduced serum folate concentration.

h. Increased serum triglyceride and phospholipid concentration.

As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy, including oral contraceptives: breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea; premenstrual-like syndrome; amenorrhea during and after treatment; increase in size of uterine fibromyomata; vaginal candidiasis, change in cervical erosion and in degree of cervical secretion; cystitis-like syndrome; tenderness, enlargement, secretion (of breasts); nausea, vomiting, abdominal cramps, bloating; cholestatic jaundice; chloasma or melasma which may persist when drug is discontinued; erythema multiforme; erythema nodosum; hemorrhagic eruption; loss of scalp hair, hirsutism; steepening of corneal curvature; intolerance to contact lenses; headache, migraine, dizziness, mental depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea, and withdrawal bleeding may occur in females.

DOSAGE AND ADMINISTRATION: 1. *Given cyclically for short term use only:* For treatment of moderate to severe *vasomotor* symptoms, atrophic vaginitis, or kraurosis vulvae associated with the menopause (0.3 to 1.25 mg or more daily).

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Administration should be cyclic (*e.g.* three weeks on and one week off).

Attempts to discontinue or taper medication should be made at three to six month intervals.

2. *Given cyclically:* Female hypogonadism. Female castration. Primary ovarian failure. Osteoporosis.

Female hypogonadism—2.5 to 7.5 mg daily, in divided doses for 20 days, followed by a rest period of 10 days' duration. If bleeding does not occur by the end of this period, the same dosage schedule is repeated. The number of courses of estrogen therapy necessary to produce bleeding may vary depending on the responsiveness of the endometrium.

If bleeding occurs before the end of the 10 day period, begin a 20 day estrogen-progestin cyclic regimen with PREMARIN (Conjugated Estrogens Tablets, U.S.P.), 2.5 to 7.5 mg daily in divided doses, for 20 days. During the last five days of estrogen therapy, give an oral progestin. If bleeding occurs before this regimen is concluded, therapy is discontinued and may be resumed on the fifth day of bleeding.

Female castration and primary ovarian failure—1.25 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Osteoporosis (to retard progression)—1.25 mg daily, cyclically.

3. *Given for a few days:* Prevention of postpartum breast engorgement—3.75 mg every four hours for five doses, or 1.25 mg every four hours for five days.

4. *Given chronically:* Inoperable progressing prostatic cancer—1.25 to 2.5 mg three times daily.

Inoperable progressing breast cancer in appropriately selected men and postmenopausal women—10 mg three times daily for a period of at least three months.

Patients with an intact uterus should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

HOW SUPPLIED: PREMARIN (Conjugated Estrogens Tablets, U.S.P.) No. 865—Each *purple* tablet contains 2.5 mg in bottles of 100 and 1,000. No. 866—Each *yellow* tablet contains 1.25 mg in bottles of 100 and 1,000. Also in unit dose package of 100. No. 867—Each *red* tablet contains 0.625 mg in bottles of 100 and 1,000. Also in unit dose package of 100. No. 868—Each *green* tablet contains 0.3 mg in bottles of 100 and 1,000.

The relationship of heart rate patterns and tissue pH in the human fetus

BRUCE K. YOUNG, M.D.*
MIRIAM KATZ, M.D.
STEVEN A. KLEIN, M.D.
New York, New York

The relationship between different FHR patterns and fetal tissue pH in 68 high-risk gravidas in labor was analyzed. A tissue pH electrode was placed in the fetal scalp and tissue pH recorded on a fetal monitor every 15 seconds along with uterine contractions and continuous fetal heart rate. The tissue pH changes correlated with the FHR patterns in a manner consistent with current concepts of fetal stress. Trend monitoring of fetal tissue pH in labor may prove useful in the management of high-risk patients in labor. (AM. J. OBSTET. GYNECOL. 134:685, 1979.)

PERINATAL MEDICINE has accepted continuous fetal heart rate (FHR) monitoring and fetal scalp blood sampling as an optimal approach to the assessment of fetal well-being in labor. Recent work has demonstrated the feasibility of continuous tissue pH (TpH) measurement in the human fetus during labor.[1, 2] This investigation focuses on the effects of different FHR patterns on the fetal TpH in 68 high-risk patients.

Material and methods

A miniature glass pH electrode with a self-contained reference solution† was utilized, as described by Stamm and associates.[3] The electrode is held in place by a specially designed double-spiral ECG electrode (Fig. 1). This system, connected to a recording device, permits display of the TpH every 15 seconds, along with FHR and uterine contractions. The technique of application begins with the introduction of a modified amnioscope into the cervix with the use of sterile procedure. The fetal scalp is cleansed with Pharmadine,* and a scalp blood sample is obtained in the conventional manner. The spiral ECG electrode is then secured to the fetal scalp with an electrode forceps. The standard pH knife is then used to make a 2 by 2 mm incision in the fetal scalp through the central opening in the ECG electrode. The TpH electrode is then inserted into the fetal subcutaneous tissue through the scalp incision and held in place by the ECG electrode. Periodic scalp blood samples were taken during labor, and at delivery umbilical artery and vein pH were measured as well. All blood pH (BpH) samples were assayed by means of a microanalyzer.†

Results

Continuous pH monitoring was attempted on 68 high-risk patients at 38 to 40 weeks' gestation, in whom

Deceleration with late component	14	0	13	1	93
Tachycardia	5	0	3	2	60

Table III. Low Apgar scores: comparison of blood and tissue pH

Diagnosis	FHR patterns	Average change with decelerations		Delivery			Apgar
		TpH	BpH	TpH	UA	UV	
Abruptio placentae	Deceleration, late component	−0.03	−0.01	7.20	7.30	7.32	5/7
Toxemia, nuchal cord	Deceleration, late component	−0.02	0	7.38	7.39	7.38	6/8
Amnionitis	Deceleration, late component, tachycardia	−0.05	−0.06	7.19	7.21	7.20	6/9

scalp blood sampling was clinically indicated, and informed consent was obtained. There were 55 cases in which data were in the physiologic range, and these were used for the study.

The TpH usually was lower than the BpH, with the average BpH-TpH difference −0.04 pH units. The data were plotted in a scattergram to compare BpH and TpH by linear regression analysis (Fig. 2). The correlation coefficient is 0.63, $p < 0.01$, a significant positive correlation. Further regression analysis by Spearman's rank correlation coefficient, used for nonrandom distributions such as might be expected for a

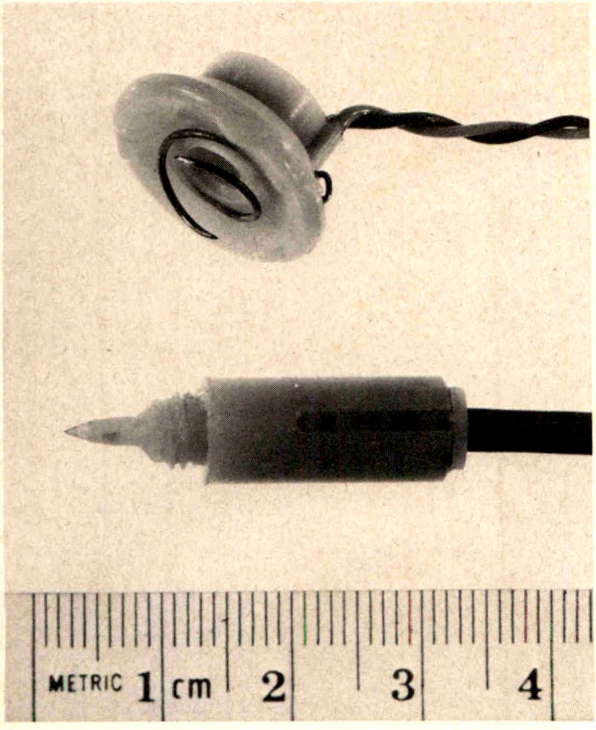

Fig. 1. The ECG electrode is seen above the pH electrode.

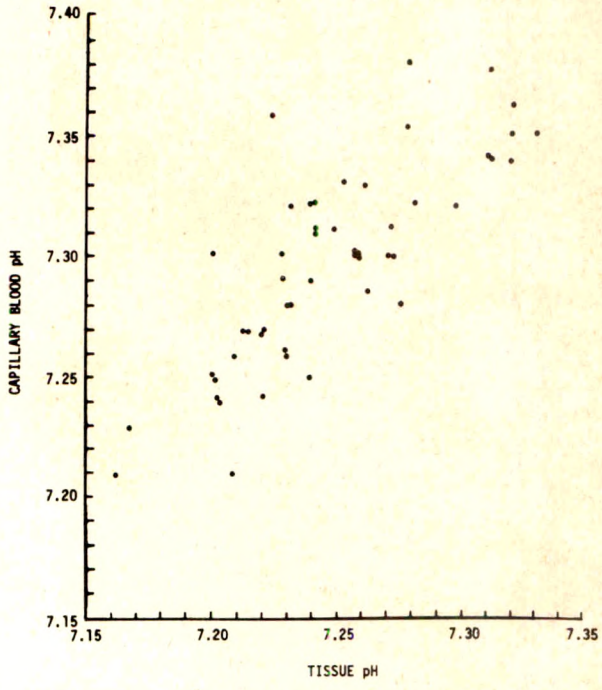

Fig. 2. Tissue pH vs. capillary blood pH in the fetal scalp. The tissue pH is shown on the horizontal scale and the blood pH on the vertical scale.

series of high-risk pregnancies, revealed rS = 0.74, $p < 0.001$, a highly significant correlation. The standard error of the estimate was 0.0354, within the range seen with scalp blood sampling alone.[4, 5] Comparison of umbilical artery and TpH by similar statistical analysis showed r = 0.73, $p < .001$, rs = 0.63, $p < .01$ (Fig. 3).

Uterine contractions were associated with no change or a slight rise in TpH in the absence of FHR changes. There was a relative fall of the TpH as labor progressed, on the order of −0.01 pH units per hour, not seen with BpH. At present it cannot be determined if the fall in the TpH is a real change or due to in vivo drift of the tissue pH electrode, which may occur at rates up to −0.005 pH units per hour. The TpH reflected FHR changes within 2 or 3 minutes (Figs. 4*A*, 4*B*, and 4*C*). The average TpH during the period of FHR change was correlated with the relative pathologic nature of the FHR change (Fig. 5). The lowest average TpH was seen during tachycardia and decelerations with a late component; the highest was seen during accelerations and the normal and relatively benign FHR patterns (Table I). When the effect of FHR changes on TpH in individual cases is considered, the relationships are further elucidated (Table II). TpH changes of 0.02 pH units or greater from the baseline TpH just before the FHR change were considered significant. The TpH changes reflect the relative serious-

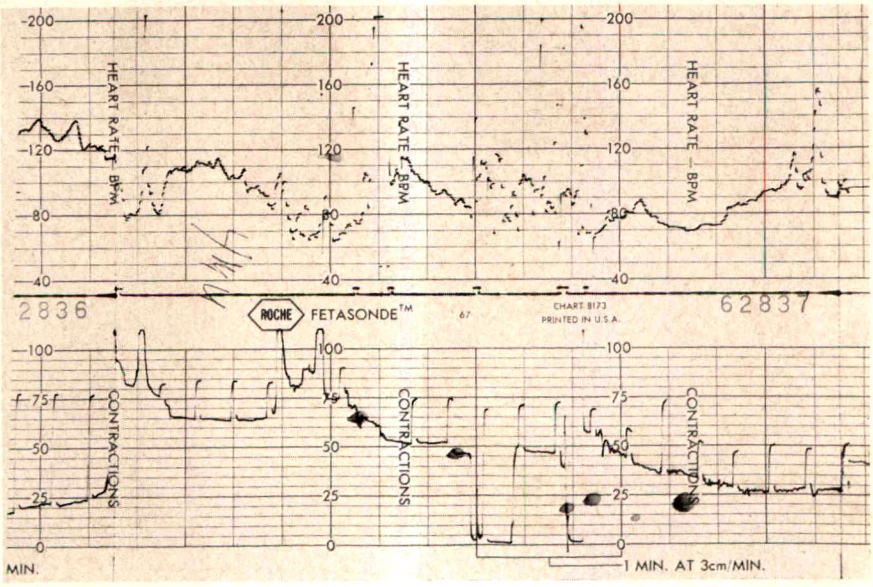

Fig. 4A. Response of TpH to FHR change. The upper portion of this figure and of Figs. 4*B* and 4*C* shows the FHR. The lower channel shows uterine contractions with the tissue pH seen as a bar graph superimposed on the contraction recording. The zero line on the contraction channel equals a pH of 7.00. The 25 line equals 7.10, 50 equals 7.20, 75 equals 7.30, and 100 equals 7.40. Depicted above are severe variable decelerations with late component associated with falling TpH. The pH falls from 7.34 to 7.20

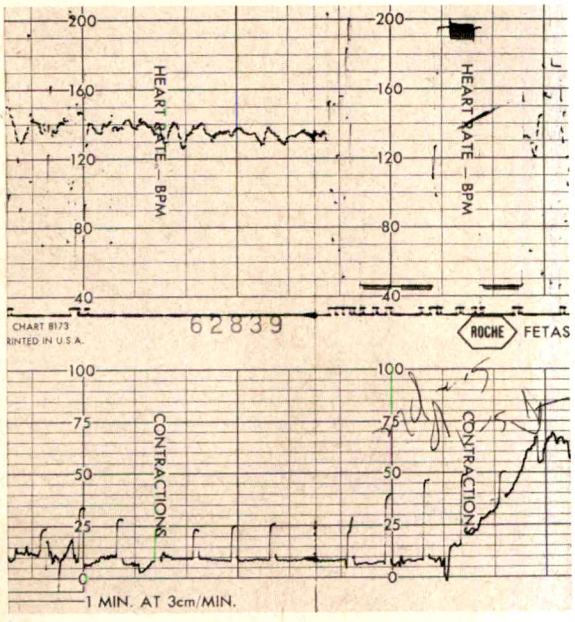

Fig. 4B. See legend of Fig. 4*A*. Bradycardia gradually recovered in 5 minutes. The TpH fell markedly, with peak effect by 10 minutes, declining to 7.10. The FHR artifact seen in the last 2 minutes is due to scalp blood pH sampling.

ness of the FHR pattern. Ninety-three percent of the cases of decelerations with a late component showed a fall in TpH. There were none in the innocent patterns of acceleration and moderate bradycardia, as well as none in the normal patterns without periodic FHR changes.

There were only three cases in which the Apgar scores were below 7 at 1 minute, and none was below 7 at 5 minutes of life. Table III shows that the TpH fell in each case and the BpH fell in two of three cases during the time of FHR change. At delivery, preacidosis levels were seen in two thirds TpH and one third BpH in the cases with low Apgar scores.

Comment

The TpH changes in the cases with low Apgar scores reflected fetal status in a manner at least comparable to the BpH, if not more accurately. TpH is correlated with BpH significantly but averages 0.04 pH units lower in the term human fetus in labor. This difference may be related to changes in calibration with time, inherent errors in the methods, or physiologic factors which may render the tissues more acid than the capillary blood. For example, such factors may be seen in any recent wound, where the initial response to injury is the formation of a relatively acid wound fluid.[6]

Changes in FHR which affect TpH do so within 2 or 3 minutes. Thus, there is a short lag time between the alteration in fetal cardiovascular function and the biochemical responses seen in the TpH. There was a clear relationship between the FHR patterns and the TpH changes. This relationship was consistent with the expected response encompassed by the known pathophysiology of FHR changes. Thus, the greatest incidence of falling TpH was in decelerations with a late component (93%) and fetal tachycardia (60%), whereas

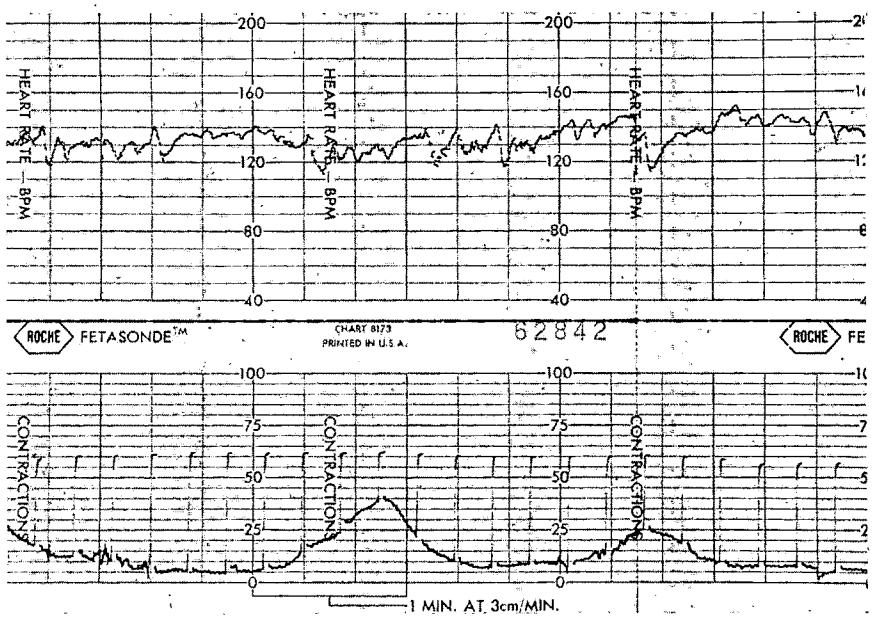

Fig. 4C. See legend of Fig. 4*A*. FHR recovery followed by recovery of TpH. BpH was 7.24 when TpH was 7.22 during recovery phase. Tissue pH has stabilized at 7.24, significantly below the 7.34 prior to the abnormal FHR pattern despite recovery of the FHR 15 minutes earlier.

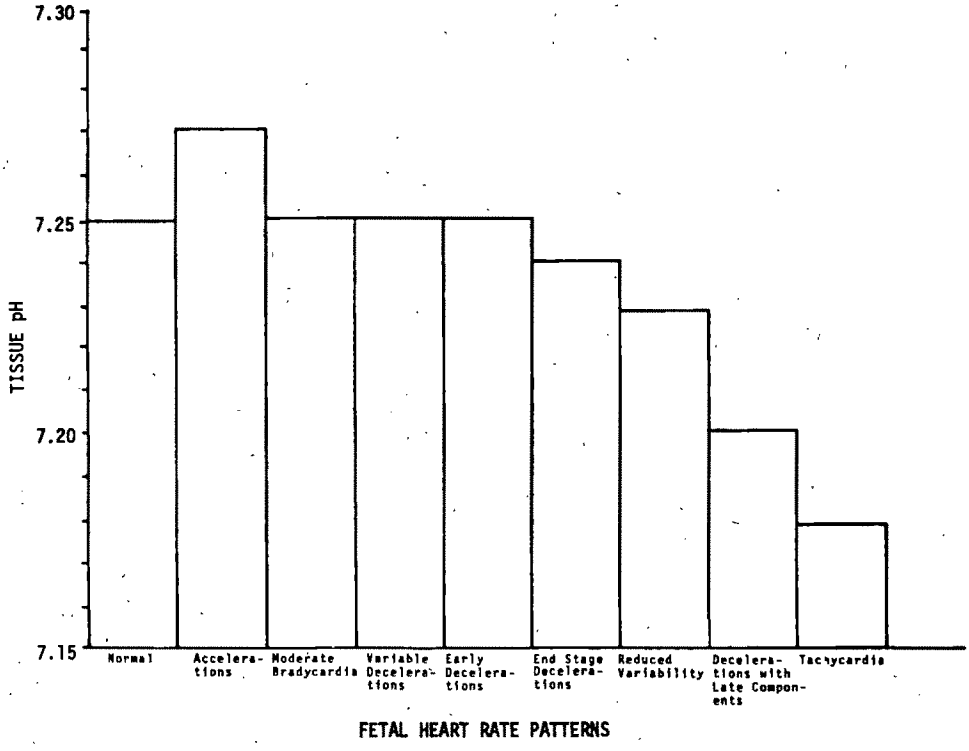

Fig. 5. Average tissue pH with various fetal heart rate patterns. The average tissue pH is shown on the vertical scale. Each bar represents a different fetal heart pattern.

the average TpH was lowest during these FHR patterns. Moreover, the innocuous FHR changes were associated with the highest average TpH and no cases of falling TpH. The TpH changes follow the current concepts of fetal stress responses, although the pathophysiology is not completely clear at present. Continuous TpH trend monitoring offers an additional modality for clinical and investigational interpretation of FHR patterns. Presently it should be considered complementary to the existing methods for evaluating fetal

condition in labor. The pathophysiologic relationships between TpH and BpH remain to be elucidated. The early diagnosis of fetal distress, avoidance of unnecessary cesarean sections, and reduction of fetal and maternal hazards are possible benefits if continuous TpH monitoring proves clinically effective. Further studies are indicated to determine the clinical value of continuous TpH monitoring as part of the optimal care of high-risk pregnancy.

Fetal heart rate variability: An approach to automated assessment

JAMES R. HUEY, JR., LIEUTENANT COLONEL, USAF (MC)*
RICHARD H. PAUL, M.D.
ALEXANDER AL. HADJIEV, M.D.
JIRI JILEK
EDWARD H. HON, M.D.

Three hundred seventy-five hours of fetal heart rate (FHR) data derived from the direct fetal electrocardiogram (ECG) were studied. This data had been stored on magnetic tape from 83 intrapartum patients. By means of a computerized technique, the FHR variability was assessed quantitatively. The degree of variability was then related to: (1) state of labor, (2) fetal scalp pH values, and (3) the 1-minute Apgar score. FHR variability was computed from differences between consecutive R-R intervals measured from the R wave of each fetal ECG. A trend of increasing variability was seen with advancing labor, defined by either time prior to delivery or cervical dilatation, but values were not statistically significant. Significantly less FHR variability was encountered when fetal scalp pH values below 7.20 were compared to higher values. FHR variability assessed during the 20 minutes immediately preceding delivery was significantly lower in infants with 1-minute Apgar scores less than 7. Machine assessment of FHR variability thus could be correlated with fetal condition as determined by scalp pH and neonatal outcome determined by Apgar score. (AM. J. OBSTET. GYNECOL. 134:691, 1979.)

IN RECENT years, variability of the fetal heart rate (FHR) has become the object of numerous studies and is currently a major focus of physiologic investigation.[1, 2] It is established that a decrease in FHR variability, evaluated visually, may be associated with fetal and neonatal compromise.[3–7]

One of the basic problems which has obstructed understanding and agreement regarding the assessment of variability has been the various instrumentation approaches used to produce a FHR. Thus, the FHR obtained from the phonocardiographic or ultrasonocardiographic signals inherently may present a false picture of variability because of (1) imprecise signal sources and variation, (2) the presence of artifacts, and (3) averaging techniques required to present "reasonable FHR" data from such sources.[8]

The assessment of the actual FHR variability as described in this study requires the direct fetal electrocardiogram (ECG) as a signal source. The interval between each QRS complex is precisely measured from the peak of successive R waves and FHR variability is computed from successive R-R interval differences. The purpose of the study was to relate a new method of machine assessment of FHR variability and to correlate the results of this method with labor advancement, fetal scalp pH, and neonatal 1-minute Apgar score.

Material and methods

Records from the Perinatal Intensive Care Unit at Los Angeles County–University of Southern California Medical Center, Women's Hospital, were reviewed for

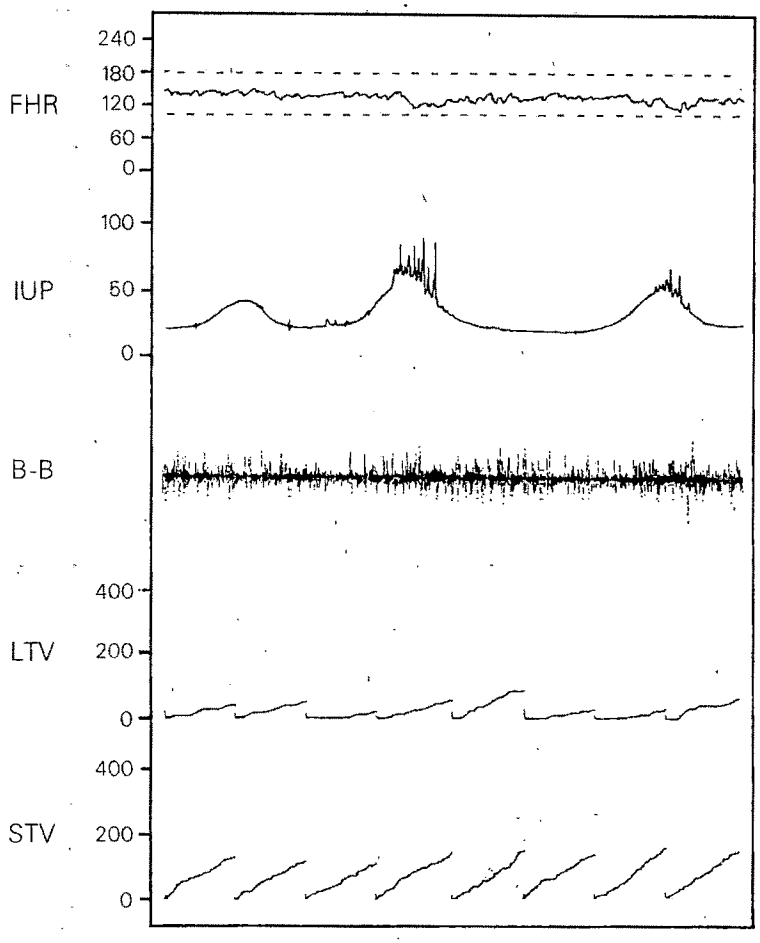

Fig. 1. The 5 channel printout. Channels 1 and 2 contain electrode FHR and internal catheter uterine pressure data. Beat-to-beat variability is displayed on the center channel. LTV and STV are shown on Channels 4 and 5 presented as beat change per 100 consecutive fetal heart beats.

Diabetes mellitus, Class B	3
Diabetes mellitus, Class C	2
Postmaturity	7
Toxemia	8
Rh isoimmunization	1
Total	83

suitability for the study. The following criteria were required for inclusion: (1) the original FHR record was of high quality and free of artifact, (2) the record contained significant labor data, such as frequent vaginal examinations, fetal scalp pH values, and immediate neonatal evaluation by a neonatal fellow, (3) the fetus was directly monitored for at least three hours with a vaginal delivery of a term newborn infant, and (4) no medications were administered during the study period or in the hour preceding the study. The selection process purposefully included a larger-than-expected number of newborn infants with low 1-minute Apgar scores. Eighty-three intrapartum patients were studied for 375 hours with the mean duration being 4 hours, 32 minutes (Tables I, II, and III).

Instrumentation. The fetal ECG was obtained with a direct electrode attached to the fetal scalp. Intrauterine pressure was obtained by means of a transcervical, open-ended, fluid-filled catheter inserted into the amniotic sac. All data were recorded on magnetic tape for subsequent study, and long- and short-term variability as subsequently described were derived from these tapes. Fetal blood sampling was accomplished as per the method of Saling[9] and pH determinations were performed using a Radiometer BMS3 microelectrode.

Variability assessment. The calculation of variability used an approach designed by two of the authors (E. H. H. and J. J.). The method was based on the precise measurement of the differences in milliseconds

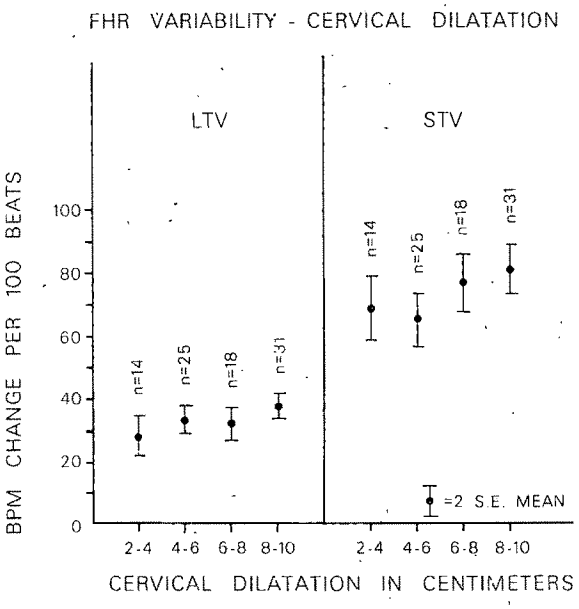

Fig. 2. Variability at progressive cervical dilatation is shown using the standard error of the mean.

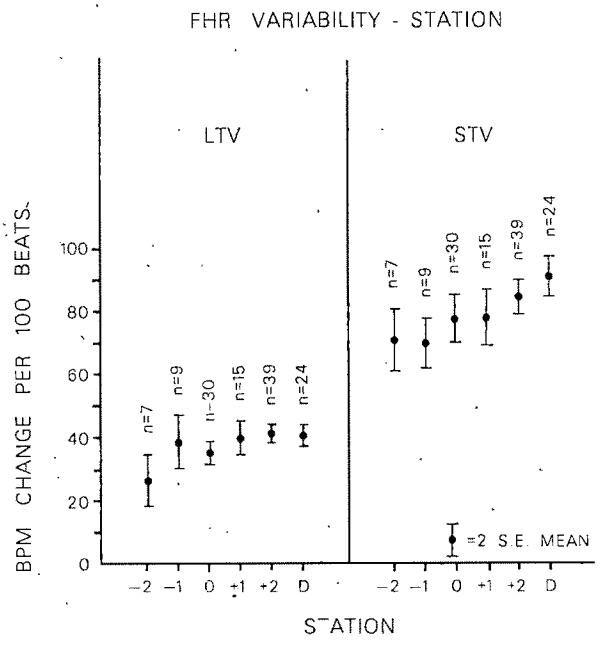

Fig. 3. Mean baseline variability is illustrated at various stations. A progressive increase in variability is seen with descent of the presenting fetal vertex. Statistically significant difference is seen between values at −2 station and those at crowning.

between the consecutive R-R intervals of the fetal ECG. The millisecond R-R interval time was converted to a corresponding beats-per-minute value, i.e., the number of beats in one minute if that R-R interval were maintained for the entire minute. The difference in the beats-per-minute value of each interval and the preceding interval was calculated and given a plus (+) or a minus (−) sign in comparison with the previous interval. For example, an interval shorter than the previous one would have a negative sign, meaning a faster corresponding beats-per-minute rate than the previous interval. The actual change in beats-per-minute (bpm) between each consecutive R-R interval was the value accumulated for the calculation of FHR variability. The sign given each interval, i.e., plus (+) or minus (−) and sign change was used to indicate whether the value or change in rate was calculated as long- or short-term FHR variability. In other words, the sign of each interval difference was compared with the sign of the previous interval and from this, the long- and short-term variability was computed.

Short-term variability was computed by totaling the values from any two consecutive R-R intervals where there was a sign change. Additionally, the second consecutive interval following an R-R interval with a sign change was calculated as short-term variability.

Whenever three or more intervals with identical signs were encountered, this was considered long-term variability. Both long-term and short-term measures were accumulated for 100 consecutive intervals and displayed graphically (Fig. 1). These accumulative values of both long- and short-term variability totaled for each 100 beats are presented as "beats-per-minute change per 100 beats."

Table II. Monitoring duration

1 min. Apgar	*No.*	*Hr. monitored*	*Average/patient*
≥7	36	154	4 hr. 17 min.
<7	47	221	4 hr. 42 min.
Total	83	375	

Table III. Patient distribution by Apgar scores

1 min. Apgar	1	2	3	4	5	6	7	8	9	10
Number	13	12	7	3	5	7	0	9	27	0

Data selection. The FHR variability was calculated continuously, but only variability values obtained during the baseline period of FHR were used. The baseline FHR variability data for each 20 minutes was averaged. The long-term and short-term measures for 20 minute periods of variability were evaluated in relationship to (1) labor progress as documented by both cervical dilatation and station change, (2) fetal scalp pH, and (3) 1-minute Apgar score.

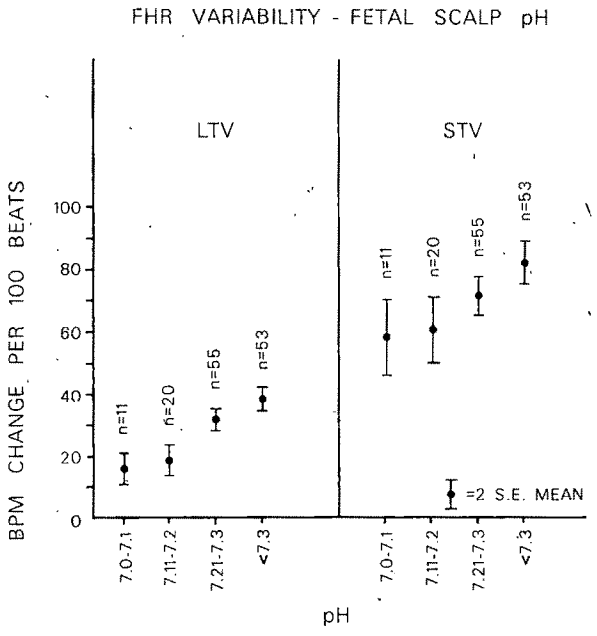

Fig. 4. Significantly increased variability values were found with higher fetal scalp pH values as demonstrated by standard error of the mean comparison.

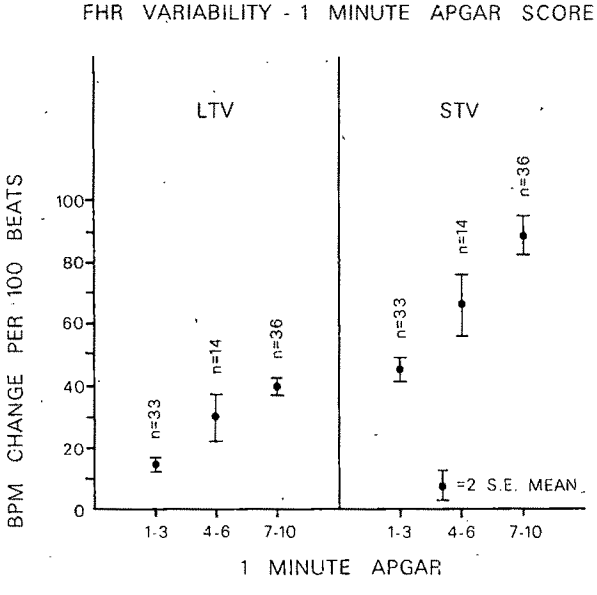

Fig. 5. Baseline variability values the 20 minutes prior to delivery are shown grouped according to the 1-minute Apgar value.

Results

A gradual increase in both long- and short-term variability was seen with advancing labor, both looking at time prior to delivery or at stage of labor relative to cervical dilatation. However, no statistical significance was found in this increasing trend (Fig. 2).

The long- and short-term FHR variability was compared at six stations of the fetal head. There is a gradual increase in FHR variability with descent of the fetal head through the pelvis. The differences found in both long- and short-term FHR variability at −2 station and crowning were statistically significant as shown by comparison of the standard error of the mean (Fig. 3).

Significant differences in both long- and short-term variability were found when fetal scalp pH values of 7.20 or less were compared to higher values (Fig. 4).

When the 20 minutes prior to delivery were evaluated, significant differences were found in both long- and short-term FHR variability in the group of infants exhibiting 1-minute Apgar scores of 6 or less when compared to those with values of 7 or more (Fig. 5).

Comment

The clinical value of variability seems to be well documented, but a detailed numerical study of variability is imprecise because of the effect of FHR variability of factors such as patient movements, vaginal examinations, and maternal medication, as well as artifacts introduced by certain equipment used to record the FHR.

Clinically important is the positive correlation between variability and the condition of the fetus as evaluated by both scalp pH and one-minute Apgar score. The correlations confirm the potential diagnostic and prognostic value of long- and short-term FHR variability as a clinical index of fetal intrapartum condition.

A recognized deficiency of this study was the failure to compare these measures of FHR variability and five-minute Apgar values. It was impossible to subsequently do this comparison because the original data had become unavailable.

This preliminary study suggests that this machine approach of variability assessment is worthwhile. Using this technique, on-line data is currently being collected in both normal and abnormal clinical conditions to further evaluate its potential clinical significance.

Short-term cycles in human fetal activity

I. Normal pregnancies

MENACHEM GRANAT, M.D.*
PERETZ LAVIE, PH.D.
DANIELA ADAR, B.SC.
MORDECHAI SHARF, M.D.
Haifa, Israel

Recordings of fetal motor activity in utero were carried out on 17 women with normal pregnancies at 23 to 37 weeks' gestation. Fetal motility was monitored by a method based on integrative EMG recordings derived through electrodes attached to maternal abdominal surface. Orthogonal spectral analysis revealed 40 minute and 80 minute cycles in fetal motility in 59% of the fetuses. The correlation between objective and subjective (maternal self-assessment) scores of fetal activity was generally confirmed. Methods of monitoring fetal activity, based on short-term recordings, are criticized in the light of the present results. (AM. J. OBSTET. GYNECOL. 134:696, 1979.)

THE INTEREST in fetal motor activity in late pregnancy as an index of fetal health has been recently renewed by the studies of Mathews[1, 2] and Sadovsky and associates.[3, 4] Maternal self-measurement of fetal movements was advocated for high-risk pregnancies as an efficient and reliable monitoring tool.[5, 6]

Nevertheless, despite its utmost simplicity, this test has not gained popularity. It has not been adopted by many obstetricians who prefer to rely on more sophisticated, though expensive, methods of fetal evaluation, involving biochemical and immunologic assays and electronic monitoring.

The general reluctance among obstetricians to rely on maternal self-assessment of fetal movement rate originates in part from the rather empirical knowledge on the existence of periods of "fetal sleep" which are unpredictable and may, therefore, affect the maternal count of fetal movements based on short-term recordings.

Various methods of continuous fetal movement recording have been described. These included an electromagnetic device,[7] an electrical device based upon the strain-gauge principle,[8] a similar device with piezoelectric material,[9] ultrasound,[10] and a conventional tocodynamometer,[11] set usually to 25 mm Hg, full-scale.[12] In none of the latter was an attempt made to investigate the possible existence of fluctuations in the amount of fetal activity during the recording periods.

Sterman,[13] who utilized pressure-sensitive devices to record fetal activity during maternal sleep, has observed a rhythmic rest-activity cycle ranging in periodicity from 40 to 60 minutes. In a further study Sterman[14] observed the existence of two consistent cycles of fetal activity throughout gestation, with interpeak intervals of 38 and 83 minutes; the latter was associated with maternal sleep REM-NONREM cycles.

The present study was designed to (1) introduce a new, simple, nonintrusive method for recording of fetal activity and (2) re-evaluate the existence and possible clinical significance of short-term cycles in the so-called fetal sleep and wake states and thus, hopefully, lead to improvement and better interpretation of results of the presently recommended methods of monitoring fetal activity.

Methods and materials

Recordings were carried out on 19 outpatients, healthy pregnant volunteers, ranging in age from 17 to 31 years, during gestational periods between 23 and 37

weeks of pregnancy. The study group comprised 17 women who were eventually delivered of normal infants (birth weights, 2,600 to 4,050 grams; Apgar scores, 9 and 10 at 5 minutes) at 39 to 42 weeks' gestation. Thirteen were delivered vaginally and in four a lower segment cesarean section was performed for obstetric indications unrelated to fetal health. All infants experienced normal neonatal periods. Data of individual subjects, including details of pregnancy outcome, are depicted in Table I. Gestational age at the time of recording was retrospectively ascertained through Dubowitz score.

To ensure the recording of unprovoked fetal activity, examination was performed in an isolated, quiet room, with the subject lying comfortably and free to change position. Recordings started following 30 minutes of adaptation, either at 10 A.M., or at 15 P.M., and lasted for 2 to 3 hours. Fetal motility was monitored by integrative EMG recordings (Beckman type 9852A Integrator Coupler derived through electrodes attached to the maternal abdominal surface, with high-frequency cut-off point set at 30 Hz (Beckman type 411R Dynograph). This method enabled the detection of all gross changes of the abdominal surface, which were registered as movement artifacts in the EMG recordings. Four large silver-chloride Beckman type electrodes were taped as in Fig. 1. Additional electrodes were taped on the dorsal surface of the thighs to monitor maternal movements; no integration was used in maternal recordings. Five channels of information were obtained from each woman: bipolar recordings from A to B, D to C, B to D, A to C, and E to F. Recording gains were adjusted to give a low and consistent level of background physiologic activity with a paper speed of 1 mm/second. Since several sources of

artifactual movements, besides fetal movements, could be induced in the recordings (e.g., subjects' somatic movements, uterine activity, maternal respiratory movements, aortic pulsations transmitted by the uterus to the abdominal wall) a conservative scoring procedure was established. A fetal movement was scored if a movement artifact appeared in all four abdominal

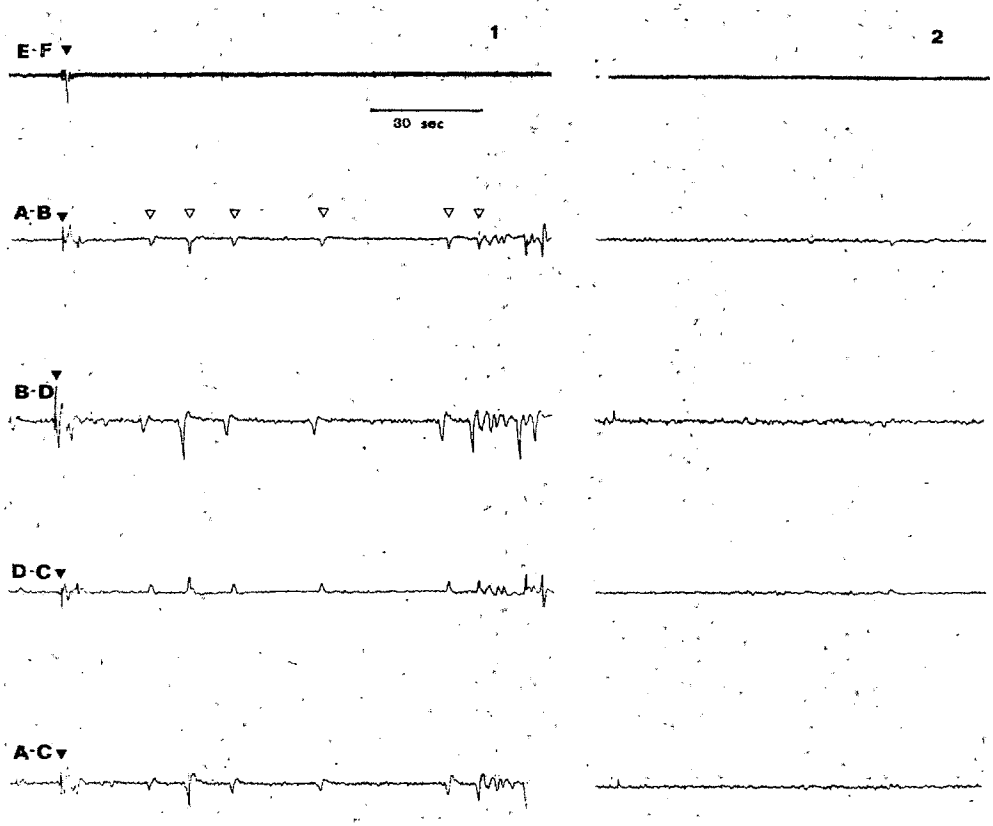

Fig. 2. Example of an original five channel recording of fetal movements. *1,* Phase of activity, characterized by parallel deflections in four channels derived through electrodes attached to maternal abdominal surface (*A-B, B-D, D-C,* and *A-C*). ▽ Fetal somatic movement. ▼ Maternal movement characterized by a concomitant deflection in channel *E-F,* derived through electrodes attached to maternal thigh. *2,* Phase of fetal rest in the same subject. The background physiologic activity is that of maternal abdominal wall.

recording channels without concomitant maternal movement (Fig. 2). Throughout the recordings subjects were under close visual observation and every change in their position was noted on the polygraphic paper. Subjects were awake throughout most of the recording sessions.

To test the validity of the recordings, five subjects were provided with a microswitch connected to a sixth polygraphic channel and were requested to press it whenever they felt a fetal movement. Pearson product moment correlation coefficients were then calculated between the subjective and objective motility scores.

Time series construction. Since we a priori hypothesized the existence of short-term periodicity in fetal motility, time series were constructed from the activity scores. These were obtained in the following way: Recordings were cut into 5 minute segments which were coded and then randomly ordered. Each 5 minute segment was subdivided into 30 second intervals, and the number of 30 second intervals containing at least one fetal movement was determined for every segment. Hence, the score of fetal activity ranged from 0, when no movements occurred in a 5 minute segment, to 10, when movements occurred in every 30 second interval. Finally, time series were constructed by reordering the fetal activity scores according to their chronological order.

Statistical analysis. To determine the rhythmic structure of the data an objective statistical procedure, orthogonal spectral analysis,[15] was employed. In this technique, the data are correlated with a set of trigonometric functions with known periodicities, and the trigonometric function with the best correlated periodicity is determined. The number of periodicities that can be correlated with the data, i.e., the resolution of the spectra, is limited by the total length of the recording and the length of the sampling interval.

Results

Fetal movements were easily detected by this method, and could be clearly differentiated from maternal movements or background respiratory activity. Pear-

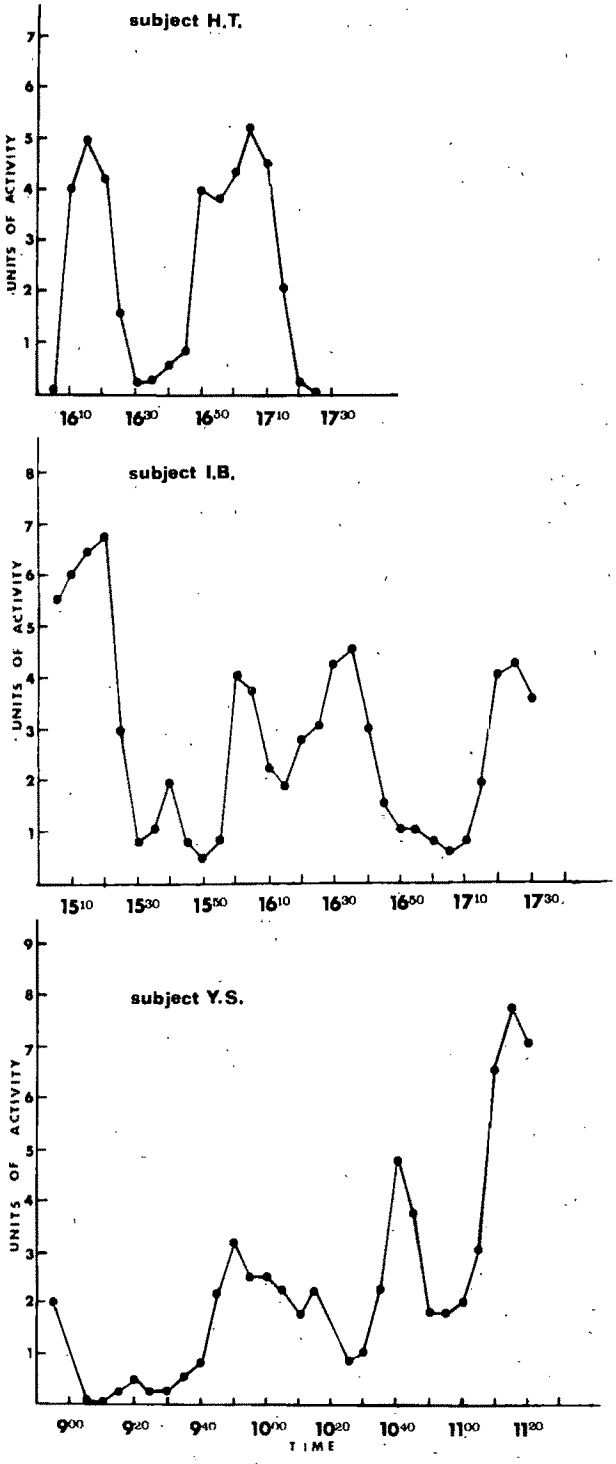

Fig. 3. Three examples of periodicities in fetal activity at different gestational ages, all within the range of 40 to 80 minutes/cycle. This pattern has been revealed by spectral analysis of the fetal movement recordings. *Time* indicates hour of recording. *Units of activity* implies a score of fetal activity ranging from 0, when no movements occurred in 5 minute segment, to 10, when movements occurred in every 30 second interval of fetal movement tracings (see text). Time series were smoothed by three point moving average procedure.

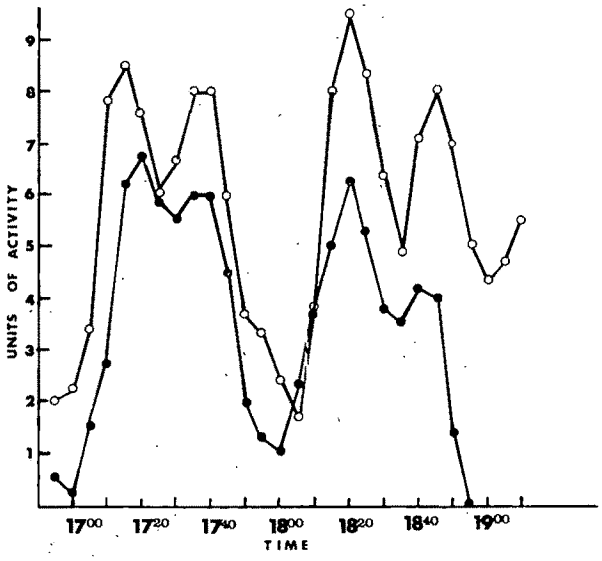

Fig. 4. Correlations between objective (empty circles) and subjective (filled circles) scores of fetal activity in a late normal pregnancy (Subject R. I., Table I). Note the accordance of periodicity, albeit the total number of maternally counted movements is consistently somewhat lower than those recorded through abdominal surface.

son product moment correlations between the objective and subjective scores of fetal activity in five cases were: 0.573 ($p < 0.001$), 0.68 ($p < 0.001$), 0.56 ($p < 0.001$), 0.364 ($p < 0.05$), and − 0.18. (Subjective scores of fetal activity were obtained in a way similar to that of the objective scores; that is, in each 5 minute segment the number of 30 second intervals with at least one movement was determined.)

Fig. 3 presents examples of three time series constructed from objective fetal activity scores. Cycles of motility are visible in all records. The mean interpeak interval was 45 minutes (SD = 7.68), well within the range of periodicities previously reported.[13, 14] Fig. 4 presents objective and subjective recordings; the similarity between the records is obvious.

Spectral analysis was calculated from the autocorrelation functions for eight spectral frequencies. Spectra were individually hanned (smoothed) and normalized to yield spectral density functions. Six subjects (35%) had the highest spectral peak at the frequency 36 cycles/day, corresponding to a periodicity of approximately 40 minutes/cycle, and four subjects (24%) had the highest spectral peak at the frequency 18 cycles/day, corresponding to a periodicity of approximately 80 minutes/cycle. The other seven subjects (41%) had the highest spectral peak at the zero frequency, which indicated either a dominant linear trend or frequencies much slower than 18 cycles/day. Three-hour recordings were too short for differentiation between

these possibilities in individual cases. The mere existence or nonexistence of short-term cyclicity in fetal activity was found to be correlated neither to gestational age at the time of recording, nor to fetal sex, birthweight, and Apgar score.

Thus, in more than 50% of the subjects spectral analysis revealed periodicities within the range of 40 to 80 minutes/cycle. Due to the limitations of the statistical technique because of the short recording periods, the range of 40 to 80 minutes/cycle is somewhat larger than the range of 40 to 60 minutes/cycle reported earlier. It seems, nevertheless, close enough to suggest the existence of short-term periodicity in fetal activity, which operates during maternal sleep and waking.

Comment

The renewed interest in fetal activity recording as a test for fetal well being has stimulated many investigators in the field of fetal monitoring. Thus, attempts were recently made to characterize various forms of fetal activity,[12] to develop a reliable device for the objective recording of fetal movements,[8, 9] and to establish the correlation between the objective (electronic) and subjective (maternal self-assessment) modes of fetal activity determination.[7, 16] Goodlin and Lowe[16] have noted a diurnal variation in fetal movements with a peak of fetal activity at around 1800 to 2100 hours. Increased fetal activity in the evening has also been noticed by Spellacy and associates[17] as well as by Wood and associates,[8] who have also observed, in some patients, the occurrence of daily and weekly variations in fetal movements.

The existence of short-term periodicity in fetal activity has been suggested by Sterman,[13, 14] but he was concerned mainly with the possible correlation between maternal sleep and fetal motor activity. Our findings confirm the existence in late normal pregnancy of a rhythmic rest-activity cycle at the range of 40 to 80 minutes/cycle which is not limited to maternal sleep. This phenomenon has been totally ignored by investigators who attempted to evaluate the correlation between fetal activity and fetal well being. This could have led to inaccuracies in fetal activity estimation. Thus it could have accounted for the sporadic daily variation that was observed in some patients by Wood and associates.[8] The 20 minute periods of maternal self-recording as recommended by these authors appear to be about half the shortest of fetal rest-activity cycles. Thus, any randomly selected period of 20 minutes can easily fall within a resting phase. Sadovsky and Polishuk[6] have suggested that whenever the estimated number of movements is less than three per day (as calculated from three self-recording periods of 30 to 60 minutes duration), the recording should be continued for 6 to 12 hours per day. By this means the difficulty raised by the short-term periodicity is virtually overcome. However, as pointed out by Wood and associates,[8] which is in agreement with our experience, patients find it difficult to concentrate on long-term self-recording, rendering their records unreliable. This is especially true in patients with high-risk pregnancies with high anxiety levels.

By 2 to 3 hour periods of recording we have confirmed the correlation between objective and subjective scores of fetal activity in four out of five patients with normal pregnancies. The lack of correlation in the fifth case demonstrates, as previously noted,[8] the variable reliability of patients as observers. In this particular case it could be due to lack of attention on the part of the subject, who had difficulties following the unusually large number of movements that occurred in this recording.

The need for a simple and reliable recording device of fetal movements is obvious. The method of maternal abdominal EMG recording, as described in this study, is nonintrusive to the fetus and is highly reliable by easy elimination of artifacts. Its clinical applicability remains questionable, and merits further investigation, yet, it seems promising and is of definite value as a tool in the research of fetal motor activity.

A longitudinal study throughout the third trimester of pregnancy may help clarify the possible existence of a changing trend in the time relations between active and resting phases of fetal behavior in utero. Such a trend could be anticipated in the light of available data on wake and sleep states in premature infants.[18]

We thank those women attending the prenatal clinic of Rothschild University Hospital who kindly consented to participate in this study. We are also grateful to the staff of our neonatal department for meticulous examination of the neonates.

The value of lecithin/sphingomyelin ratios in diabetes: A critical review

RICHARD I. LOWENSOHN, M.D.
STEVEN G. GABBE, M.D.
Los Angeles, California

The value of the lecithin/sphingomyelin (L/S) ratio in the management of high-risk pregnancies has been widely accepted. A group for which major controversy still exists is the pregnancy complicated by diabetes mellitus. Some studies, such as our own, report great success with the use of the test in this disorder, while others have been unable to rely upon it. This problem prompted a closer look at our own data, with a specific analysis of the factors which may explain the discrepancies. Specifically, a subgroup of our population was selected by limiting the study to 93 patients in White Classes B through R whose L/S ratio determinations were 2.0 or above within three days of delivery. A comparison was made of this group of patients with those of the most recent conflicting report, that of Mueller-Heubach and co-workers[8] at the Magee-Women's Hospital in Pittsburgh. The study populations appeared similar in the distribution of disease severity and gestational ages of those patients with L/S ratios over 2.0. The incidence of respiratory distress syndrome (RDS) in those infants with L/S ratios over 2.0 was compared. The group in Pittsburgh reported an 18% incidence, while we have observed a 5% incidence in this population. The factors which may explain this difference include the definition of RDS, the inclusion of Class A patients in a series, and methodologic differences in the preparation of specimens for the determination of the L/S ratio. None of these factors can conclusively explain the disparity in these studies. However, when taken together they do appear to offer a plausible explanation for such differences. It appears essential to standardize both laboratory procedures and criteria for evaluation of neonatal outcome before comparing results. (AM. J. OBSTET. GYNECOL. 134:702, 1979.)

THE CONTRIBUTION made to the management of high-risk pregnancies by the lecithin/sphingomyelin (L/S) ratio cannot be overstated. Respiratory distress syndrome (RDS) due to iatrogenic premature delivery is no longer an everyday concern. One area where this has not been clearly resolved appears to be that of the diabetic pregnancy.

Although many reports in the past indicate that the L//S ratio is just as reliable in diabetic as in other pregnancies,[1–4] some have claimed that it has led them astray.[5–8] Several articles have appeared within months of each other with conflicting results.

Dahlenburg and associates[5] in Melbourne noted a 27% incidence of mild or moderate RDS with an L/S ratio of 2.0 or greater in their diabetic patient population. They seriously questioned whether or not the risk of amniocentesis is justified in this group.

Mueller-Heubach and coworkers[8] have reviewed 101 diabetic pregnancies, primarily White[9] Classes B through D, delivered between 34 and 41 weeks gestation. They report an 18% incidence of RDS among 54 infants with L/S ratios of 2.0 or greater. Fifty-nine percent of these infants were delivered by cesarean section and had a 28% incidence of RDS. RDS occurred in 4.5% of babies with a mature L/S ratio who were delivered vaginally.

Our report a few months earlier[3] reviewed 210 diabetic pregnancies, Classes B through R. Two hundred L/S ratios were 2.0 or higher. We noted a 3% incidence of RDS in this group, which was not different from the 2.6% noted in our general population.[10] This disparity in results prompted the following evaluation of our data.

Patients and procedures

For this study, our examination was limited to those diabetic women who were delivered within three days of determination of the L/S ratio. Only those patients with an L/S ratio of 2.0 or greater were accepted, and those whose fluid was contaminated with blood or meconium were also excluded. All patients were managed at Women's Hospital, Los Angeles County–University of Southern California Medical Center.

The study group consisted of 93 patients delivered between 1970 and 1977. The original study concluded in June, 1976, but additional patients meeting these criteria in the following year were accepted for study. The breakdown by White classification was as follows: 63 Class B, 16 Class C, 10 Class D, 3 Class F, and 1 Class R. The distribution by weeks of gestation completed is shown in Table I.

All amniotic fluid specimens were spun for ten minutes at 2,200 rpm, which corresponds to 1,660 × g. The L/S ratios were determined by the method of Gluck with the Borer modification and the planimetric method.

Results

In the Los Angeles County–Women's Hospital series, the incidence of RDS remained 5.4%. The individual cases are shown in Table II. RDS occurred in 3/20 cases with an L/S ratio between 2.0 and 2.49, 1/27 between 2.50 and 2.99, 1/15 between 3.0 and 3.49, and 0/31 with a value of 3.5 or above. When analyzed by route of delivery, there were four cases of RDS in 56 patients delivered by cesarean section, for an incidence of 7.1%, and one case in 37 patients who had a vaginal delivery, for a 2.7% incidence. These numbers are too small for statistical tests of significance.

Comment

Our data continue to show that the reliability of the L/S ratio is no different in the woman with diabetes than in the nondiabetic patient. Why then does the same test run on an equivalent population in Pittsburgh give markedly different results? Possible explanations include a statistical accident, different patient populations, lack of consistency in neonatal diagnosis, or alterations in methods of L/S analysis. We will now examine these possibilities.

The statistical problem can be addressed easily. The chance of our finding five cases of RDS out of 93 patients, while another group finds 23 out of 101 cases, when both come from the same basic population, yields a chi square value of 10.49. Thus this would occur by chance with $p = 0.0012$, or once in a thousand times.

Table I. Distribution of gestational ages in the study population

	Weeks' gestation at delivery							
	34	*35*	*36*	*37*	*38*	*39*	*40*	*41*
No. of patients	6	7	14	12	32	11	8	3

Table II. Deliveries associated with RDS in diabetic pregnancies with L/S ratios of 2.0 or above obtained within 72 hours of delivery

Class	*Weeks' gestation*	*L/S ratio*	*Route of delivery*
B	38	2.1	Cesarean
B	35	2.3	Cesarean
D	35	2.4	Cesarean
B	36	2.8	Vaginal
B	38	3.3	Cesarean

Do the patient populations differ? Gluck and associates[11] have reported that Class A diabetes is characterized by a delay in pulmonary maturation as reflected in the L/S ratio. These patients have been excluded from our series. We do not use the L/S ratio in their management, and only rarely resort to early intervention in this group.[12] The magnitude of this problem is difficult to evaluate, as the report by Mueller-Heubach does not give the number of Class A patients with L/S ratios over 2.0. There were at least six patients with values of less than 2.0, and two cases of RDS with values of 2.0 or above. If one excludes the six immature cases, one is left with a maximum of 13 Class A patients with L/S ratios over 2.0, and two cases of RDS. The remaining group then comprises 14 cases of RDS in 70 patients, or a 20% incidence. This analysis implies that the Class A group has not contributed an excessive amount to the incidence of RDS.

The mean gestational age at delivery in our present series from Los Angeles County-Women's Hospital is 37.5 weeks, while the subpopulation in the Mueller-Heubach series with L/S ratios greater than 2.0 appears to have a mean age of 37.2 weeks.* These figures are certainly comparable.

The next area to consider is the diagnosis of RDS itself. It is probable that all of the cases described by Mueller-Heubach have RDS, but when reporting on this condition, it would be preferable to specifically state the radiologic criteria used for the diagnosis. This is important as transient tachypnea of the newborn infant, sepsis, and some congenital heart lesions can pre-

*Data derived from their graphs and tables.

sent with identical clinical pictures. Definitive diagnosis is essential.

The final problem which remains is the methodology of the test itself. Since the original publication of Gluck's work, there have been scores of different approaches to the determination of the L/S ratio or measurement of surfactant. Two of the most crucial differences in L/S ratio techniques may be the inclusion or exclusion of the acetone precipitation step (used by both papers discussed here), and the use of the planimetric method as opposed to the densitometric method of measurement. Our laboratory has used the planimetric method, which may lead to a false elevation of the ratio.[13] This should give us a higher incidence of unsuspected RDS than a laboratory using a densitometer. The report from Pittsburgh involved the use of both methods, which may add some variability to their results.

Recently, Cherayil and colleagues[14] reported yet another source for nonreproducibility of the L/S ratio. They discovered that the g-force used in centrifugation can have a major effect upon the L/S ratio found in amniotic fluid. The method used at Los Angeles County-Women's Hospital falls in the steepest portion of their curve. This is apparently enough force to change a fluid with a L/S ratio of 2.6 when unspun to a value of less than 2.0 after centrifugation. The report from Pittsburgh suggests that fluid was not centrifuged if the determination was done immediately. This technique could lead to values which are misleadingly high.

When taken individually, it is difficult to say that any one of these differences has led to our conflicting results. When taken together, however, it would seem reasonable to conclude that they do explain the discrepancies. Specifically, an L/S ratio of 2.0 or above, done in our laboratory on spun fluid from an overtly diabetic patient, appears to provide assurance that that infant will not develop RDS any more often than a nondiabetic infant in the same circumstance. Before any further claim to the contrary is made, it seems essential that we agree upon our methodology, terminology, and study populations.

Performance of the amniotic fluid foam stability–50 percent test

A bedside precedure for the prenatal detection of hyaline membrane disease

GEOFFREY SHER, F.A.C.O.G., M.R.C.O.G.(LOND.), F.C.O.G.(S.AFR.)
BERNARD E. STATLAND, M.D., PH.D.
DENNIS E. FREER, M.S.
JOHN C. HISLEY, F.A.C.O.G.
Chapel Hill and Charlotte, North Carolina, and Sacramento, California

A study was conducted on 394 patients in order to evaluate a modified foam stability (FS) test for the prenatal evaluation of fetal pulmonary maturity. We termed the assay the "FS-50 test" because of its dependence upon the maintenance of a 50% ethanol concentration in the final assay mixture. The FS-50 test was regarded as "positive" when an uninterrupted ring of stable bubbles formed around the meniscus of the tube at the air-fluid interface, following vigorous shaking. Anything less was regarded as a "negative" result. Neonatal hyaline membrane disease (HMD) did not occur in association with a "positive" FS-50 test result. However, when the FS-50 test was "negative," 35.8% of the neonates developed HMD. In 164 of the 394 patients studied, sufficient amniotic fluid was available so as to enable us to perform the FS-50 and the lecithin/sphingomyelin (L/S) ratio assay concurrently. L/S ratio values of greater than 2.0 correctly predicted a sufficient degree of fetal pulmonary maturity so as to protect against the subsequent development of HMD in 97.8% of the cases. L/S ratio values of less than 2.0 were predictive of HMD in 28.4% of the cases studied, while a "negative" FS-50 test correctly predicted that HMD would subsequently occur in 46.9% of the cases. The FS-50 test promises to provide a reliable screening method for the prenatal detection of HMD. The practicability and sensitivity of this simple assay makes it a potentially valuable addition to our diagnostic armamentarium. (AM. J. OBSTET. GYNECOL. 134:705, 1979.)

THE IDEAL prenatal test of fetal pulmonary maturity should be simple, sensitive, accurate, and inexpensive. At present, the two most widely used methods of predicting fetal pulmonary maturation are the lecithin/sphingomyelin (L/S) ratio[1] and foam stability tests.[2–4] The L/S ratio has been found to be reliable in normal obstetric cases but has shown less predictive value in complicated situations.[5–7] The assay is time consuming, requires sophisticated equipment and technical expertise, and in most laboratories cannot be performed on a stat basis.

We recently reported on a preliminary evaluation of a modified amniotic fluid, foam stability test for the prenatal detection of neonatal hyaline membrane disease (HMD).[4] The assay is a modification of a procedure first described by Clements and colleagues[2] in 1972. We termed the assay the FS-50 test because it makes use of 100% ethanol in a 1:1 ratio with uncentrifuged amniotic fluid to produce an ethanol volume fraction of 50% in the final assay mixture. This distinguishes it from the procedure originally described by Clements' group in which the final ethanol volume fraction in the assay mixture was 47.5%. We were able to demonstrate that a positive result using the FS-50

P(HMD | FS-50 minus)	46.9	35.8

test provided 100% assurance of protection against the subsequent development of HMD in the neonatal period.[1]

While the results of our preliminary study were extremely encouraging, the sample size was relatively small (i.e., only eight cases of HMD in a total of 104 patients studied) and the assay was performed under optimal conditions by a laboratory-trained technologist.[3] This present study presents an evaluation of the FS-50 test under routine clinical conditions with the assay being performed by a number of clinicians as a bedside procedure. In addition, the sample size is now much larger (i.e., 39 cases of HMD in a total of 394 patients studied).

Patients and methods

This study represents a collaborative undertaking between the North Carolina Memorial Hospital in Chapel Hill and the Charlotte Memorial Hospital in Charlotte; both are institutions affiliated with the University of North Carolina School of Medicine. Amniotic fluid was obtained by amniocentesis performed for clinical reasons and done within 48 hours of delivery in all cases. Fluid found to be macroscopically contaminated with blood or meconium was discarded.

Table I presents the demographic characteristics of the 394 patients studied. The majority of patients had complicated gestations. Pulmonary status of the neonate was defined as either "hyaline membrane disease" or "normal" on the basis of criteria previously defined in our earlier publication.[4]

We performed the FS-50 test on each of the amniotic fluid specimens obtained from the 394 patients included in the study. Both institutions had at their disposal previously provided Kimax glass tubes measuring 5 cm × 1.3 cm, each of which contained exactly 1.0 ml of 100% (absolute) ethanol which had been dispensed into the tubes in a moisture-free environment. All tubes were sealed with an air-tight, screw-on cap. This procedure insured maintenance of the anhydrous nature of the absolute ethanol reagent. The procedure of the FS-50 test was performed as follows: One milliliter of freshly obtained amniotic fluid was dispensed into a glass tube containing 1.0 ml of ethanol. The tube was recapped and then vigorously shaken for a period of 30 seconds. It was then allowed to settle for 15 seconds after which the air-fluid interface was examined for the absence or presence of stable foam. The presence of an uninterrupted ring of bubbles around the entire meniscus of the tube was interpreted as "positive" and anything less was called "negative".[4]

In 164 of the 394 patients studied, the lecithin/sphingomyelin (L/S) ratio was also performed on the same specimen of amniotic fluid. The L/S ratio was performed according to the method described by Gluck and associates[1] and included the acetone precipitation step.

Results

Table II compares the results obtained with the FS-50 test versus neonatal clinical outcome. The incidence of hyaline membrane disease was 11%. In no instance did hyaline membrane disease occur in association with a "positive" FS-50 test. HMD occurred in

39 of 109 cases where the FS-50 test was "negative" (i.e., 35.8%).

Table III depicts the results obtained on each of the 164 cases where both the L/S ratio and FS-50 test were performed on the same specimen. In this subset, the incidence of hyaline membrane disease was approximately 14% (i.e., 23 cases of hyaline membrane disease out of a total of 164 patients studied). Two cases of hyaline membrane disease occurred in association with L/S ratio values of greater than 2.0, i.e., 2.5 and 2.8, respectively. In both instances, delivery was achieved by elective cesarean section. One- and five-minute Apgar scores were greater than 7.0 in both cases. In the case associated with the L/S ratio of 2.5, pregnancy was complicated by the nephrotic syndrome and hypertension while the case associated with an L/S ratio of 2.8 was a patient in preterm labor who had had a previous cesarean delivery.

Table IV presents the predictive values of the L/S ratios as compared to the FS-50 test results, based upon the data presented in Tables II and III. We selected a cutoff value of 2.0 for the L/S ratio which is generally accepted as the value above which neonatal HMD will not occur. Using this cutoff value for the L/S ratio, we note a 97.8% predictive reliability for results of greater than 2.0 and 28.4% for values below 2.0. For the FS-50 test, we note that when a "positive" result was assumed to indicate that neonatal HMD will not occur, the predictive reliability was 100%. A "negative" FS-50 result, on the other hand, correctly predicted that HMD would occur in 46.9% of the 164 cases.

Comment

Hyaline membrane disease is one of the major causes of perinatal death throughout the world. In the United States alone it is responsible for approximately 25,000 deaths and numerous serious sequelae each year. The major method for the prenatal detection of this disease is the L/S ratio which is employed to measure surfactant in the amniotic fluid. Unfortunately, however, this assay is expensive and requires the availability of a significant amount of technical expertise. In Addition, it is time consuming and therefore is not readily available on a 24 hour stat basis. Moreover, we as well as other workers have noted hyaline membrane disease in association with L/S ratio values of greater than 2.0, especially in pregnancies complicated by diabetes mellitus and Rhesus disease.[4, 5–7] In addition, this study revealed that when L/S ratio values were less than 2.0, 71.6% of the neonates had mature lungs, as compared with 53.1% when the FS-50 test was "negative."

The FS-50 test as described here, by providing prefilled glass tubes containing the required amounts of absolute ethanol, significantly simplifies the shake test procedure, thereby reducing the likelihood of variation in the final ethanol volume fraction. We are convinced that it is this factor more than any other which has avoided the occurrence of "false positive" results in our study. All that is required of the analyst (e.g., the clinician doing the assay) is the ability to pipette the prescribed volume of amniotic fluid and then to shake the assay mixture for 30 seconds. While the results would suggest that the FS-50 test provides a reliable screening method for hyaline membrane disease, final clinical acceptance of this assay must await the outcome of a more extensive study.

Collection and use of autologous fetal blood

CHARLES L. PAXSON, JR., M.D.
Omaha, Nebraska

A prospective study was completed to evaluate the feasibility of autologous fetal blood collection. Following puncture on the umbilical vein, fetal blood was drawn into sterile heparinized plastic syringes and aliquots were subjected to coagulation and culture studies. None of the blood samples exhibited significant growth of bacterial pathogens and all patients had normal coagulation studies at 24 hours of age. These data demonstrate that fetal blood can be safely collected and given to infants subjected to shock or iatrogenic blood loss. (AM. J. OBSTET. GYNECOL. 134:708, 1979.)

PRETERM INFANTS may exhibit hypotension following hemorrhage or iatrogenic blood loss. The mortality rate in these infants is higher than 50%.[1, 2] Current blood-banking techniques do not provide autologous blood, and heterologous blood for emergency transfusion is not always readily available. We have completed the following study to evaluate the safety of one method of collecting autologous fetal blood.

Material and methods

Patient population. This study was the predecessor of a two-year clinical investigation designed to evaluate the efficacy of fluid therapy for neonatal shock. Thus, all blood withdrawn and infused into the infants described herein was used with full consent of the parents and approval of the University's Human Protection Committee.

The author was present in the delivery room for collection of fetal blood from each of the infants in the study. In each instance, an attempt to withdraw fetal blood from the umbilical cord–placental unit was made. The infants in shock received initial empiric therapy of 25 ml/kg body weight, and the other infants received 10 ml intravenous aliquots of autologous blood to replace volume loss on a milliliter-per-milliliter bases.

All infants had venipuncture samples drawn for completion of coagulation studies before and after transfusion, and at 4 and 24 hours. Blood cultures were completed on each sample withdrawn.

Fetal blood collection. Prior to delivery of the placenta, umbilical cords were doubly clamped and the infants were removed. After each infant has been separated from its clamped cord, fetal blood was obtained from the umbilical cord–placental vascular compartment by an adaptation of the federal regulations for heparin collection of human blood products.[3] A sterile heparin solution (aqueous United States Pharmacopeia grade porcine intestine heparin, Abbott Labs.) was diluted with sodium chloride to prepare a final solution containing 320 units of heparin per milliliter of solution. Thirty-five-milliliter plastic syringes were fitted with 18 gauge needles and then aseptically "primed" with heparin by aspiration of 0.5 ml of the final heparin solution into the syringes. All syringes were prepared daily under laminar flow conditions.

Seventy milliliters of blood was drawn into the two heparin "primed" syringes following a single needle puncture of the umbilical vein. The umbilical cord was washed with Betadine and rinsed with sterile saline prior to venipuncture. Ten milliliters of blood from the second syringe was separated into aliquots for aerobic and anaerobic bacterial cultures and for coagulation studies. The remaining blood (approximately 60 ml) was filtered through a microaggregate administration set just prior to infusion using a high-capacity 10 μ transfusion filter as shown in the diagram (Fig. 1).

After the blood was filtered, it was used as dictated by each infant's blood pressure or by the volume of iatrogenic blood sampling. The blood was suspended at each infant's Isolette until each infant was four hours of age. For the infants in shock most of the blood was used in the initial transfusion. For the other infants, the blood packet was used a second time in 48 instances. If

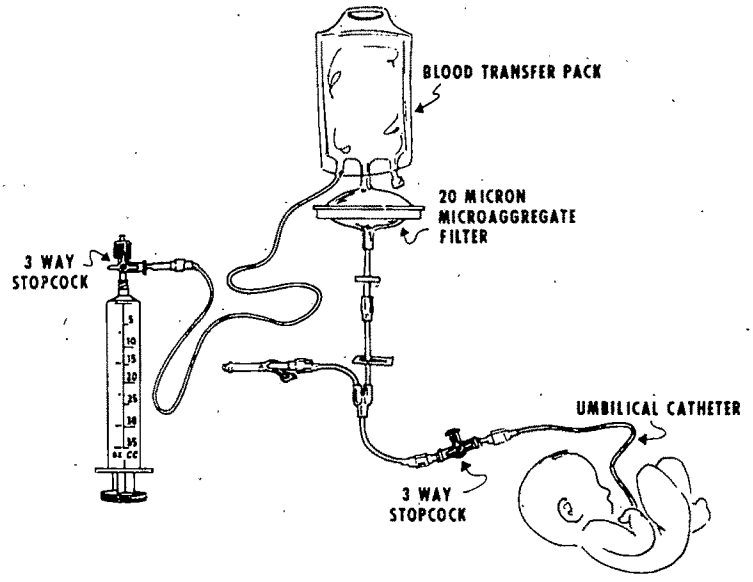

Fig. 1. Diagram of fetal blood administration apparatus.

the infant was not hypotensive, or in need of volume replacement by four hours of age, the blood was refrigerated. No packet was sampled a third time, and no fetal blood more than 12 hours old was used.

Fetal blood testing. Samples of 1 ml. of fetal blood were placed into peptone transfer broth tubes and then plated onto chocolate agar, defibrinated sheep blood agar, and Brewer thioglycollate agar for aerobic and anaerobic cultures. All samples were grossly and microscopically examined at 1, 2, and 7 days.

Samples of 4½ ml of fetal blood were placed into tubes containing 0.5 ml of 3.8% sodium citrate. Samples were centrifuged and plasma removed and tested within 1 hour. All specimens for coagulation were tested in duplicate by fibrometer techniques previously reported for partial thromboplastin times (PTTs).[4]

Results

Patient population. Twenty-five of the infants in shock survived. Demographic factors and each infant's pressure response will be described elsewhere.[2] None of the patients who received blood transfusions to prevent iatrogenic hypovolemia demonstrated hypotension by 4 hours of age. Without these immediate transfusions, several could have become hypotensive from iatrogenic hypovolemia.

Coagulation studies on the peripheral blood samples demonstrated prolonged PTTs in more than half of the patients who were in shock. However, by 24 hours of age, all patients had normal PTT values (±10% of control values). None of the blood samples obtained prior to or following fetal blood transfusion demonstrated significant anaerobic bacterial growth. Only a single aerobic culture obtained following the second transfusion to one infant grew out diptheroid organisms. The infant survived and never exhibited clinical signs of infection.

Fetal blood collection and testing. On three occasions, difficulty in collection of fetal blood was encountered and only 6, 20, and 25 ml were obtained. In all other instances, a single venipuncture produced a free flow of blood and uncomplicated collection of 35 ml of blood or more. Of the blood placed into the filtration apparatus, approximately 10 ml was "lost." Nearly 50 ml of blood was available for transfusion to each patient. Coagulation tests demonstrated adequate anticoagulation of all fetal blood samples prior to infusion (PTT > 180 seconds). None of the fetal blood samples demonstrated significant bacterial growth at any of the time intervals examined.

Comment

The most optimum technique for supplying fresh blood for the ill human newborn infant is a controversial subject. The two techniques most commonly employed are the use of "walking blood donors" and banked adult whole blood.[5]

Those physicians who argue in favor of the use of "banked blood" state that the "walking donor" system is not a "controlled, safe" technique. Those physicians who favor the "walking-donor" systems argue that this procedure reduces the risk of infectious hepatitis and the lag time from need of blood until transfusion. In our experience, the major advantage of the "walking-

donor" system is its ready availability, but this is often impractical because each infant's donor may be at home, and a long delay from time of need to time of transfusion occurs. Furthermore, the lower hematocrit of the healthy human adult makes it necessary to prepare partially packed red blood cells to provide a "whole blood" transfusion with normal neonatal hematocrit of 55 to 60%. Banked citrated whole blood carries similar disadvantages and it too must be processed to a higher hematocrit before transfusion.

The major advantages of using fetal blood are its immediate availability and its autologous nature. Neither of the other two techniques can provide "compatible" blood immediately at the time of delivery. Neither technique can offer the newborn patient fresh whole blood with no potential risk from foreign erythrocytic, leukocytic, platelet, or protein antigens. A preliminary report has suggested that transfusion of adult heterologous blood to preterm babies may increase the risk of retrolental fibroplasia.[6] Although this potential risk requires further documentation, use of autologous fetal blood allows avoidance of this problem.

No medical therapy is without some potential risk. The problems which could result from use of heparinized autologous fetal blood are the problems of infection, hyperbilirubinemia, or excessive heparinization. Because none of the fetal blood samples revealed significant bacterial growth after 7 days of culture, we conclude that our method of collection following sterile delivery is safe.

Theoretically, hyperbilirubinemia could result from heparin-induced displacement of bilirubin from albumin.[7] It is difficult to evaluate this potential problem in human infants; however, only one of these patients required an exchange transfusion for hyperbilirubinemia (indirect bilirubin > 15 mg/dl).

The possibility of excessive heparinization in patients treated with heparinized blood is one concern partially substantiated by the prolonged PTT studies in our patients treated for shock. However, normal coagulation studies in all of the infants by the end of the first day suggest that heparinization was minimal. Furthermore, comparison of our survival rate for patients in shock with those rates previously reported (86% versus 50%) demonstrates that the benefit of transfusion is well worth the risk of excessive heparinization.

This study suggests that fetal blood may be safely collected and used up to 12 hours following delivery of the ill human newborn infant. To date, we have observed no detrimental effects of use of heparinized autologous fetal blood.

The effects of prolactin on pulmonary maturation in the fetal rabbit

G. R. VAN PETTEN, PH.D.
R. BRIDGES
Calgary, Alberta, Canada

The effect of ovine prolactin administration on the fetal rabbit pulmonary pressure volume relationship was determined. Using pentobarbital anesthesia, on Day 24 of gestation, a midline incision on the maternal abdomen was made to expose the bicornuate uterus. Fetal rabbits in one horn of the uterus were injected intramuscularly with a dose of 1.0 mg (0.05 ml) of prolactin solution. Similarly, fetuses in the opposite horn were administered an equivalent volume of control vehicle. On Day 26 of gestation, no significant enhancement of lung maturation, as judged from the pressure volume relationship, was found to result from prolactin administration. These results suggest that prolactin does not initiate the secretion of surface active material into the alveolar lumen of the fetal lung in sufficient amounts to induce physiologic maturation of the rabbit fetal lung. (AM. J. OBSTET. GYNECOL. 134:711, 1979.)

RESPIRATORY distress syndrome, characteristic of premature infants,[1] has been found to be the clinical consequence of high surface tension at the alveolar air-tissue interface.[2] This results in the collapse of the alveoli at low transpulmonary pressures, that is, during expiration. The abnormally high surface tension is the result of a low concentration of pulmonary surfactant lining the alveoli.[3, 4] Normally, the presence of surfactant reduces surface tension at the air-tissue interface and thus prevents collapse of the alveoli at low pressures.[5, 6] Current evidence suggests that most of the surface active material present in the lung is synthesized, stored, and secreted by type II alveolar pneumocytes.[7] This sequence of events is thought to occur late in gestation.[8] Many drugs, including glucocorticoids,[9] beta mimetics,[10] and NA872,[11] when administered to the fetus, have been shown to increase surfactant synthesis and secretion. However, the search continues to establish the endogenous factor(s) that stimulates lung maturation and surfactant synthesis in the fetus. Corticosteroids were eliminated as the natural trigger for surfactant synthesis when it was shown that surfactant production precedes the rise in fetal plasma corticoids.[12] On the other hand, it has been shown that human fetal surfactant levels increase[13] at a time in gestation which is preceded by a large increase in serum prolactin levels.[14] In addition, recent evidence suggests that pharmacologic doses of prolactin increase the synthesis of pulmonary surfactant as measured by a rise in phospholipid, lecithin, and dipalmitoyl lecithin concentrations in lung tissue homogenates from the fetal rabbit.[15] In order to determine whether these biochemical changes are associated with a physiologic maturation of the fetal lung, the present study assessed the effect of prolactin on the fetal rabbit pulmonary pressure volume relationship.

Materials and methods

Eight New Zealand white rabbits, with timed pregnancies, were used in these experiments. The time of mating (8:00 to 10:00) was taken as time zero for the calculation of gestational age. Ovine prolactin* was dissolved in hormone solvent composed of 3 mg of phenol and 50 mg of glucose per milliliter in water. In addition, the hormone solvent was employed as the control vehicle. Five pregnant does were anesthetized with sodium pentobarbital (30 to 35 mg/kg intravenously) on Day 24 of gestation. Under sterile conditions, a midline incision was made to expose the fetal rabbits. Approximately half the fetuses were injected, into the rump, with 1.0 mg (0.05 ml) of prolactin. The remainder of

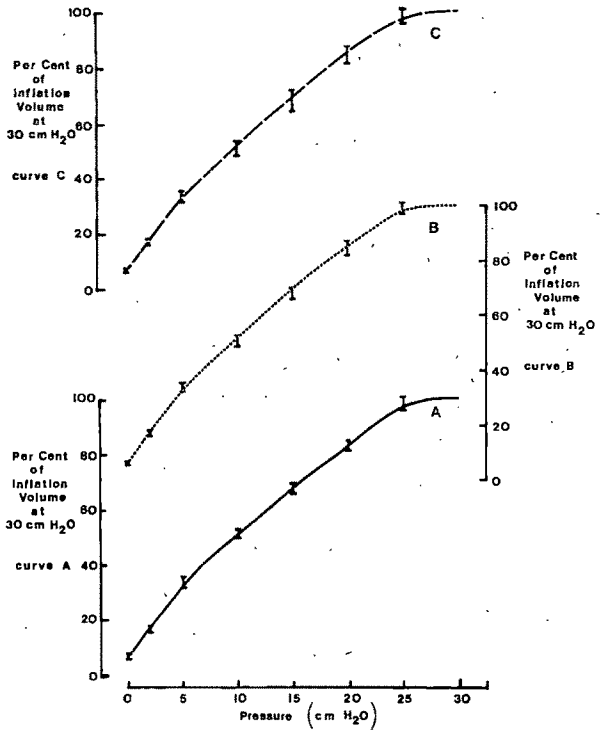

Fig. 1. Pressure-volume relationships in 26 day rabbit fetal lung after treatment of the fetus as follows: *Curve A* = fetal rabbits injected intramuscularly with 1.0 mg prolactin on Day 24 of gestation (N = 12); *Curve B* = fetal rabbits injected intramuscularly with equivalent volume of prolactin control vehicle on Day 24 of gestation (N = 10); *Curve C* = normal fetal rabbits not injected. All values are the volumes retained at the pressures indicated and are expressed as % of the total volume required to inflate the lungs to a pressure of 30 cm of water. Standard deviations of the mean are shown by the vertical bars.

the fetuses served as control subjects and were given an equivalent volume of control vehicle. Following prolactin and control vehicle administration, the abdomen was closed and the doe was allowed to recover. On Day 26 of gestation the doe was killed by means of an effective dose (45 to 55 mg/kg by rapid intravenous injection) of pentobarbital. Subsequently, the fetuses were removed from the doe and prepared for determination of deflation pressure volume curves using the method previously described.[11] Thus, estimation of lung maturation in the prolactin-treated fetuses (N = 12), control (N = 10) fetuses, or normal untreated fetuses (N = 15) obtained from three additional does was made by means of a pressure volume apparatus similar to that previously described.[16] The lungs were inflated to a pressure of 30 cm H_2O held stable for five minutes. At the end of each experiment, fetal body weight, body length, and lung wet weight were determined. Using a similar protocol, experiments were then carried out using older fetuses (Day 28 of gestation).

Results

The effect of ovine prolactin administration to the fetal rabbit on fetal lung maturity, as judged by pressure volume curves, at Day 26 of gestation is illustrated in Fig. 1 (Curve A). Compared with injected control subjects (Curve B) prolactin-treated fetuses did not significantly differ in their pressure volume relationship. Furthermore, the pressure volume deflation curves for these two groups were not significantly different from those of a normal group of the same gestational age, that was not injected with control vehicle (Curve C). Thus, the injection procedure utilized to administer prolactin and control vehicle to the fetuses did not increase fetal lung maturation. Experiments carried out using older fetuses (Day 28 of gestation) gave similar results. However, the pressure volume relationship of the fetal rabbit lungs at Day 28 of gestation resembled the full-term pressure volume profile more than that of the fetal rabbit lungs at Day 26 of gestation. This is expected due to the normally occurring maturation of the lung.[16] In prolactin-treated, injected control, and noninjected normal fetuses, the measures of fetal body length, body weight, lung wet weight, and lung wet weight as a percentage of total body weight were not found to be significantly different (Table I).

Comment

The present experiments in the rabbit indicate that intramuscular administration of a pharmacologic dose of prolactin, on Day 24 of gestation, produced no significant enhancement of lung maturation in the 26 day fetal rabbit lung. In contrast, earlier evidence suggests that prolactin stimulates the synthesis of surfactant in the fetal rabbit lung.[15] Thus, Hamosh and Hamosh[15] found that after fetal prolactin administration there was a significant increase in dipalmitoyl lecithin, the primary constituent of surfactant,[17] in the fetal rabbit lung. The apparent discrepancy between these biochemical data and our physiologic data may be due to several factors. The biochemical method used by Hamosh and Hamosh[15] involved the isolation of surface active material from a lung tissue homogenate.[18] Thus, it is likely that the dipalmitoyl lecithin was derived from both intra- and extracellular sources. The possibility exists that distinct and specific factors are required to initiate the intracellular synthesis and the secretion of surfactant from the alveolar type II pneumocytes. This is consistent with the suggestion

Table I. Physical characteristics of 26 day fetal rabbits

Characteristics	*Normal (no injection)*	*Control (injected with control vehicle)*	*Prolactin (1 mg intramuscularly)*

that lung maturation and surfactant synthesis could be under multiple hormone control.[15] Thus prolactin may trigger the synthesis of surfactant in type II alveolar pneumocytes, but it may not initiate the secretion of surfactant into the alveolar lumen. Such a proposal could explain the finding of increased amounts of surfactant in lung tissue homogenates of prolactin-treated fetuses, compared to control subjects, while no difference in the pulmonary pressure volume relationship for two similarly treated groups was found. According to this suggestion, the increased amount of synthesized surfactant in the prolactin-treated fetuses would remain intracellular in location. As a result, surface tension at the air-tissue interface of prolactin-treated fetuses would not significantly differ from that in control fetuses. If prolactin induced both the synthesis and secretion of surfactant, one would expect to see a pressure volume relationship in the prolactin-treated fetuses characteristic of more mature fetal rabbit lungs.

On the other hand, prolactin may trigger the synthesis and secretion of surfactant that is defective in its ability to reduce surface tension or prolactin may not be responsible for the induction of surfactant synthesis. The former view is consistent with previous evidence that shows surfactant to be composed of more than dipalmitoyl lecithin[17]; proteins and other lipids are also present in surfactant. It is possible that prolactin stimulates the synthesis and secretion of surfactant that is lacking an important protein component required to effectively reduce surface tension in the alveoli.

In these experiments the use of two control groups was considered essential. Previous experiments suggested that fetal distress was responsible for the production of surfactant at earlier stages of gestation than normally observed.[11] Thus, it is possible that the injection procedure used to administer the prolactin and control vehicle could result in lung maturation. However, the finding that the pressure volume relationships for the injected fetuses are the same as the pressure volume relationship for the noninjected control fetuses suggests that the injection procedure did not cause fetal distress in these experiments. A variety of other differences including nutritional status and housing conditions may contribute to the apparent difference in our data and those of Hamosh and Hamosh.[15] In this regard the effect of the apparently very large litter size of eight fetuses found by Hamosh and Hamosh[15] is unknown. However, it is concluded that the current data do not support a postulated role for prolactin in physiologic maturation of the rabbit fetal lung.

Regeneration of the uterine mucosa after delivery, with especial reference to the placental site

JOHN WHITRIDGE WILLIAMS

American Journal of Obstetrics and Gynecology, vol. 22, pp. 664-696 and 793-796, 1931

time there is a good deal of free blood in the superficial layers, associated with a moderate amount of leucocytic infiltration, which, however, is not pronounced unless it is associated with infection. As the puerperium advances a portion of the superficial tissue undergoes necrosis and is cast off with the lochia, but the greater part of the placental site is retained and is gradually cast off or exfoliated as will be explained later.

On the eighth day, the conditions remain essentially the same, except that the placental site has become definitely smaller, but at the same time somewhat thicker than during the first few days. Even at this time, however, not all of the thrombosed vessels have become or-

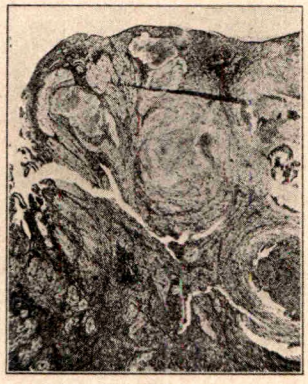

Fig. 22.—Part of placental site seventeenth day postpartum, with undermining at left margin (×18).

ganized, as is shown by Fig. 19. At this time, the placental site is not yet covered by epithelium, which appears to be limited to its margins and to its basal portion. In these locations, however, it is seen that well-developed endometrial tissue is present and apparently is extending beneath the thrombosed vessels which now make up the greater part of the placental site. This is still more clearly shown by Fig. 20, which represents sections from the twelfth day.

A few days later, the placental site is constituted by a dense mass of tissue consisting of obliterated arteries and thrombosed and organized veins, while a good deal of the tissue between them has undergone hyalin degeneration. Figs. 21 and 22 show the conditions in two specimens at the seventeenth day. In the first, the placental site ex-

The events associated with involution of the placental site and other changes in the uterus during the puerperium have interested numerous investigators. William Hunter, who originally described the decidua, observed that it ". . . is an effloresence of the internal coat of the uterus itself; and is therefore shed, as often as a woman bears a child, or suffers a miscarriage. It is of considerable thickness, and one stratum of it is always left upon the uterus after delivery, most of which dissolves and comes away with the lochia" (*An Anatomical Description of the Human Gravid Uterus and Its Contents,* London, 1794 J. Johnson, p 55). Carl Friedlander described the superficial compact and deeper spongy layers of the decidua and stated that placental separation occurred in the deeper part of the former, so that the endometrium regenerated from the glands in the spongy layer. In addition, he demonstrated that while most of the uterine mucosa had regenerated by 4 weeks this did not occur for several additional weeks at the placental site (*Physiol. Anat. Untersuchugen über den Uterus,* Leipzig, 1870). A few years later C. Gerhard Leopold stated that the decidua was cast off post partum and new endometrial glands were derived from serotinal cells interspersed between bundles of myometrial cells (Studien über die Uterusschleimhaut während Menstruation, Schwangerschaff und Wochenbett, Arch. Gynaekol. 11:443, 1877). Emil Ries first suggested that exfoliation of the decidua at the placental site occurs by an undermining of new endometrium (Klinische und anatomische Studien über Zurückbildung des puerperaten Uterus, Z. Geburtshilfe Gynaekol. 24:33, 1892). It was Williams, however, who most completely described the morphologic changes associated with involution of the placental site; his conclusions were based on a study of normal uteri surgically removed from shortly after delivery to the fourth month post partum. He confirmed earlier reports that the cervical mucosa is restored by the end of the first week, and the endometrium, other than at the placental site, is restored completely during the third week. One of Williams' chief contributions was to describe the mechanism of exfoliation of the placental site, and he also showed that exfoliation is not normally associated with inflammation or extensive necrosis. Fig. 22 (see illustration) shows this undermining by endometrium of the thrombosed vessels in part of the placental site.

0002-9378/79/140715+02$00.20/0 © 1979 The C. V. Mosby Co.

Regarding the fate of the placental site, Williams wrote: ". . . six to seven weeks are required for its disappearance, and that it is not effected by absorption in situ, but rather by a process of exfoliation which is in great part brought about by the undermining . . . by the growth of endometrial tissue. This is effected in part by extension and downgrowth of endometrium from the margins of the placental site, and partly by the development of endometrial tissue from the glands and stroma left in the depths of the decidua basalis after separation of the placenta. In general, I am inclined to attach more importance to the former than to the latter mechanism . . . such a process of exfoliation should be regarded as very conservative, and as a wise provision on the part of Nature; otherwise great difficulty might be experienced in getting rid of the obliterated arteries and organized thrombi, which if they remained in situ would soon convert a considerable part of the mucosa into a mass of scar tissue, with the results that after a few pregnancies it would no longer be possible for it to go through its useful cycle of changes, and the reproductive career would come to an untimely

ENDO LABORATORIES TAMES THE POPPY—
TO BRING YOU
new NUBAIN®
nalbuphine HCl
ANALGESIA COMPARABLE TO MORPHINE,
WITH IMPORTANT DIFFERENCES

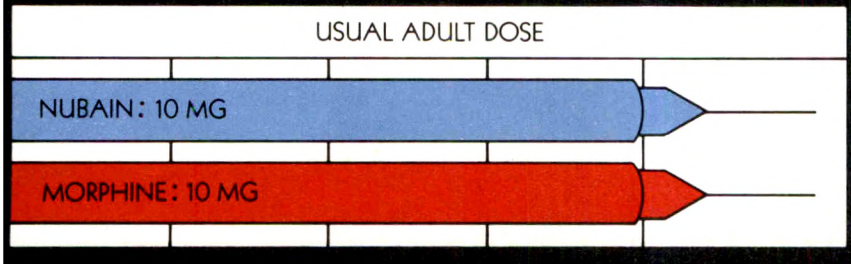
new

NUBAIN®

AMPULS AND VIAL

nalbuphine HCl

ANALGESIA COMPARABLE TO MORPHINE

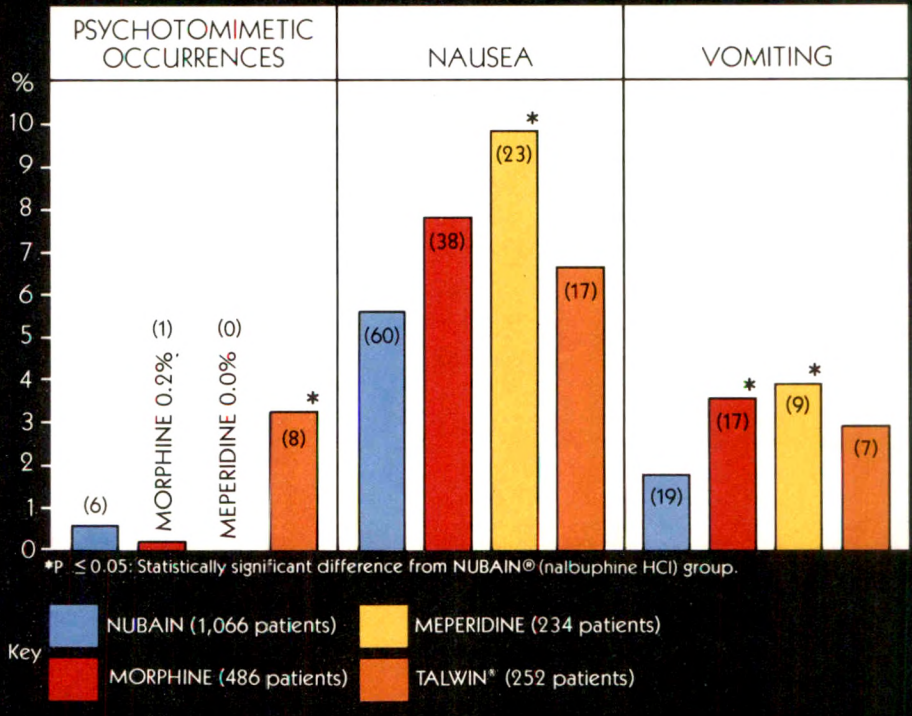


NUBAIN offers:
- Onset, peak and duration
- Comparable to morphine

10 mg of NUBAIN is comparable in analgesic effect to 10 mg of morphine

Onset of action with NUBAIN begins within 2 to 3 minutes I.V., and less than 15 minutes I.M. or S.C.

Analgesic effect of NUBAIN lasts from 3 to 6 hours

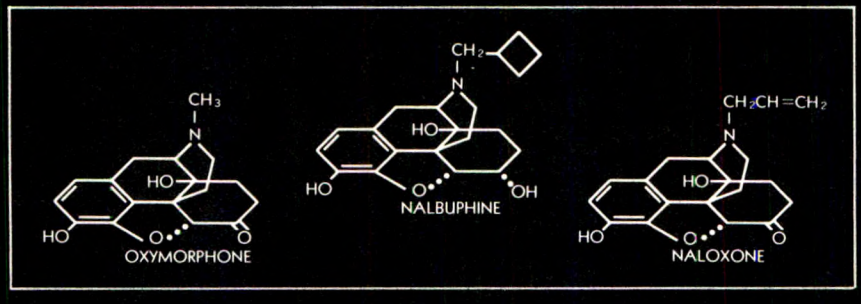


NUBAIN is an Endo registered U.S. trademark.

WITH A LOW INCIDENCE OF SIDE EFFECTS

Clinical studies show: low incidence of nausea, vomiting and psychotomimetic effects

IN 27 SINGLE OR CROSS-OVER CLINICAL STUDIES (2,038 DRUG EVALUATIONS) THESE SIDE EFFECTS WERE OBSERVED:[1]

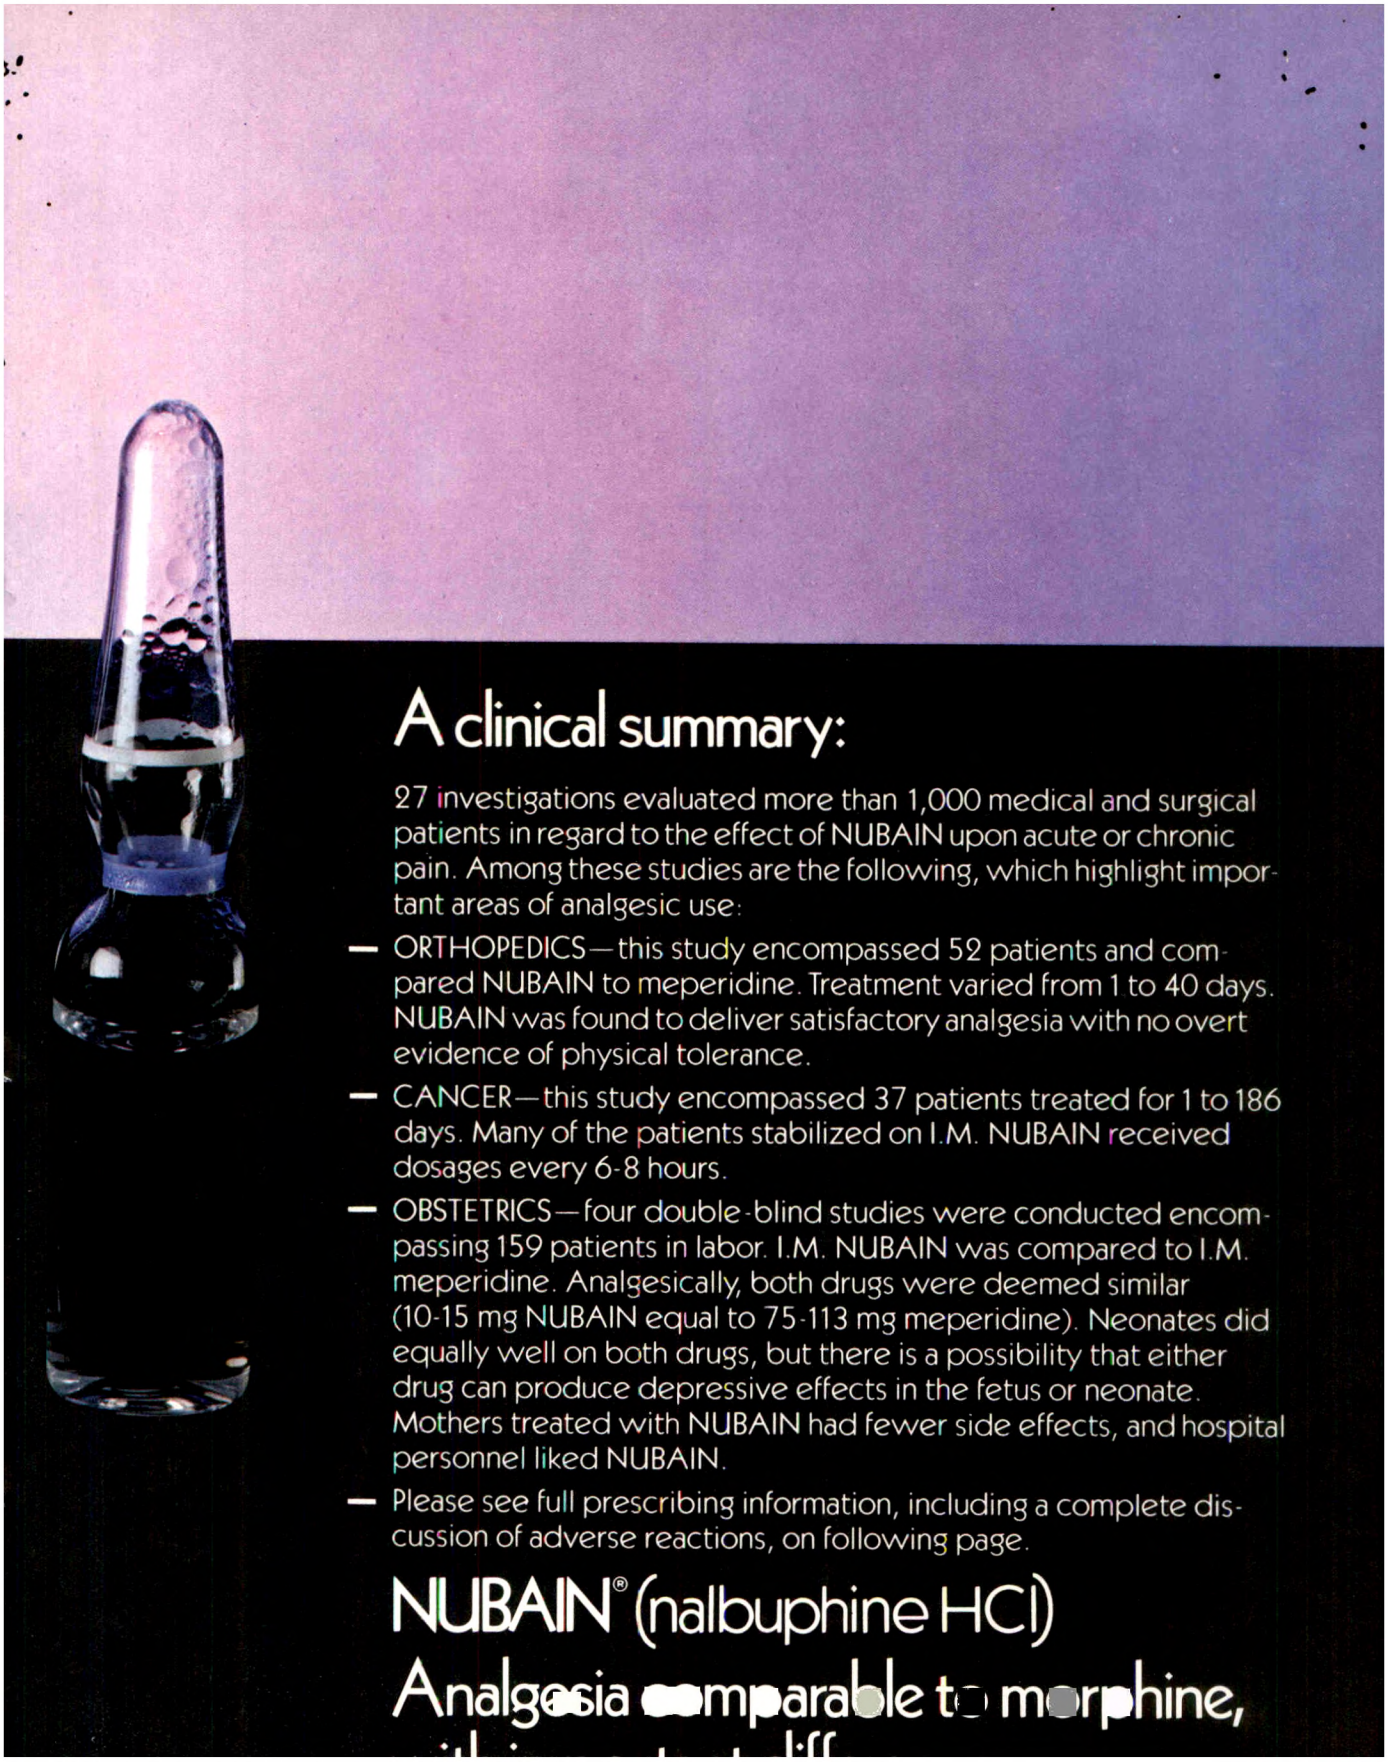


1. These clinical studies involved patients with pain from a variety of medical causes, including labor, cancer, and orthopedic and general surgical procedures. Actual number of patients experiencing each side effect is shown in parentheses on the bar.

new NUBAIN®
nalbuphine HCl

OFFERS LOW POTENTIAL FOR ABUSE

- NUBAIN requires no special storage or additional paperwork beyond your normal order or prescription.
- The unique properties of NUBAIN may be found in its molecular structure.



- Certain substances, such as NARCAN® (naloxone HCl), counteract or antagonize the effects and side effects of potent narcotics, such as morphine or NUMORPHAN® (oxymorphone HCl). NUBAIN was designed to incorporate important molecular features of the antagonist NARCAN and the potent analgesic NUMORPHAN, resulting in a drug with strong analgesia but limited abuse potential.

And a lower respiratory effect

- At dosages of 10 mg/70 kg, NUBAIN causes respiratory depression comparable to that of morphine. In contrast to morphine, higher doses of NUBAIN do not increase respiratory depression appreciably (see Precautions).

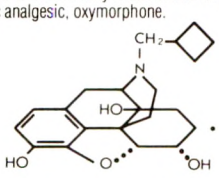
NARCAN is an Endo registered U.S. trademark.

NUMORPHAN is an Endo registered U.S. trademark.

A clinical summary:

27 investigations evaluated more than 1,000 medical and surgical patients in regard to the effect of NUBAIN upon acute or chronic pain. Among these studies are the following, which highlight important areas of analgesic use:

- ORTHOPEDICS—this study encompassed 52 patients and compared NUBAIN to meperidine. Treatment varied from 1 to 40 days. NUBAIN was found to deliver satisfactory analgesia with no overt evidence of physical tolerance.
- CANCER—this study encompassed 37 patients treated for 1 to 186 days. Many of the patients stabilized on I.M. NUBAIN received dosages every 6-8 hours.
- OBSTETRICS—four double-blind studies were conducted encompassing 159 patients in labor. I.M. NUBAIN was compared to I.M. meperidine. Analgesically, both drugs were deemed similar (10-15 mg NUBAIN equal to 75-113 mg meperidine). Neonates did equally well on both drugs, but there is a possibility that either drug can produce depressive effects in the fetus or neonate. Mothers treated with NUBAIN had fewer side effects, and hospital personnel liked NUBAIN.
- Please see full prescribing information, including a complete discussion of adverse reactions, on following page.



NUBAIN® (nalbuphine HCl)

Analgesia comparable to morphine,

new NUBAIN®
nalbuphine HCl

DESCRIPTION

NUBAIN (nalbuphine hydrochloride) is a synthetic narcotic agonist-antagonist analgesic of the phenanthrene series. It is chemically related to both the widely used narcotic antagonist, naloxone, and the potent narcotic analgesic, oxymorphone.

NALBUPHINE HYDROCHLORIDE

(-)-17-(cyclobutylmethyl)-4,5α-epoxy-morphinan-3, 6α, 14-triol,hydrochloride

• HCl

Each ml of the injectable aqueous solution of NUBAIN contains 10 mg of nalbuphine hydrochloride.

ACTIONS

NUBAIN is a potent analgesic. Its analgesic potency is essentially equivalent to that of morphine on a milligram basis.

Its onset of action occurs within 2 to 3 minutes after intravenous administration, and in less than 15 minutes following subcutaneous or intramuscular injection. The plasma half-life of nalbuphine is 5 hours and in clinical studies the duration of analgesic activity has been reported to range from 3 to 6 hours.

The narcotic antagonist activity of NUBAIN is one-fourth as potent as nalorphine and 10 times that of pentazocine.

INDICATIONS

For the relief of moderate to severe pain. NUBAIN can also be used for preoperative analgesia, as a supplement to surgical anesthesia, and for obstetrical analgesia during labor.

CONTRAINDICATIONS

NUBAIN should not be administered to patients who are hypersensitive to it.

WARNINGS

Drug Dependence NUBAIN has been shown to have a low abuse potential which is approximate to that of pentazocine. When compared with drugs which are not mixed agonist-antagonists, it has been reported that nalbuphine's potential for abuse would be less than that of codeine and propoxyphene. Psychological and physical dependence and tolerance may follow the abuse or misuse of nalbuphine. Therefore, caution should be observed in prescribing it for emotionally unstable patients, or for individuals with a history of narcotic abuse. Such patients should be closely supervised when long-term therapy is contemplated.

Care should be taken to avoid increases in dosage or frequency of administration which in susceptible individuals might result in physical dependence.

Abrupt discontinuation of NUBAIN following prolonged use has been followed by symptoms of narcotic withdrawal, i.e., abdominal cramps, nausea and vomiting, rhinorrhea, lacrimation, restlessness, anxiety, elevated temperature and piloerection.

Use in Ambulatory Patients NUBAIN may impair the mental or physical abilities required for the performance of potentially dangerous tasks such as driving a car or operating machinery. Therefore, NUBAIN should be administered with caution to ambulatory patients who should be warned to avoid such hazards.

Use in Emergency Procedures Maintain patient under observation until recovered from NUBAIN effects that would affect driving or other potentially dangerous tasks.

Use in Children Clinical experience to support administration to patients under 18 years is not available at present.

Use in Pregnancy (other than labor) Safe use of NUBAIN in pregnancy has not been established. Although animal reproductive studies have not revealed teratogenic or embryotoxic effects, nalbuphine should only be administered to pregnant women when, in the judgement of the physician, the potential benefits outweigh the possible hazards.

Use During Labor and Delivery NUBAIN can produce respiratory depression in the neonate. It should be used with caution in women delivering premature infants.

Head Injury and Increased Intracranial Pressure The possible respiratory depressant effects and the potential of potent analgesics to elevate cerebrospinal fluid pressure (resulting from vasodilation following CO_2 retention) may be markedly exaggerated in the presence of head injury, intracranial lesions or a pre-existing increase in intracranial pressure. Furthermore, potent analgesics can produce effects which may obscure the clinical course of patients with head injuries. Therefore, NUBAIN should be used in these circumstances only when essential, and then should be administered with extreme caution.

Interaction With Other Central Nervous System Depressants Although NUBAIN possesses narcotic antagonist activity, there is evidence that in nondependent patients it will not antagonize a narcotic analgesic administered just before, concurrently, or just after an injection of NUBAIN. Therefore, patients receiving a narcotic analgesic, general anesthetics, phenothiazines, or other tranquilizers, sedatives, hypnotics, or other CNS depressants (including alcohol) concomitantly with NUBAIN may exhibit an additive effect. When such combined therapy is contemplated, the dose of one or both agents should be reduced.

PRECAUTIONS

Impaired Respiration At the usual adult dose of 10 mg/70 kg, NUBAIN causes some respiratory depression approximately equal to that produced by equal doses of morphine. However, in contrast to morphine, respiratory depression is not appreciably increased with higher doses of NUBAIN. Respiratory depression induced by NUBAIN can be reversed by NARCAN® (naloxone hydrochloride) when indicated. NUBAIN should be administered with caution at low doses to patients with impaired respiration (e.g., from other medication, uremia, bronchial asthma, severe infection, cyanosis or respiratory obstructions).

Impaired Renal or Hepatic Function Because NUBAIN is metabolized in the liver and excreted by the kidneys, patients with renal or liver dysfunction may overreact to customary doses. Therefore, in these individuals, NUBAIN should be used with caution and administered in reduced amounts.

Myocardial Infarction As with all potent analgesics, NUBAIN should be used with caution in patients with myocardial infarction who have nausea or vomiting.

Biliary Tract Surgery As with all narcotic analgesics, NUBAIN should be used with caution in patients about to undergo surgery of the biliary tract since it may cause spasm of the sphincter of Oddi.

ADVERSE REACTIONS

The most frequent adverse reaction in 1066 patients treated with NUBAIN is sedation (381, 36%). Less frequent reactions are: sweaty/clammy (99, 9%), nausea/vomiting (68, 6%), dizziness/vertigo (58, 5%), dry mouth (44, 4%), and headache (27, 3%).

Other adverse reactions which may occur (reported incidence of 1% or less) are:

CNS Effects nervousness, depression, restlessness, crying, euphoria, floating, hostility, unusual dreams, confusion, faintness, hallucinations, dysphoria, feeling of heaviness, numbness, tingling, unreality. The incidence of psychotomimetic effects, such as unreality, depersonalization, delusions, dysphoria and hallucinations has been shown to be less than that which occurs with pentazocine.

Cardiovascular Hypertension, hypotension, bradycardia, tachycardia.

Gastrointestinal Cramps, dyspepsia, bitter taste.

Respiration Depression, dyspnea, asthma.

Dermatological Itching, burning, urticaria.

Miscellaneous Speech difficulty, urinary urgency, blurred vision, flushing and warmth.

DOSAGE AND ADMINISTRATION

The usual recommended adult dose is 10 mg for a 70 kg individual, administered subcutaneously, intramuscularly or intravenously; this dose may be repeated every 3 to 6 hours as necessary. Dosage should be adjusted according to the severity of the pain, physical status of the patient, and other medications which the patient may be receiving. (See Interaction with Other Central Nervous System Depressants under WARNINGS.) In non-tolerant individuals, the recommended single maximum dose is 20 mg, with a maximum total daily dose of 160 mg.

Patients Dependent on Narcotics Patients who have been taking narcotics chronically may experience withdrawal symptoms upon the administration of NUBAIN. If unduly troublesome, narcotic withdrawal symptoms can be controlled by the slow intravenous administration of small increments of morphine, until relief occurs. If the previous analgesic was morphine, meperidine, codeine, or other narcotic with similar duration of activity, one-fourth of the anticipated dose of NUBAIN can be administered initially and the patient observed for signs of withdrawal, i.e., abdominal cramps, nausea and vomiting, lacrimation, rhinorrhea, anxiety, restlessness, elevation of temperature or piloerection. If untoward symptoms do not occur, progressively larger doses may be tried at appropriate intervals until the desired level of analgesia is obtained with NUBAIN.

Management of Overdosage The immediate intravenous administration of NARCAN® (naloxone hydrochloride) is a specific antidote. Oxygen, intravenous fluids, vasopressors and other supportive measures should be used as indicated.

The administration of single doses of 72 mg of NUBAIN intramuscularly to eight normal subjects has been reported to have resulted primarily in symptoms of sleepiness and mild dysphoria.

HOW SUPPLIED

NUBAIN® (nalbuphine hydrochloride) injection for intramuscular, subcutaneous, or intravenous use (10 mg/ml) is available in:

NDC #0056-0385 10 mg/ml, 1 ml ampuls (box of 10)
NDC #0056-0384 10 mg/ml, 2 ml ampuls (box of 10)
NDC #0056-0386 10 mg/ml, 10 ml vials

Each ml contains 10 mg nalbuphine hydrochloride, 0.1% sodium chloride, 0.94% sodium citrate, 1.26% citric acid anhydrous, 0.1% sodium metabisulfite, and 0.2% of a 9:1 mixture of methylparaben and propylparaben as preservative; pH is adjusted with hydrochloric acid.

PAUL GREENBERG, M.D.
ROGER K. FREEMAN, M.D.

Division of Maternal/Fetal Medicine, Women's Hospital Medical Center and Memorial Hospital Medical Center, Long Beach, California, and Department of Obstetrics, University of California at Irvine, Orange, California

SEVERAL RECENT REPORTS have described acute pulmonary edema in patients treated simultaneously with beta-sympathomimetic agents to stop premature labor and corticosteroids to accelerate fetal pulmonary maturation.[1–3] There were eight cases in Germany involving fenoterol, a case from England involving ritodrine, and a case from Boston, involving terbutaline. Both betamethasone and dexamethasone have been used as the glucocorticoid drug in these 10 cases. There was one maternal death. Recently magnesium sulfate has been advocated as a tocolytic agent.[4] This report describes acute pulmonary edema in two patients treated with magnesium sulfate and betamethasone.

In Case 1, L. N., a 37-year-old woman, gravida 9, para 7, abortions 1, with six living children, had an uneventful twin pregnancy until 34 weeks' gestation when she had spontaneous rupture of the membranes with no labor. Her past medical history was unremarkable with no known rheumatic fever; a cardiac history included a murmur detected 18 months prior to pregnancy. Cardiologic evaluation including echocardiography concluded that it was a benign flow murmur.

Physical examination was normal. Vital signs were: blood pressure, 130/80; respirations, 16/min; pulse, 76/min. The lungs were clear to auscultation and percussion. The heart had a regular sinus rhythm, with no murmurs. Hematocrit was 27.2%. After amniocentesis revealed a lecithin/sphingomyelin (L/S) ratio of 1.2/1, she was treated with 2 ml Celestone* intramuscularly (6 mg betamethasone acetate and 6 mg betamethasone phosphate) and was started on a regimen of magnesium sulfate, as described by Steer and Petrie,[4] to prevent labor. Forty-eight hours later, an elective cesarean section was performed following epidural anesthesia due to transverse lie of both fetuses. Forty-five minutes after operation, respirations were noted to be labored. She complained of shortness of breath and developed a cough with lower lobe rales and wheezes, with x-ray evidence of bilateral infiltration, consistent with pulmonary edema.

The patient initially developed wheezing and dyspnea, which was felt to be an asthmatic type of reaction, and aminophylline treatment was instituted. A chest roentgenogram, however, showed clear evidence of pulmonary venous hypertension and pulmonary edema. The patient had a good response to diuretic therapy. The remainder of the hospital course was normal. Both infants did well and were discharged with the mother.

In Case 2, J. C., a 22-year-old woman, gravida 2, para 0, abortions 1, had an uncomplicated pregnancy until 33 weeks' gestation when she developed severe pre-eclampsia with blood pressure of 150/100, proteinuria (4+), edema (2+), and hyperreflexia (3+). L/S ratio was 1.0/1 and she was treated conservatively with bed rest and phenobarbitol. She developed a pruritic rash and the phenobarbitol was stopped. One week later the blood pressure was up to 148/104, with proteinuria (2+) and hyperreflexia (3+). She was transferred to Women's Hospital, Long Beach, at this time in premature labor.

Past medical history revealed no major medical problems, including a totally negative cardiac history. Vital signs consisted of: blood pressure, 160/110; respirations, 18/min; temperature, 98.4° F; pulse, 80/min. Pertinent physical findings included lungs that were clear to percussion and auscultation. Heart examination revealed normal sinus rhythm with no murmurs. The fundal height was 32 cm, with fetal heart tones

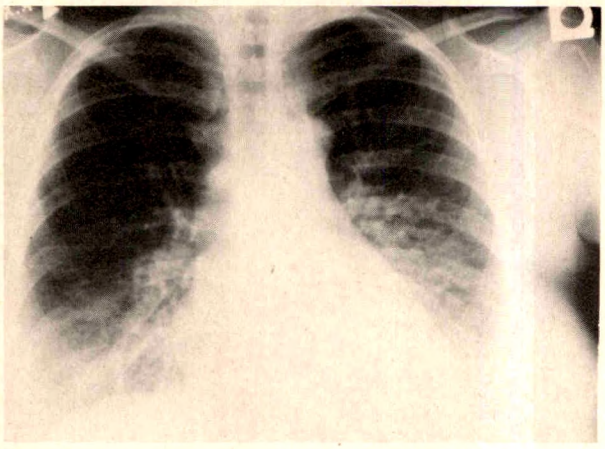

Fig. 1. Case 2. Chest roentgenogram demonstrating pulmonary edema and congestive heart failure.

of 144/min. The cervix was 50% effaced and closed with a ballotable vertex presentation. There was (2+) edema of the extremities with no cyanosis. There was deep tendon hyperreflexia (3+) with no clonus. Hematocrit was 27.2%.

On the monitor, contractions were every 3 to 5 minutes. The baby's heart rate pattern was reactive with no decelerations.

A repeat L/S ratio was 1.0/1. Magnesium sulfate was administered as described by Steer and Petrie,[4] as a tocolytic agent and to increase the seizure threshold.

With pre-eclampsia worsening and premature labor present, a decision was made to administer betamethasone, with the patient continuously on the fetal monitor. Celestone (12 mg) was administered intramuscularly. Contractions stopped and blood pressure ranged from 120 to 130/80 to 90. Deep tendon reflexes (1+) and proteinuria (1+) remained. Fifteen hours after the second dose of 12 mg Celestone she complained of increasing difficulty in breathing and cough.

Physical findings then showed a blood pressure of 164/98; respirations, 30/min; pulse, 112/min; temperature, 98.8° F. Bibasilar rales were heard and cardiovascular examination was consistent with congestive heart failure with an S_3 and S_4 gallop present. Reflexes (2+) and edema (2+) were present.

Chest roentgenography was consistent with pulmonary edema and congestive heart failure (Fig. 1). The maximum serum magnesium level was 5.6 mg/100 ml. Echocardiogram revealed no evidence of cardiac disease. A total of 4,400 ml of 5% dextrose in lactated Ringer's solution and 5½% dextrose in ½N saline had been given intravenously with nothing by mouth, and total urinary output was 2,800 ml. A Schwann-Ganz catheter was inserted. Right atrial pressure was 18 mm Hg; right ventricle, 40/15 mm Hg; pulmonary artery, 40/25 mm Hg; wedge pressure, 30 mm Hg. She was treated with Lasix, 40 to 80 mg as needed, to lower wedge pressure, digitalis, oxygen, and fluid restriction, with resolution of congestive heart failure over the next 16 hours. Labor was induced the following morning, with subsequent vaginal delivery of a viable, 2,015 gram male infant, Apgar scores 8 and 9. Her postpartum course was normal.

The effective use of magnesium sulfate as a tocolytic agent has been described.[4] At Women's Hospital, Long Beach, we have used this drug recently for the treatment of premature labor and it appears to be reasonably effective. The mechanism of its action on the uterine musculature is unknown but may be due to an inhibitory effect on calcium transport in the muscle cell. Magnesium sulfate has been shown to have a profound effect of the cardiovascular system in the nonpregnant human.[5] There is a decrease in peripheral vascular resistance, and in hypertensive patients a decrease in mean arterial blood pressure has been shown. There is also an increase in cardiac index and often an increase in heart rate. This increased stroke volume and cardiac output must result in increased cardiac work. Similar cardiovascular changes have been attributed to beta-sympathomimetic agents.[2]

Corticosteroids have myriad diverse effects but little known direct effects on the cardiovascular system. The role they may play is uncertain.

Corticosteroids and tocolytic agents (magnesium sulfate, ritodrine hydrochloride, and intravenous alcohol) have been used extensively in our hospital, and only these two cases of pulmonary edema and congestive heart failure have been found. These cases are the first reported of the association of magnesium sulfate and corticosteroids with acute pulmonary edema in pregnant patients. Previous reports in the literature strongly implicate various beta-sympathomimetic amines as the causative agents, with the role of the corticosteroid uncertain. Although there is a clinically observed association, there is no clear physiologic basis to implicate the steroids in this process. At least in some pregnant patients magnesium sulfate appears to have cardiovascular effects that are similar to those of beta-mimetic amines. The low incidence of this complication leads to speculation about other predisposing factors in those patients who develop acute pulmonary edema. Both of our patients were anemic; one had a twin gestation and the other, severe pre-eclampsia. Some of the reported cases had predisposing factors, and in the fatal case from Germany the patient appeared to have organic heart disease.

This report of pulmonary edema associated with magnesium sulfate and corticosteroid administration, used to improve fetal outcome where premature delivery is imminent, should point to the possibility that some maternal risk may be involved. When using beta-mimetic amines or magnesium sulfate in association with corticosteroids (or perhaps alone) this complication must be kept in mind.

Tuberculous peritonitis and endometritis mimicking a "frozen pelvis"

LOUIS J. FREEDMAN, M.D.
BEVERLY COLEMAN, M.D.
LUIS BLASCO, M.D., F.A.C.O.G.

Departments of Obstetrics and Gynecology and Radiology, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

A CASE OF genital tuberculosis with tuberculous peritonitis is reported.

A 15-year-old black female patient, gravida 0, para 0, ABO, presented with a 3 month history of a progressively enlarging pelvic mass, amenorrhea, a 15 kilogram weight loss, anorexia, malaise, fatigue, and lower abdominal discomfort. She denied all history of fevers, chills, night sweats, diarrhea, constipation, increasing abdominal girth, tuberculosis in the family, or foreign travel. Physical examination was unremarkable except for a very firm mass filling the cul-de-sac, extending to both pelvic side walls and reaching the level of the umbilicus.

Laboratory data on admission included negative pregnancy test, absence of fetal heart sounds by Doptone, hemoglobin of 9.3, sedimentation rate of 64, and a leukocyte count of 5,200, with normal differential. The chest x-ray was normal, and a B-mode ultrasound scan of the abdomen revealed a complex, sharply marginated, predominantly solid pelvic mass extending superiorly several centimeters above the umbilicus and laterally to involve both adnexal regions (Figs. 1 to 3). The acoustic characteristics of the mass suggested ovarian neoplasm or uterine sarcoma. An intravenous urogram demonstrated an extrinsic impression on the dome of the bladder. A barium colon examination showed deviation and narrowing of the bowel lumen. The margin of the bowel was serrated, with a "thumbprint" appearance characteristic of edema, hemorrhage, or inflammation of the bowel wall (Figs. 4 to 6), without mucosal invasion, fixation, or rigidity.

Examination under anesthesia confirmed the presence of a "frozen pelvis." A dilatation and curettage revealed caseating granulomas. At laparotomy, multiple grayish nodules were seen studding the peritoneal surfaces and bowel, with matted bowel completely obscuring the pelvis. Biopsy of several of the

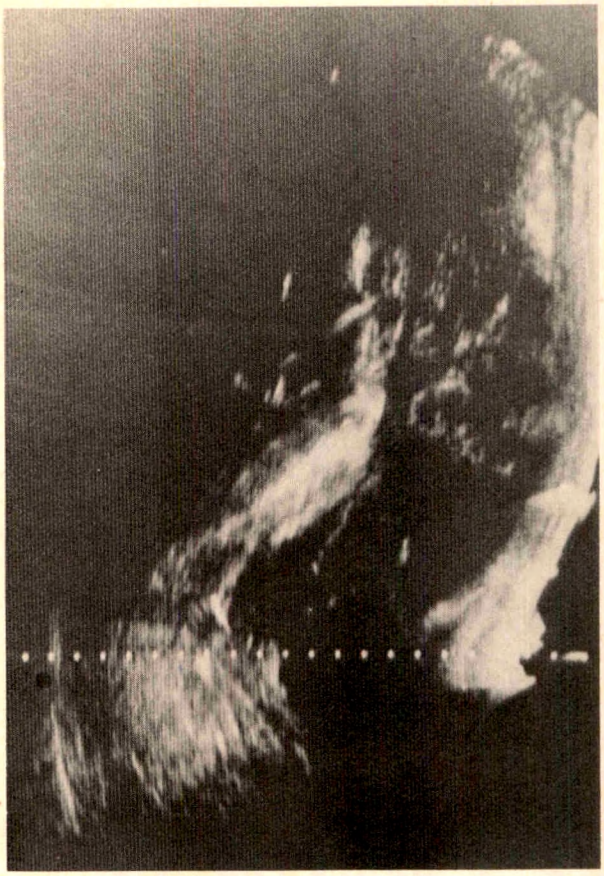

Fig. 1. Longitudinal scan of the pelvis 1 cm to the right of midline. Markers delineate the interface between the mass superiorly and the bladder inferiorly.

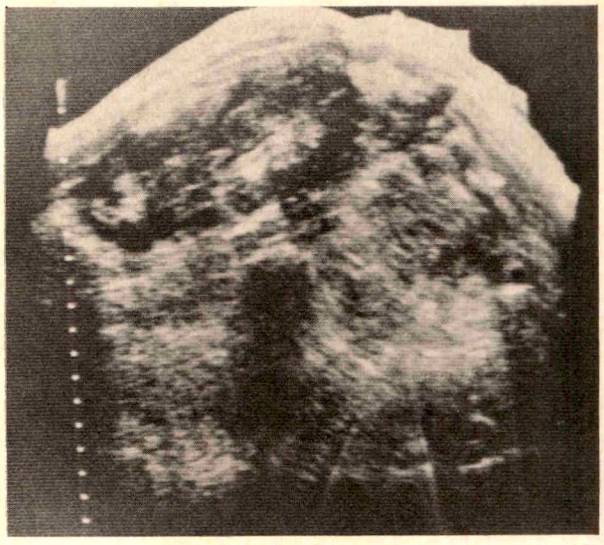

Fig. 2. Transverse scan of the abdomen at the level of the umbilicus. Markers delineate the right lateral margin of the mass which extends across the midline. The superior portion of the mass is predominantly solid.

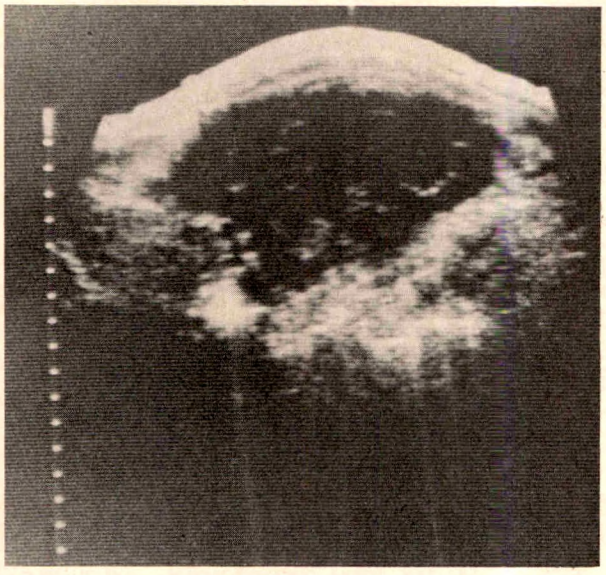

Fig. 3. Transverse scan of the pelvis 5 cm above the symphysis pubis. The inferior portion of the mass has cystic elements with scattered echoes.

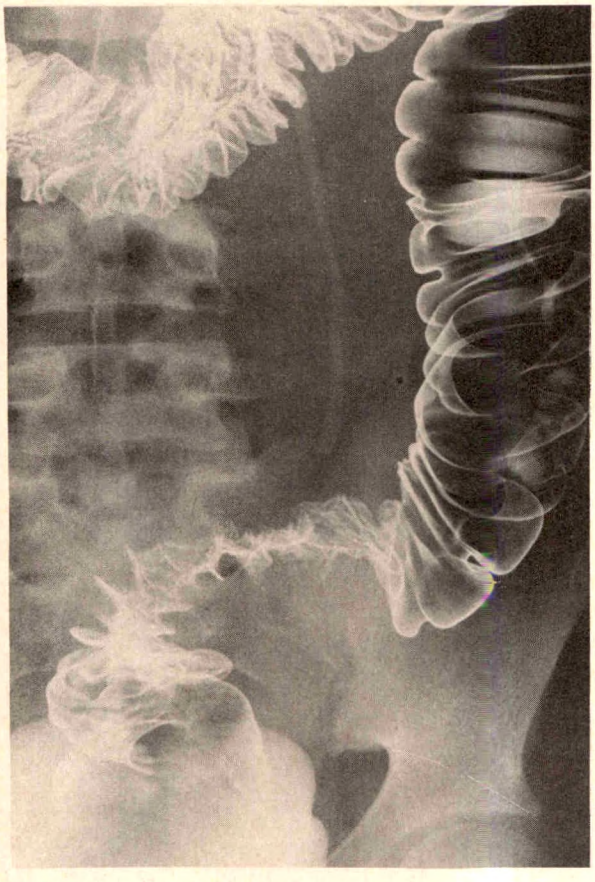

Fig. 4. AP view from the barium enema showing elevation and narrowing of the sigmoid colon. There is residual contrast in the bladder and left ureter.

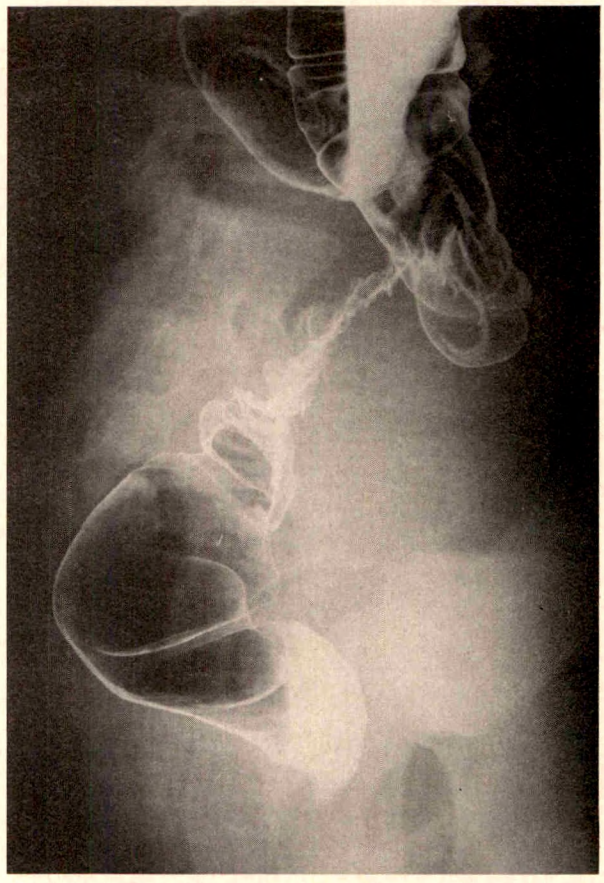

Fig. 5. Lateral view of the colon showing a large pelvic mass between the bladder and sigmoid.

nodules revealed caseating granulomas. Both endometrial and peritoneal tissue were positive for acid-fast bacilli with Ziehl-Nielsen stain, and final culture revealed *Mycobacterium tuberculosis*. Multiple cultures of sputum, nasogastric aspirate, and urine were negative for *M. tuberculosis*. Postoperatively the patient was begun on isoniazid 300 mg/day and ethambutol 25 mg/kg per day and recovered uneventfully. An intermediate strength PPD was strongly reactive on the second postoperative day and liver-spleen and bone scans were within normal limits. Three months postoperatively the patient felt well, and had resumed all normal activities; the abdominal mass had disappeared. The ethambutol dosage was decreased to 15 mg/kg per day then, and a 2 year course of double antibiotic therapy was planned.

This disease is seen in young female patients (2:1 F/M ratio), with abdominal pain, fever, weight loss, ascites, and a mass. Fever is present but episodic. The peritoneal exudate may be scanty, and is culture positive if enough fluid is submitted (83% with 1 L cultured.[1] Skin test for tuberculosis is positive in 100% of the cases, but chest x-ray is frequently normal. A mass is found in 50% of cases. Diagnosis is made by percutaneous or laparoscopic needle biopsy, or preferably by exploratory laparotomy.

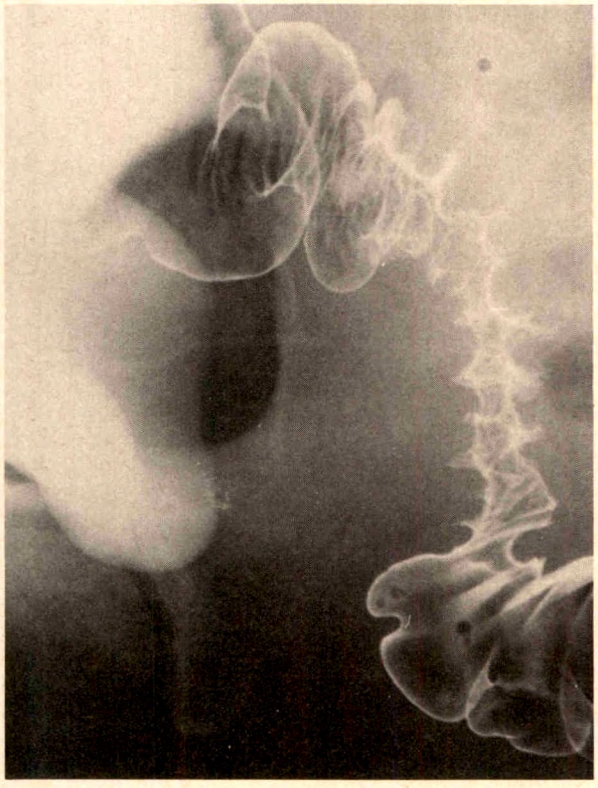

Fig. 6. Oblique view of the sigmoid colon showing the serrated margin and "thumbprinting" without mucosal destruction. There is residual contrast in the bladder and left ureter.

Management consists of a 2 year course of antituberculosis chemotherapy with isoniazid and ethambutol. Rifampin is reserved for resistant organisms. The addition of steroids cannot be supported by the available data.

The prognosis, once poor with less than a 50% 5 year survival, is good, with few reported deaths once antituberculous therapy is begun. Surgical treatment is indicated when chemotherapy fails to decrease the size of the tuboovarian abscesses after 2 months, when there is recurrence of endometrial tuberculosis after 1 year of antimicrobial therapy, when patients are over 40 and will not continue long-term therapy, and when there are fistulas which fail to heal.[2] If tubal patency is documented by hysterosalpingogram, prolonged isoniazid therapy might be advisable. Attempts at tuboplasty are doomed to failure; the prognosis for fertility is generally hopeless, with only 31 documented term pregnancies in patients with genital tuberculosis.

Pregnancy in a woman with xanthinuria: Study of amniotic fluid uric acid

PIERO CURIEL
RENZO BANDINELLI

Department of Obstetrics and Gynecology and Clinical Chemistry Laboratory, Santa Maria Nuova Hospital, Florence, Italy

XANTHINURIA is a rare metabolic disease in which, due to the deficiency of xanthine oxidase, very low levels of uric acid are found in the blood and in the urine, while abnormally high quantitites of xanthine are present in the circulation and eliminated through the kidney. Fewer than 20 cases have so far been described in the literature,[1] the main reason probably being the fact that the condition is asymptomatic except for the occasional formation of xanthine stones in the bladder.

To our knowledge no cases of this condition have been described in pregnancy.

D. C., 22 years of age was first seen on March 10, 1975, in week 12 of pregnancy. She had already had two previous pregnancies: the first ended spontaneously at week 36 and the male infant (2,100 grams) died 72 hours later, probably because hyaline membrane disease. The second pregnancy terminated spontaneously at week 26 and the small baby died soon afterward. Because of the obstetric history and also because of a certain opening of the cervical os, a cerclage was performed in week 15 of pregnancy. Findings of the routine examinations were all in the normal range except for serum uric acid, which was 0.6 mg/100 ml. Other assays were 0.3, 0.5, and 0.7 mg/100 ml (mean 0.52 mg/100 ml). Mean urinary uric acid was 50 mg/24 hours (range 20 to 75 mg/24 hours). Total purine excretion (expressed as milligrams of uric acid) was 526 mg/24 hours (range 405 to 602 mg/24 hours). Urinary oxypurines were 2,730 μmol/24 hours (range 2,100 to 3,050 μmol/24 hours). A diagnosis of xanthinuria was therefore made; the parents, one sister, and one brother of the patient were examined but normal values were found. In week 34 an amniocentesis was performed and 15 ml of amniotic fluid, slightly contaminated with blood, were recovered. Uric acid in the sample was 2.8 mg/100 ml. In week 37 the amniocentesis was repeated and the fluid was grossly contaminated with blood; since an ultrasonogram showed that the placenta was inserted in the anterior uterine wall, no more amniocenteses were attempted. The pregnancy went uneventfully to term, after the cerclage was removed in week 38. The patient gave birth spontaneously to a female baby, in good condition, who weighed 3,850 grams on September 23, 1975. Amniotic fluid was recovered at the beginning of labor through an intrauterine catheter. In this sample uric acid was 8.2 mg/100 ml. Some colostrum was recovered in the first days of puerperium but the sample could not be examined for

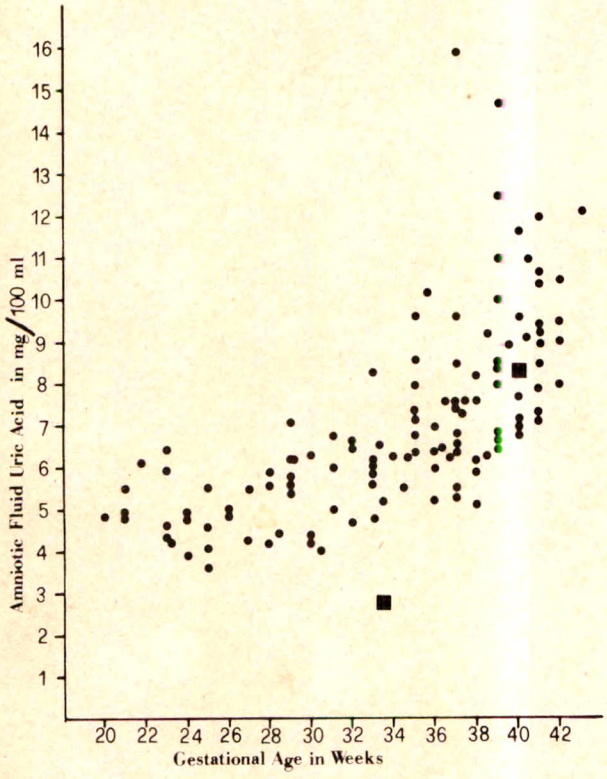

Fig. 1. Uric acid levels in amniotic fluid (■ indicates values observed in the patient with xanthinuria).

xanthine oxidase activity because of technical reasons. Serum uric acid of the newborn infant was 7.5 mg/100 ml.

The first case of xanthinuria in pregnancy has been presented. The pregnancy seemed not to be affected by the condition, and the previous perinatal losses of the patient were apparently due to a different cause.

The study of the amniotic fluid, however, offered interesting information in regard to the origin and levels of uric acid. Uric acid is known to be present in the amniotic fluid in increasing quantities from the beginning to the end of pregnancy.[2] The values observed in our laboratory in cases of normal pregnancy are presented in Fig. 1. The level of amniotic uric acid in the patient with xanthinuria was about half of the mean value observed in normal pregnancies at week 34; the level found at term was within the normal range.

Since no maternal contribution to the uric acid found in the amniotic fluid was possible, it seems logical that at term, when the major mechanism for amniotic fluid formation is fetal urination, normal values were found, whereas 6 weeks earlier, when maternal participation is supposedly more important, a much lower level than normal was observed. Nevertheless, the presence of uric acid in the amniotic fluid at this stage of pregnancy probably shows that fetal urination is already present and might account for up to 50% of amniotic fluid formation.

We thank Dr. Edward W. Holmes, Jr., Assistant Professor of Medicine, Duke University Medical Center, Durham, North Carolina, for his advice and help.

CORRESPONDENCE

Diploid nuclear replacement in mature human ova with cleavage

To the Editors:

We have read with interest and, I am afraid, some distress the recent article by Dr. Landrum B. Shettles entitled "Diploid nuclear replacement in mature human ova with cleavage" (AM. J. OBSTET GYNECOL. 133:222, 1979). I am sure your reviewers were aware of the potential importance of Dr. Shettles' claim—that he had, in fact, replaced the nucleus of a human oocyte by a nucleus isolated from a spermatogonium with subsequent successful division and early development. Given the fact that cell biologists have been attempting nuclear replacement in mammalian ova unsuccessfully for many years, one would think that the review process would have been unusually rigorous, with careful examination of the available evidence.

Several specific points should be made concerning the nature of the evidence presented by Dr. Shettles:

1. Your reviewers failed to recognize that Dr. Shettles, in his Fig. 1, presented a biologically impossible combination of morphologic features. The first polar body is extruded by the oocyte after the resumption of meiosis, which is invariably accompainied by germinal vesicle breakdown. This means that the nucleus is no longer enclosed by a nuclear envelope and, as such, is not identifiable within the cytoplasm. The chromosomes themselves appear in the periphery of the cytoplasm in various configurations and can be identified by special stains. On this basis alone, the reviewers should have questioned the claim that Dr. Shettles extracted a nucleus from an egg which had released its first polar body.

2. Dr. Shettles claims to have removed the zona pellucide in preparation for piercing the oocyte with a micropipette during aspiration of the intact nucleus, yet the photograph of the oocyte from which the nucleus was extracted (Fig. 4) includes a zona pellucida.

3. Dr. Shettles claims to have removed nuclei from spermatogonia by microsurgical dissection. Those with extensive experience with microsurgical techniques would insist that isolation of individual nuclei by this techniques is highly improbable. In any case it certainly must be documented to be credible. No details as to the actual approach used are included in the manuscript.

4. Finally the photograph contained in Fig. 6 labeled "living morular stage of ovum" is most likely a degenerating egg. In the absence of morphologic documentation of the presence of nuclei in the individual "blastomeres," one would have to assume that it is such.

It is difficult to understand how a manuscript on such a potentially important subject which contains not only biologic inaccuracies but also incomplete documentation could be considered for publication by a journal which supports the concept of peer review.

Luigi Mastroianni, Jr., M.D.
William Goodell Professor and Chairman
Don P. Wolf, Ph.D.
Associate Research Professor of Obstetrics and Gynecology and of Biochemistry and Biophysics
Department of Obstetrics and Gynecology
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania 19104

Reply to Drs. Mastroianni and Wolf

To the Editors:

In regard to any unsuccessful attempts by cell biologists to replace nuclei in mammalian ova, my experience with microdissecting and micromanipulating apparatus began in 1935 while working for the doctorate in cytogenetics, with exchanging the nucleus, food vacuoles, and certain granules between the amoeba and paramecium. Work along these lines began with the human oocyte in 1951 and has been continued to the present time. Details of observations are presented in the atlas, *Ovum Human,* and in some 30 other published papers.

In gathering material on mammalian ova for the *Handbook of Biological Data* by invitation for the National Research Council, Washington, D. C., in 1956, I learned that in all mammals, with the exception of the dog and horse, at the time the mature ovum (secondary oocyte with the first polar body extruded) is ready for release from the mature ovarian follicle, the double-stranded chromosomes are arrested at the metaphase II on the maturation spindle. With phase-contrast microscopy with the ovum denuded of all the corona radiata and granulosa cells through the enzymatic action of the follicular fluid at body temperature, the ooplasm is sufficiently translucent to permit visualization of the chromosomes on the maturation spindle. With experience, one does not have to employ any special stains, as are apparently required by these critics, in order to locate the aggregate of chromosomes for aspiration. In the event the egg is penetrated by the entire fertilizing spermatozoon, meiosis resumes with

the first polar body already formed, after which the second body is released. When one ascertains the order of events carefully, no "biologically impossible combination of morphologic features" is encountered. They should set the sequence of events straight.

Their criticism regarding the zona pellucida is misrepresenting and incorrect. The zona pellucida removed from the oocyte illustrates the high degree of elasticity of this pellucid membrane and how it may be pierced and yet remain intact upon aspiration of the chromosomes from within the ooplasm. No statement or claim is made that the zona pellucida has to be removed for enucleation. The paper speaks for itself.

In the "Communication in Brief," it is simply stated that the spermatogonial nuclei were dissected free and taken up in the micropipettes. Glass needles were employed. One skilled in microsurgical techniques with micropipettes possessing lumina of only a few microns and glass needles is aware of how this is done. Armchair speculation does not afford the insight.

Inspection of the morula readily reveals chromosomes and chromatin configurations in the nuclei of the blastomeres. Variation in cell size arises when the mitoses become asynchronous. At a given focal level, not all cells are in sharp focus; however, this does not reflect degeneration.

The National Library of Medicine Literature Search (1972 to 1978 inclusive) shows one review by Dr. Mastroianni for 1975, concerning the physiology of the oviduct in cattle and the monkey. No original observations on the human oocyte are listed. Consequently, I fail to see the basis for his assuming the role of final assessor. This quotation appears to be very apropos: "Judge ye not, lest ye be judged." In *Science News*, March 3, 1979, p. 3, Dr. Pierre Soupart stated, "I am also very surprised that the points I am making have escaped Dr. Mastroianni's scrutiny."

Fetal movements associated with fetal heart rate accelerations and decelerations

To the Editors:

I am referring to the interesting investigations reported by Drs. Timor-Tritsch, Dierker, Zador, Hertz, and Rosen, about fetal movements (FM) associated with fetal heart rate (FHR) accelerations and decelerations (Am J. Obstet. Gynecol. 131:276, 1978).

They say that in their study of 23 low-risk pregnant patients decelerations following accelerations were quite common; they were noted to follow 66.7% of the FHR accelerations; it also appears that, if the duration of the FM increases of 1 to 3 seconds (or longer), correlation of acceleration and deceleration increases from 44.1 to 73.8%. The authors defined deceleration as a decrease of the FHR of at least 6 beats per minute below the baseline; this is established as the average FHR in the 20 seconds prior to each FM.

In general, analysis of the records is often difficult, as Curran,[7] from Glasgow, confessed, despite his great experience on the subject. Kariniemi and Hukkinen[2] advised quantification of the antepartum FHR variability by fetal magnetocardiography and direct electrocardiography. Krebs and Tetres[3] believed that external systems employing ultrasonographic and phonocardiographic recording cannot give FHR variability accurately and may show an apparent increase in variability.

In the splendid tracing of the authors (Fig. 3) we can really see that the basal line goes down after going up. But, in our judgment, it is difficult to ascertain if it goes down under the initial level, because the tracing before the rising of the basal line is not shown. We do not know exactly the height of the basal line before the registered FM. It is necessary to take into consideration that the paper speed was 25 mm/sec. Besides, the authors confess that with the methodology used (tocodynamometer placed on the maternal abdomen) not all the FM are recorded.

The decelerations above mentioned by Timor-Tritsch and associates are observed in normal pregnant women, prior to birth, in association with FM; they are of small amplitude and short duration; they usually indicate fetal well being.

They are quite different from the decelerations that very frequently are observed during labor and delivery: the early decelerations, the late decelerations, and the variable decelerations known by all obstetricians. They must not be confused with the decelerations observed in the antepartum stress test (oxytocin challenge test).

To the decelerations so well described by the authors of the Cleveland Metropolitan General Hospital it is quite necessary to give another name, different from this response, and because they disappear after the administration of atropine, they might be called *small gravidic decelerations of the FHR by vagal stimulation with baseline variability*.

In our country, together with Prof. Josué A. Beruti and Dr. Jorge Diradourian or alone, for many years, we have been working on the registration of the uterine contractions and FM with external hysterodynamography; this is why we are making this commentary because in a few weeks we are presenting two papers on this subject to the Obstetrical and Gynecological Society of Buenos Aires.

Reply to Dr. Leon

To the Editors:

It seems to be true that with the increase of the duration of the fetal movements (FM) we observe a larger percentage of deceleration of the fetal heart rate FHR following the acceleration. With FM of very short duration (less than 1 second) we observed that these might not be associated with changes in the FHR or, if the origin of the movement is a deep breath or a sigh (as observed with the real-time ultrasound scanning), there might be only a deceleration of the FHR. We did not include in our article movements that lasted 1 second or less. If we look at the decelerations following an acceleration it seems that the less mature the fetus is, the deceleration appears to be more prominent compared to the amplitude and duration of the preceding acceleration.[1] FM prior to 25 weeks seem to be associated with a relatively marked deceleration following an acceleration with a very small amplitude. This observation gains support from the recent work of T. Wheeler and Murrils.[2]

As to the baseline FHR, this was selected as an average of the rate during the 20 seconds prior to the movement. It was obvious from the 1,541 movements analyzed during the study that the baseline FHR could easily be determined and that any increase in the FHR associated with FM was recognized and classified by our definitions.

We agree with Dr. Leon that the decelerations mentioned in our article should not be mistaken for antepartum or intrapartum decelerations or decelerations occurring with contractions of the uterus. We speculated upon the physiologic basis of their occurrence and we feel that these decelerations reflect normal central and peripheral nervous system function.

The prevention of cervical cancer

To the Editors:

An informative article on the prevention of cervical cancer, "Risk of cervical cancer among an electrocoagulated population," by Tapani Kauraniemi, Ulla Räsänen-Virtanen, and Matti Hakama, appeared in THE JOURNAL in the July 1, 1978, issue on page 533. This article was interesting to me since, in 1932, Dr. Willard R. Cooke, professor of obstetrics and gynecology at Texas University School of Medicine, showed me an infected cervix. He emphasized the importance of cauterization of all cervices with any kind of lesions. He showed us how to do "whole-area cauterization," since the streak method leaves scar tissue between the streaks. The whole area is cauterized.

At Dr. Cooke's suggestion, a "cervicitis" clinic was established in the City and County Hospital and in the Obstetrical and Gynecological Research Institute, Houston, Texas. For more than 40 years, special "cervicitis" clinics and treatment programs have been set up in the gynecology clinics. The cancer clinic and the cervicitis clinic were held in the same part of the gynecology clinic, with red ink used on the chart when the cervix was treated. With this red writing indicating the cases with treated cervices, one could tell which patient has a cauterization, conization, or coagulation (freezing) of the cervix. I have worked in both the cancer and the cervicitis clinics for about 30 years. I have determined that those women in whom the cervix was cauterized seldom had to be referred to the cancer clinic, substantiating the report of Kauraniemi and associates. More than 50,000 patients have been treated in these clinics.

Our group, who "popularized the Papanicolaou smear" for Drs. Trout and Papanicolaou, fully agrees that cauterization of the cervix is many times more important than the present-day mass screening with the Papanicolaou smear. As this article stated, "The potential effect of electrocoagulation in the reduction of cervical cancer may be of major importance and may even exceed the effect of organized mass screening programs practiced all over the world." This statement has been substantiated in my practice of gynecology for over 41 years. Cauterization of the cervix is a more important operation than most hysterectomies. Before performing hysterectomy, we make sure the cervix is clear of all lesions. In private practice, one price was set for cauterization and all of the follow-up so that the patient would return and we could see what happened to the cervix years later. In over 5,000 cauterization, conizations, coagulations, and cryocauterization, not one patient has developed cervical cancer. Lugol's staining and biopsies were routinely utilized in all cases. Dr. Emil Novak, of Baltimore, had a Henslman's colposcope sent to our clinic for studying the cervix. Later several brands of colposcopes were used. For the past 5 years we have made colposcopes with an ordinary dissecting microscope, turned down, and the 1975 strong cool-light sources, a colposcope costing less than $500.

These cervicitis clinics presented an entire exhibit at a May, 1945, meeting in Atlantic City on "Cervicitis: The Lesions and Their Treatments." There were about

150 5-by-7 colored photographs shown. Other scientific exhibits on cervicitis have been presented all over America. In 1962, an article was published, "A simple, self-administered treatment for the prevention of and the destruction of cervical ulcers and pre-cancerous lesions" (Med. Rec. Ann. 55:200, 1961). Here for the first time a method, suitable for use by the patient, of eliminating cervical dysplasia of high and low degrees, carcinoma in situ, ectropions, and ulcers of the cervix and vagina was presented. In 1967, a "Letter to the Editor" also described how a powder, instilled by the patient, at home, with an applicator, could prevent cervical cancer (AM. J. OBSTET. GYNECOL. **115**:867, 1973), destroying these lesions as if cautery had been used (Comparison of cautery and acid powder in benign cervical lesions, Southwest. Med. J. 50:111, 1969).

An Ultra-Scientific electronic pH recorder determines the acidity and alkalinity of the vagina and cervix any time that the small, fine tips touch the cervix. We have recorded the pH in more than 5,000 cervical ectropions, ulcers, dysplasias, and carcinomas in situ. Every dysplastic cervix was on the alkaline pH side of the scale. In over 15,000 vaginas which had acidity or pH values in the normal vaginal range of 3.0 to 3.5 to 4.2, not one case of cervical dysplasia has been found. Coppleson and Reid, in their textbook, *Pre-Cancer Cervical Lesions,* also reported electronic pH recordings of dysplastic cervical lesions. Under their study of the "Nature of the Stimulus to Produce Metaplasia," they mentioned the suggestion of Carmichael and Jeaffreson who stated that some "vaginal factor may be the cause" and Walz who thought that a pH vaginal variation could be a cause or the cause. There are very few sites in the body where the pH range or variation are as great as in the cervix. Coppleson and Reid observed columnar mucus-secreting cells at a pH above 7.4 while below this pH only squamous epithelial cells or normal vaginal cells were seen. The acid pH range acts on the columnar cell lysosomes, causing their breakdown and release of the 36 lysosomal enzymes which destroy dysplastic cells and those of carcinoma in situ. Alkaline and weakly acid pH levels favor growth of these abnormal cells and finally lead to invasive cancer. The pH variations may have other effects, as Coppleson and Reid mentioned, such as profound effects on a variety of biochemical synthesis and energy production systems of cells, by influencing the optimal "working conditions" of the enzymes concerned. Acidity and alkalinity have been observed to play a very important part in the development of dysplasia, carcinoma in situ, and invasive cervical cancer. We have verified this in studying hydrogen and hydroxyl ions of the cervix for over 35 years with an electronic pH recorder. All cases of cervical dysplasia, carcinoma in situ, and invasive cancer have had an alkaline recording.

It is believed by our group that it is the hydrogen ion which maintains the cervix in its normal, healthy condition. Up to now, we had no way to bring about and maintain the acidity of the cervix in the normal pH range of 3.0 to 3.5 to 4.2. This has been accomplished in the Obstetrical and Gynecological Research Institute over the past 40 years. "Micronized or finely pulverized aluminum powder"* is made so that it will maintain the cervix in its healthy condition, and all dysplasia and carcinoma in situ will be destroyed. If the powder is used instead of douches and after coitus or weekly in the sexually active woman, there will be no dysplasia or carcinoma in situ; cervical cancer can be reduced by as much as 95%.

Which patients should have cervical cauterization? Any woman who has had a baby and is aged 40 or more should undergo cervical cauterization. The large majority of women who have had babies do have some lesions of the cervix, due to a cervical tear. Cooke's "whole-erosion" cauterization is done. Streak cauterization is no longer used because of fibrous formation in the cut streaks. The whole cervical surface is cauterized until it is white like coagulated egg white. One cannot harm the cervix by cautery but dysplasia can develop if it is not carried out.

Any woman with a cervical lesion must undergo Lugol's staining and biopsy of the white areas. The whole area is whitened, with treatment of even that part of the cervix which does not have some ectropionic tissue.

In 1948, in my textbook, *Practical Office Gynecology,* I reported that packing the normal vagina and cervix with hydroxyl ions produced cervical ulcers and ectropions and adenosis, as seen in young women whose mothers received diethylstilbestrol during pregnancy. The ectropions even grew over the vaginal walls. Then normal physiologic vaginal acid powder was instilled in the vagina and the vaginal and cervical ulcers atrophied. We have so many cervical lesions today that we do not have enough time or physicians to treat them, so we began to use the "hydrogen" or "micronized or pulverized aluminum powder," which, when instilled by the patient or by the physician, produces a vaginal acidity in the normal physiologic acid pH range of 3.0 to 4.2. In this pH range there will be no dysplasia or carcinoma in situ. The patient can instill this powder any time that she wishes or feels that the vagina is not "clean," after coitus, or instead of douches. If the woman is sexually active it should be used twice weekly. The powder destroys not only dysplasia and carcinoma in situ but also *Trichomonas vaginalis, Candida albicans, Hemophilus vaginalis,* and all fungi, molds, and yeasts. One treatment will eliminate vaginitis and cervicitis from the practice of medicine and use of this powder after coitus and instead of douching will prevent these pathogens from reinfecting the vagina.

*Micronized aluminum powder can be obtained at any chemical supply house or in package form from Oakdale Laboratory, 1101 Oakdale Laboratory, 1101 Oakdale, Houston, Texas 77004.

In the article by Kauraniemi and associates, the risk of malignant or premalignant lesions was lower than in the rest of the population. They believe that the cautery and we believe the hydrogen ions destroyed the atypical epithelium at some stage of the natural progression of the disease. They also stated that even if it is impossible to prove cauterization of benign cervical lesions is the reason for the reduction of cervical cancer, the treatment should be seriously considered as a means of preventing cervical cancer.

In our gynecology clinics we think the most important procedures in gynecology are cauterization, conization, coagulation, and cryocauterization of benign cervical lesions.

Now with this powder the patient can destroy all benign cervical lesions. This powder is prescribed in all sexually active women, instead of water-made douches, so that any dysplastic lesion or carcinoma in situ will not become malignant and will revert back into normal vaginal cells. The acid environment has definitely been shown to cause endocervical cells to remain high in the cervical canal where they normally thrive in the alkaline environment, thereby maintaining the cervix free of dysplasia and carcinoma in situ and, in so doing, preventing the development of cervical cancer.

Fetal heart rate response to amniocentesis

To the Editors:

I read with interest the article, "Fetal heart rate reaction to amniocentesis as an indicator of fetal well-being" by John T. Harrison, M.D., F.A.C.O.G., and Joseph F. Marino, D.O., in the JOURNAL (132:49, 1978). I wish to add to their interesting findings our own experience of a study of 107 amniocenteses under continuous fetal heart rate (FHR) monitoring which was published in 1976[1] and since then has grown to 250 cases, being a routine procedure in our Department for assessment of fetal well-being in any case in which amniocentesis is indicated.

The two typical patterns of reaction, namely, tachycardia and bradycardia, correspond well with the findings of Harrison and Marino.[1, 2] There are, however, two points which should be clarified according to our experience. As the "normal" response of the fetus to the stimulus of amniocentesis is tachycardia (82.2% in our first series) "no response" or an "equivocal" response should be regarded as a sign of the existence of some degree of fetal jeopardy (proved in 42.2% of the cases of our first series), and sometimes as an indication of severe distress as in these cases which show a response of bradycardia.[2] Therefore, those cases in which an "equivocal" response is found need close observation and evaluation by additional methods, such as an oxytocin challenge test and a fetal nonstress reactive test.

In cases in which fetal bradycardia follows amniocentesis, maternal hypotension due to a maternal "vasovagal" reflex should be ruled out as the cause of fetal bradycardia.[3] Maternal "vasovagal" reflex can be observed clinically during the procedure. Another helpful point in recognizing this apparently harmless and transient cause of fetal bradycardia is a "normal" acceleration which precedes the bradycardia. By recognizing this cause of fetal bradycardia (which occurred in 6.6% of our second series) false positive results can be minimized.

We fully agree with the authors that in any amniocentesis procedure continuous FHR monitoring can contribute additional valuable information, as suggested by us in 1974.[4, 5]

Perinatal mortality rate associated with diabetic pregnancy

To the Editors:

In their stimulating article entitled "Diabetic pregnancy and perinatal morbidity," published in the "Current Developments" section in THE JOURNAL (131:560, 1978), Kitzmiller and associates have provided a wealth of information helpful to any endocrinologist caring for pregnant diabetic patients. However, one finds it difficult to accept that the perinatal mortality rate was 3.4%, particularly when the authors deleted seven patients who underwent elective abortions (4%), including three women (2%) in whom pregnancy was terminated after antenatal diagnosis of fetal anencephaly. Their delection cannot be justified since these patients were registered with the pregnancy clinic of the Joslin Foundation and must have been provided the same kind of antenatal care as the others received. Apparently the authors deleted this group of patients to achieve an impressive perinatal mortality figure of

3.4%. If one includes this group of patients for purposes of calculating the perinatal mortality rate, the true figures would be 5.4%, which is still impressive but takes away the claim of best figures from the authors, since a rate of 5% or less has been already reported by various centers.[1]

Reply to Dr. Khardori

To the Editors:

In the closing paragraph of our article, we tried to emphasize the many factors which play a role in improved perinatal survival in pregnancies attaining a stage of viability in women with insulin-dependent diabetes. We cited a high proportion of cooperative, well-motivated patients, a low incidence of pyelonephritis and pre-eclampsia, application of measures that can assess fetal well-being, prediction of fetal pulmonary maturity by amniotic fluid analysis, and advances in neonatal care. We also stated that "the availability of the α-fetoprotein assay and ultrasonography has allowed the early diagnosis of anencephaly so that pregnancies may be terminated." This is an example of the application of new medical technology to reduce the incidence of severely abnormal infants delivered after 24 weeks' gestation. We also would not include pregnancies aborted due to the diagnosis of Down's syndrome in our perinatal mortality figures—they would be considered in our abortion statistics.

On the other hand, we completely agree with Dr. Khardori that congenital anomalies are a very important outcome variable to consider when assessing management of diabetic patients before pregnancy and in early pregnancy. For this reason, our three cases of anencephaly were included in our incidence of 9% major congenital anomalies. In the article, we emphasized that the relationship of the metabolic perturbations of maternal diabetes to birth defects in the offspring is a very important area for research.

Finally, I believe it is demeaning and trivial to claim the best record for anything in this complicated and changing world. In the paper we stated that "the perinatal mortality rate in this [1975 to 1976] series (34/1,000) is among the best reported to date for large groups of women with severe diabetes." Over the four years, 1975 to 1978, our perinatal mortality rate for 270 diabetic women was 36/1,000.

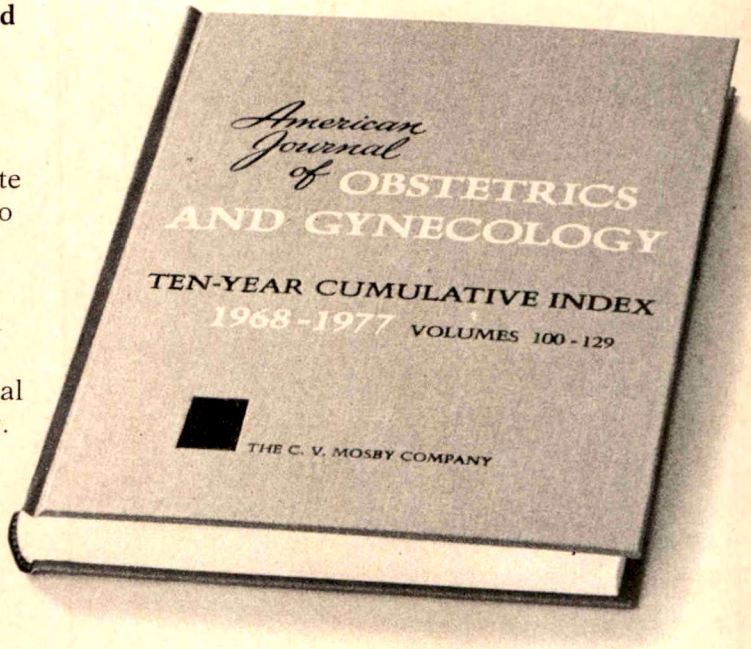
Prior immunization by herpesvirus

To the Editors:



In their article concerning the effects of prior immunization by herpesvirus type 1, Asher and his coworkers were not able to demonstrate protection from challenge with herpesvirus type 2 (AM. J. OBSTET. GYNECOL. 131:788, 1978). They attributed this to possible strain difference among type 2 virus.

As reported previously (AM. J. OBSTET. GYNECOL. 125:41, 1976), we *were* able to demonstrate protection of newborn mice from lethal infection due to maternal vaginal challenge with type 2 herpesvirus after maternal immunization with type 1 virus. Perhaps this is an example of strain differences suggested by the authors. I would encourage them to continue with their model of latent infection to test this hypothesis.

New! Available for the first time

The ten-year **cumulative author and subject index** to volumes 100-129 (1968-1977) of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY is now available for your journal collection. It is a complete and comprehensive reference guide to over 28,000 pages of authoritative articles published in the Journal during the past ten years.

The world-renowned "Gray Journal" is the oldest specialty journal devoted to obstetrics and gynecology.

Now these influential papers, appearing between 1968-1977, have been cross-referenced to include over 23,100 subject entries. Each entry lists the complete article title, author(s), volume, page, and year of publication.

The author index lists more than 13,850 contributors from this period, along with respective article title, author-to-author referral, volume, page, and publication date.

The 479-page index is handsomely presented in a rust and gold cloth-cover volume. It is a must for every library concerned with obstetrics and gynecology. Send for your copy of this valuable reference today!

Flagyl® (metronidazole) 250 mg.

Warning
Metronidazole has been shown to be carcinogenic in mice and possibly carcinogenic in rats. (See *Warnings*.) Unnecessary use of the drug should be avoided. Its use should be reserved for the conditions described in the *Indications* section.

Indications: For the treatment of symptomatic trichomoniasis in both females and males when the presence of the trichomonad has been confirmed by appropriate laboratory procedures (wet smears and/or cultures). Also for the treatment of asymptomatic females when the organism is associated with endocervicitis, cervicitis, or cervical erosion. *T. vaginalis* infection is a venereal disease and therefore, asymptomatic sexual partners of infected patients should be treated simultaneously if the organism is present. The decision to treat an asymptomatic male partner who has a negative culture or smear, or one in whom no culture has been attempted, is an individual one. In any event, the consort should be treated with Flagyl in cases of reinfection. Flagyl is also indicated for acute intestinal amebiasis (amebic dysentery) and for amebic liver abscess.

Contraindications: Evidence or history of blood dyscrasia, active organic disease of the CNS, the first trimester of pregnancy and a hypersensitivity to metronidazole.

Warnings: Flagyl should not be used in the first trimester of pregnancy (see *Contraindications*). Use with discretion during the second and third trimesters of pregnancy and restrict to those pregnant patients not cured by topical measures. Flagyl (metronidazole) is secreted in the breast milk of nursing mothers. It is not known whether this can be injurious to the newborn. If used during lactation, an alternative method of feeding may be elected.

Note: Tumorigenicity Studies in Rodents. Metronidazole has shown evidence of tumorigenic activity in a number of studies involving chronic, oral administration in mice and rats.

Most prominent among the effects in the mouse was the promotion of pulmonary tumorigenesis. This has been observed in all five reported studies in that species, including one study in which the animals were dosed on an intermittent schedule (administration during every fourth week only). The published results of one of the mouse studies indicate increases in the incidence of malignant lymphomas as well as pulmonary neoplasms associated with lifetime feeding of the drug. All these effects are statistically significant.

Two long-term toxicity studies in the rat have been completed. There was a statistically significant increase in the incidence of various neoplasms, particularly mammary tumors, among female rats administered metronidazole over that noted in the concurrent female control groups.

Two lifetime tumorigenicity studies in hamsters have been performed and reported to be negative.

Metronidazole has been reported to potentiate the anticoagulant effect of coumarin and warfarin resulting in a prolongation of prothrombin time. This possible drug interaction should be considered when Flagyl is prescribed for patients on this type of anticoagulant therapy.

Precautions: Mild leukopenia has been reported during Flagyl use; total and differential leukocyte counts are recommended before and after treatment with the drug, especially if a second course is necessary. Avoid alcoholic beverages during Flagyl therapy because abdominal cramps, nausea, vomiting, headaches and flushing may occur. Discontinue Flagyl promptly if abnormal neurologic signs occur. Exacerbation of moniliasis may occur. In amebic liver abscess, aspirate pus during metronidazole therapy.

Adverse Reactions: Nausea, headache, anorexia, vomiting, diarrhea, epigastric distress, abdominal cramping, constipation, a metallic, sharp and unpleasant taste, furry tongue, glossitis and stomatitis possibly associated with a sudden overgrowth of *Candida*, exacerbation of vaginal candidiasis, an occasional reversible moderate leukopenia, dizziness, incoordination and ataxia, numbness or paresthesia of an extremity, fleeting joint pains, confusion, irritability, depression, insomnia, mild erythematous eruptions, "weakness," urticaria, flushing, nasal congestion, dryness of the mouth, vagina or vulva, pruritus, dysuria, cystitis, a sense of pelvic pressure, dyspareunia, fever, polyuria, incontinence, decrease of libido, proctitis, pyuria and darkened urine have occurred in patients receiving the drug. Patients receiving Flagyl may experience abdominal distress, nausea, vomiting, flushing or headache if alcoholic beverages are consumed. The taste of alcoholic beverages may also be modified. Flattening of the T-wave may be seen in ECG tracings.

Dosage and Administration: ***For Trichomoniasis:*** The recommended dosage for both male and female is one 250-mg. tablet orally three times daily for seven days. When repeat courses of the drug are required, it is recommended that an interval of 4 to 6 weeks elapse between courses and that the presence of the trichomonad be reconfirmed by appropriate laboratory measures. Total and differential leukocyte counts should be made before, during and after retreatment. The male consort should be treated in any event in cases of reinfection.

For Amebiasis: *Adults:* For acute intestinal amebiasis, 750 mg. orally three times daily for 5 to 10 days.

For amebic liver abscess: *Adults:* 500 mg. or 750 mg. orally three times daily for 5 to 10 days.

Children: 35 to 50 mg./kg. of body weight/24 hours, divided into three doses, orally for 10 days.

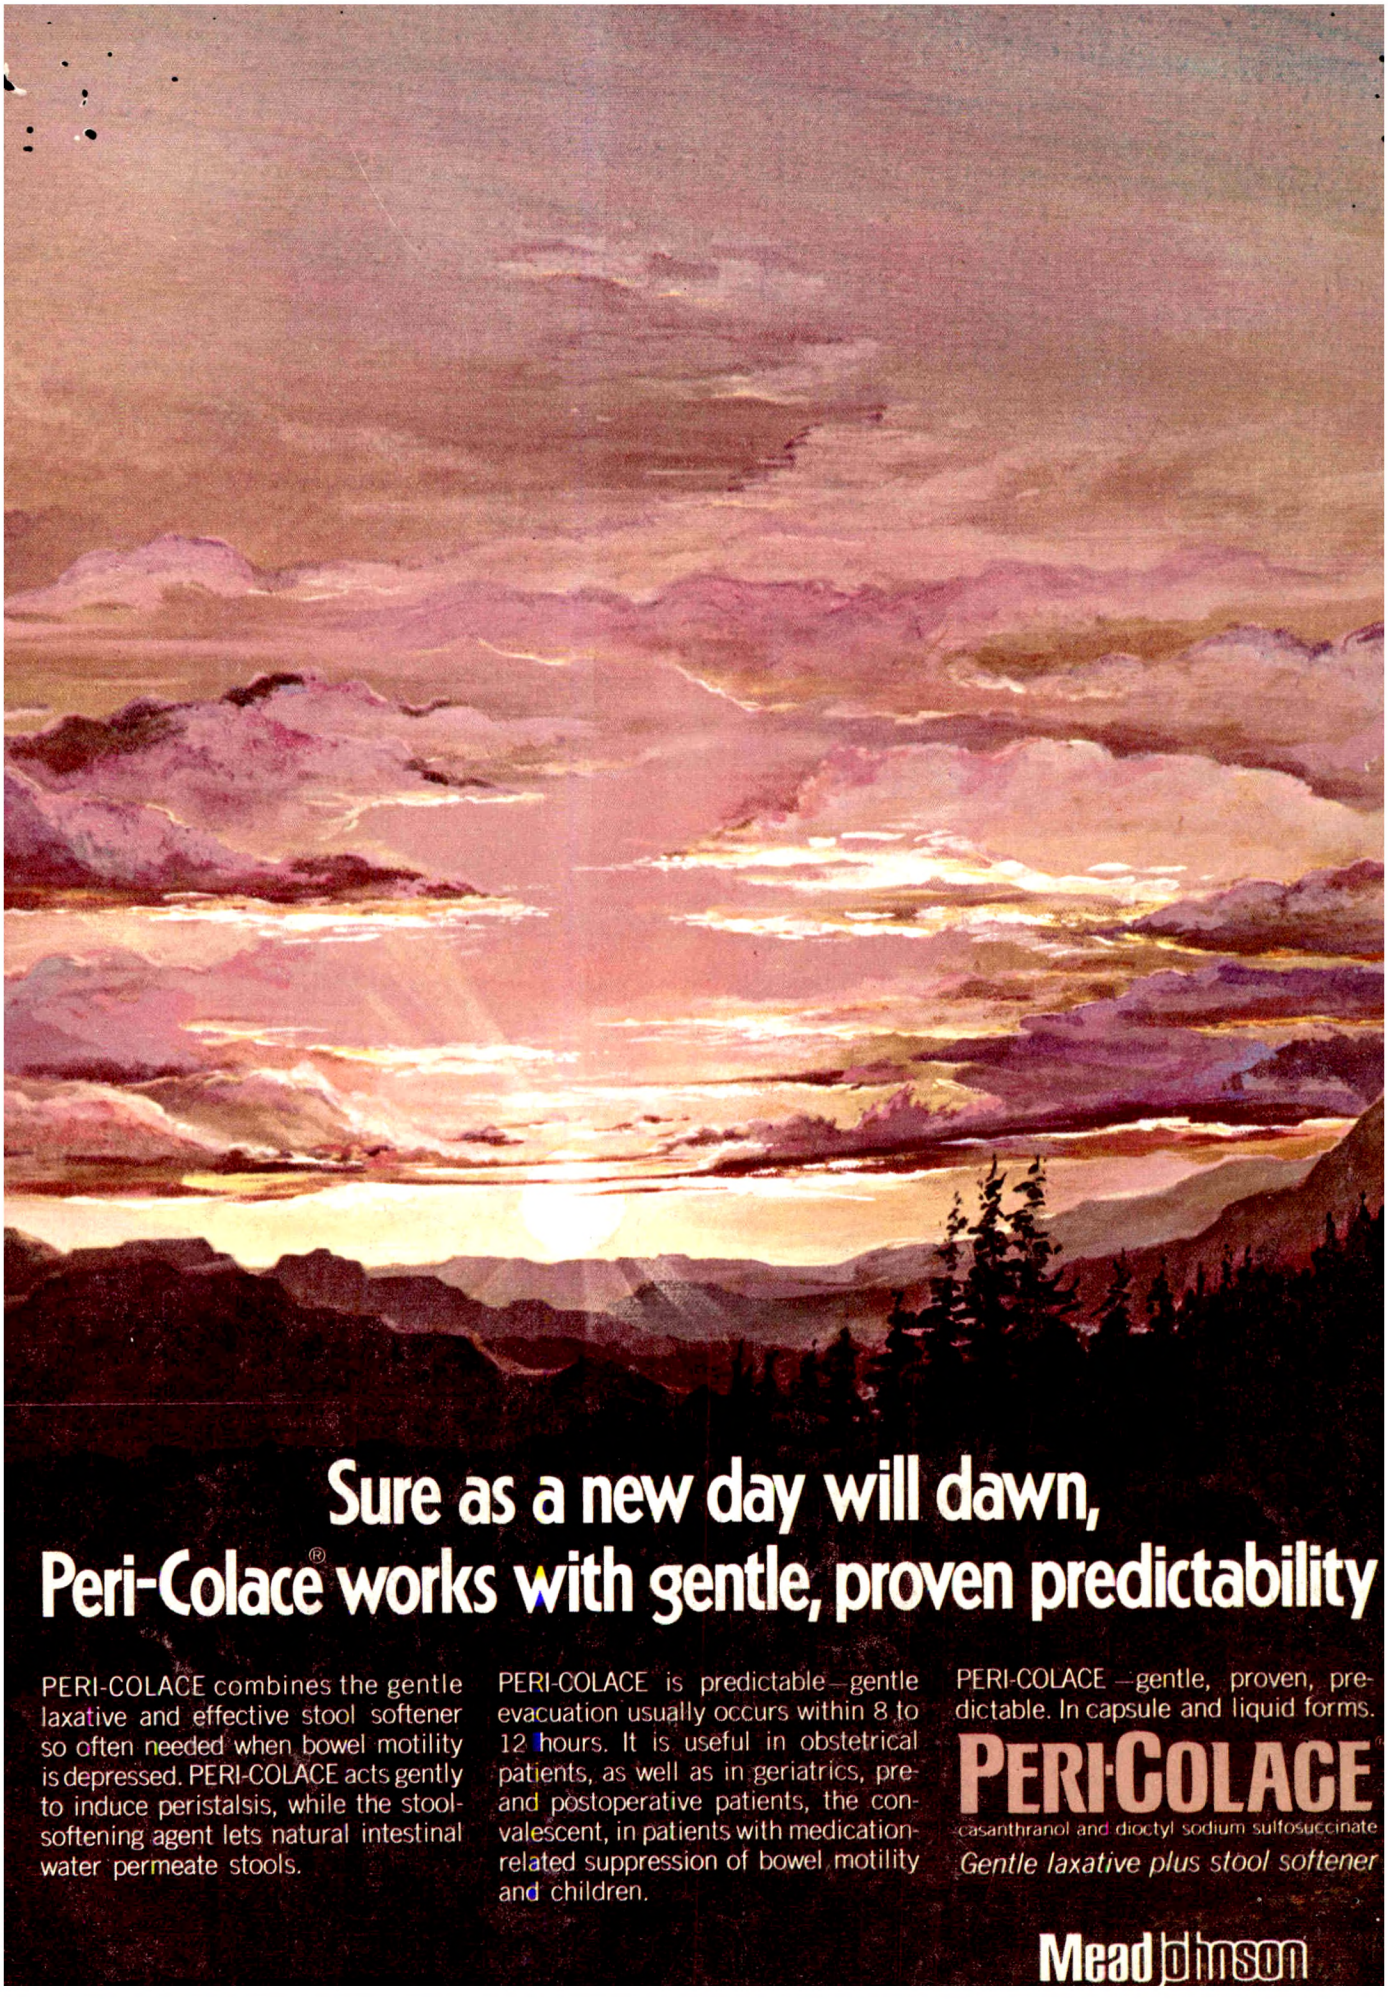
His trichomoniasis can make her therapy useless unless they both take..

When the male is not treated for *Trichomonas vaginalis,* the female—no matter how well she cooperates with therapy—probably will become reinfected. To arrest this infection/reinfection cycle, both infected partners must be treated simultaneously.

The only systemic trichomonacide—In the female, trichomoniasis is a multiorgan disease. Trichomonads invade the vagina, and are often deeply entrenched in the endocervix, Skene's and Bartholin's glands, the urethra, and the bladder. The male genitourinary tract has seven possible sites of infection. Only the systemic action of Flagyl can eliminate sequestered trichomonads from these sites; topical treatments are ineffective.

Effective in both partners—Because it reaches infection sites via the bloodstream, Flagyl is the only trichomonacide that is effective in both men and women. And Flagyl is the only available agent of its kind.



The only effective trichomonacide for couples

Flagyl® 250-mg. tablets (metronidazole)

Sure as a new day will dawn, Peri-Colace® works with gentle, proven predictability

PERI-COLACE combines the gentle laxative and effective stool softener so often needed when bowel motility is depressed. PERI-COLACE acts gently to induce peristalsis, while the stool-softening agent lets natural intestinal water permeate stools.

PERI-COLACE is predictable—gentle evacuation usually occurs within 8 to 12 hours. It is useful in obstetrical patients, as well as in geriatrics, pre- and postoperative patients, the convalescent, in patients with medication-related suppression of bowel motility and children.

PERI-COLACE—gentle, proven, predictable. In capsule and liquid forms.

PERI-COLACE

casanthranol and dioctyl sodium sulfosuccinate

Gentle laxative plus stool softener

Why the choice is Cu-7®

intrauterine copper contraceptive

1. She wants nonhormonal contraception.
2. She wants to space her family.
3. She smokes.
4. She has passed the "Pill" years.

Freedom—intrauterine contraception is the most convenient of all contraceptive methods.

Comfort—smallest inserter diameter of all IUDs. This means minimal discomfort during insertion.

Cu-7	Lippes Loop® D	Saf-T-Coil® (Nullip)	Saf-T-Coil® (Standard)
3.07 mm.	5.33 mm.	3.76 mm.	4.50 mm.

Security—high efficacy and relatively low incidence of expulsion and medical removal.

(Rates—based on labeling claims—expressed as events per 100 women through 12 months of use for parous women)*	Cu-7[1]	Lippes Loop D[2]	Saf-T-Coil
Pregnancy	1.9	2.7	2.4
Expulsion	5.7	12.7	18.3
Medical Removal	10.9	15.2	15.6

*These rates are derived from separate studies conducted by different investigators in several population groups. Different rates have been reported from other clinical trials.

References: 1. Data on file at Searle Laboratories. 2. Physicians' Desk Reference, Medical Economics Company, Oradell, N.J., 1978, pp. 1216, 1521.

Intrauterine contraception is not appropriate for all women. Please see complete product information prior to use. A brief summary of product information appears on the next page.

Description: The plastic component of the Cu-7 is composed of pharmaceutical grade polypropylene homopolymer with barium sulfate added to render it radiopaque. Its shape approximates the number 7. It is substantially smaller than previously available intrauterine devices; the vertical dimension measures 36 mm. and the horizontal, 26 mm.

Coiled around the vertical limb is a pure, virgin electrolytic copper wire providing approximately 200mm^2 of exposed copper surface area. A retrieval thread is fastened to the free end of the vertical limb of the Cu-7.

The Cu-7 is supplied with a simple tubular polypropylene inserter. All components are sterile.

Mode of Action: Available data indicate that the contraceptive effectiveness of the Cu-7 is enhanced by a minute quantity of copper released continuously from the coiled copper into the uterine cavity.

The exact mechanism by which metallic copper enhances the contraceptive effect of an IUD has not been conclusively demonstrated. Various hypotheses have been advanced, the most common being that copper placed in the uterus interferes with enzymatic or other processes that regulate blastocyst implantation.

Animal studies suggest that copper may play an additional role by reduction of sperm transport within the uterine environment.

Indication and Usage: The Cu-7 is indicated for contraception.

Contraindications: The Cu-7 should not be inserted when any of the following conditions exist: pregnancy or suspicion of pregnancy; abnormalities of the uterus resulting in distortion of the uterine cavity; acute pelvic inflammatory disease or a history of repeated pelvic inflammatory disease; postpartum endometritis or infected abortion in the past three months; known or suspected uterine or cervical disease such as hyperplasia or carcinoma including unresolved, abnormal "Pap" smear; vaginal bleeding of unknown etiology; untreated acute cervicitis until infection is controlled; diagnosed Wilson's disease; known or suspected allergy to copper; previous ectopic pregnancy, and significant anemia.

Warnings

1. Pregnancy: (a) Long-term effects. The long-term effects on the offspring of the presence of copper in the uterus when pregnancy occurs with the Cu-7 are unknown.

(b) Septic abortion. Reports have indicated an increased incidence of septic abortion associated in some instances with septicemia, septic shock and death in patients becoming pregnant with an IUD in place. Most of these reports have been associated with the mid-trimester of pregnancy. In some cases, the initial symptoms have been insidious and not easily recognized. If pregnancy should occur with a Cu-7 in situ, the Cu-7 should be removed if the thread is visible or, if removal proves to be or would be difficult, interruption of the pregnancy should be considered and offered to the patient as an option, bearing in mind that the risks associated with an elective abortion increase with gestational age.

(c) Continuation of pregnancy. If the patient chooses to continue the pregnancy and the Cu-7 remains in situ, she must be warned of the increased risk of spontaneous abortion and the increased risk of sepsis, including death. The patient must be closely observed and she must be advised to report immediately all abnormal symptoms, such as flu-like syndrome, fever, abdominal cramping and pain, bleeding, or vaginal discharge, because generalized symptoms of septicemia may be insidious.

2. Ectopic pregnancy: (a) A pregnancy which occurs with an IUD in situ is more likely to be ectopic than a pregnancy occurring without an IUD. Therefore, patients who become pregnant while using a Cu-7 should be carefully evaluated for the possibility of an ectopic pregnancy.

(b) Special attention should be directed to patients with delayed menses, slight metrorrhagia and/or unilateral pelvic pain, and to those patients who wish to interrupt a pregnancy occurring in the presence of a Cu-7, to determine whether ectopic pregnancy has occurred.

3. Pelvic infection: An increased risk of pelvic inflammatory disease associated with the use of IUDs has been reported. While unconfirmed, this risk appears to be greatest for young women who are nulliparous and/or who have a multiplicity of sexual partners. Salpingitis can result in tubal damage and occlusion, thereby threatening future fertility. Therefore, it is recommended that patients be taught to look for symptoms of pelvic inflammatory disease. The decision to use an IUD in a particular case must be made by the physician and patient with the consideration of a possible deleterious effect on future fertility.

Pelvic infection may occur with a Cu-7 in situ and at times result in the development of tubo-ovarian abscesses or general peritonitis. The symptoms of pelvic infection include: new development of menstrual disorders (prolonged or heavy bleeding), abnormal vaginal discharge, abdominal or pelvic pain, dyspareunia, fever. The symptoms are especially significant if they occur following the first two or three cycles after insertion. Appropriate aerobic and anaerobic bacteriologic studies should be done and antibiotic therapy initiated promptly. If the infection does not show marked clinical improvement within 24 to 48 hours, the Cu-7 should be removed and the continuing treatment reassessed on the basis of the results of culture and sensitivity tests.

4. Embedment: Partial penetration or lodging of the Cu-7 in the endometrium or myometrium can result in a difficult removal. This may occur more frequently in smaller uteri. (See removal instructions.)

5. Perforation: Partial or total perforation of the uterine wall or cervix may occur with the use of the Cu-7, usually during insertions into patients sooner than two months after abortion or delivery or in uterine cavities too small for the Cu-7. The possibility of perforation must be kept in mind during insertion and at the time of any subsequent examination. If perforation occurs, laparotomy or laparoscopy should be performed as soon as medically feasible and the Cu-7 removed. Abdominal adhesions, intestinal penetration, intestinal obstruction, and local inflammatory reaction with abscess formation and erosion of adjacent viscera may result if the Cu-7 is left in the peritoneal cavity.

6. Medical diathermy: The use of medical diathermy (short-wave and microwave) in a patient with a metal-containing IUD may cause heat injury to the surrounding tissue. Therefore, medical diathermy to the abdominal and sacral areas should not be used on patients using a Cu-7.

7. Effects of copper: Additional amounts of copper available to the body from the Cu-7 may precipitate symptoms in women with undiagnosed Wilson's disease. The incidence of Wilson's disease is 1 in 200,000.

Precautions

1. Patient counseling: Prior to the insertion the physician, nurse, or other trained health professional must provide the patient with the Patient Brochure. The patient should be given the opportunity to read the brochure and discuss fully any questions she may have concerning the Cu-7 as well as other methods of contraception.

2. Patient evaluation and clinical considerations: a) A complete medical history should be obtained to determine conditions that might influence the selection of an IUD. A physical examination should include a pelvic examination, "Pap" smear, gonorrhea culture and, if indicated, appropriate tests for other forms of venereal disease. The physician should determine that the patient is not pregnant.

(b) The uterus should be carefully sounded prior to the insertion to determine the degree of patency of the endocervical canal and the internal os, and the direction and depth of the uterine cavity. Exercise care to avoid perforation with the sound. DO NOT USE THE Cu-7 INSERTION INSTRUMENT AS A SOUND. In occasional cases, severe cervical stenosis may be encountered. Do not use excessive force to overcome this resistance.

(c) The uterus usually sounds to a depth of 6 to 8 cm. Insertion of a Cu-7 into a uterine cavity measuring less than 6.5 cm. by sounding may increase the incidence of pain, bleeding, partial or complete expulsion, perforation, and possibly pregnancy.

(d) To reduce the possibility of insertion in the presence of an existing undetermined pregnancy, the optimal time for insertion is the latter part of the menstrual flow or one or two days thereafter. The Cu-7 should not be inserted post partum or post abortion until involution of the uterus is complete. The incidence of perforation and expulsion is greater if involution is not complete.

It is, however, necessary to place the Cu-7 as high as possible within the uterine cavity to help avoid partial or complete expulsion that could result in pregnancy.

Since the Cu-7 represents a different design in intrauterine contraception, physicians are cautioned that it is imperative for them to become thoroughly familiar with the instructions for use before attempting placement of the Cu-7.

(e) IUDs should be used with caution in those patients who have an anemia or a history of menorrhagia or hypermenorrhea. Patients experiencing menorrhagia and/or metrorrhagia following IUD insertion may be at risk for the development of hypochromic microcytic anemia. Also, IUDs should be used with

(f) Syncope, bradycardia or other neurovascular episodes may occur during insertion or removal of IUDs, especially in patients with a previous disposition to these conditions.

(g) Patients with valvular or congenital heart disease are more prone to develop subacute bacterial endocarditis than patients who do not have valvular or congenital heart disease. Use of an IUD in these patients may represent a potential source of septic emboli.

(h) Use of an IUD in those patients with acute cervicitis should be postponed until proper treatment has cleared up the infection.

(i) Since the Cu-7 may be partially or completely expelled, patients should be reexamined and evaluated shortly after the first postinsertion menses, but definitely within three months after insertion. Thereafter annual examination with appropriate medical and laboratory evaluation should be carried out. The Cu-7 should be replaced every three years.

(j) The patient should be told that some bleeding or cramps may occur during the first few weeks after insertion, but if these symptoms continue or are severe she should report them to her physician. She should be instructed on how to check after each menstrual period to make certain that the thread still protrudes from the cervix and cautioned that there is no contraceptive protection if the Cu-7 has been expelled. She should also be cautioned not to dislodge the Cu-7 by pulling on the thread. If a partial expulsion occurs, removal is indicated and a new Cu-7 may be inserted. The patient should be told to return within three years for removal of the Cu-7 and for replacement if desired.

(k) A copper-induced urticarial allergic skin reaction may develop in women using a copper-containing IUD. If symptoms of such an allergic response occur, the patient should be instructed to tell the consulting physician that a copper-containing device is being used.

(l) The Cu-7 should be removed for the following medical reasons: menorrhagia and/or metrorrhagia producing significant anemia; uncontrolled pelvic infection; intractable pain often aggravated by intercourse, dyspareunia; pregnancy, if the thread is visible; endometrial or cervical malignancy; uterine or cervical perforation; or any indication of partial expulsion.

(m) If the retrieval thread cannot be visualized it may have retracted into the uterus or have been broken off, or the Cu-7 may have been expelled. Localization usually may be made by feeling with a probe; if not, x-ray or sonography can be used. When the physician elects to recover a Cu-7 with the thread not visible, the removal instructions should be considered.

(n) If any patient with a Cu-7 suddenly develops overt clinical hepatitis or abnormal liver function tests, appropriate diagnostic procedures should be initiated.

Adverse Reactions: Perforations of uterus and cervix have occured. Perforation into the abdomen has been followed by abdominal adhesions, intestinal penetration, intestinal obstruction, local inflammatory reaction with abscess formation and erosion of adjacent viscera. Pregnancy has occurred with the Cu-7 in situ and when the Cu-7 has been partially or completely expelled.

The incidence of spontaneous abortion, when conception occurs with intrauterine devices in situ, appears to be increased over that in unprotected women. Insertion cramping, usually of no more than a few seconds duration, may occur; however, some women may experience residual cramping for several hours or even days. Intermenstrual spotting or bleeding or prolonged or increased menstrual flow may occur.

Pelvic infection including salpingitis with tubal damage or occlusion has been reported. This may result in future infertility. Complete or partial expulsion of the Cu-7 may sometimes occur, particularly in those patients with uteri measuring less than 6.5 cm. by sounding. Urticarial allergic skin reaction may occur. The following complaints have also been reported with IUDs although their relation to the Cu-7 has not been established: amenorrhea or delayed menses, backaches, cervical erosion, cystic masses in the pelvis, vaginitis, leg pain or soreness, weight loss or gain, nervousness, dyspareunia, cystitis, endometritis, septic abortion, septicemia, leukorrhea, ectopic pregnancy, difficult removal, uterine embedment, anemia, pain, neurovascular episodes including bradycardia and syncope secondary to insertion, dysmenorrhea, and fragmentation of the IUD.

Directions for Use: The Cu-7 is to be placed within the uterine cavity. See the Procedure for Insertion for two insertion techniques.

The small diameter of the Cu-7 facilitates easy insertion in nulligravidous and nulliparous, as well as parous women. The optimal time of insertion is during the latter part of the menstrual flow or one or two days thereafter. The cervical canal is relatively more patent at this time, and there is little chance that the patient may be pregnant.

Present information indicates that efficacy is retained for 36 months. There is no evidence that contraceptive efficacy decreases with time up to three years of use, but until adequate data indicating a longer effective life become available, the Cu-7 must be removed within 36 months from the date of insertion and a new one inserted if desired. If partial expulsion occurs, removal is indicated, and a new Cu-7 may be inserted. Removal of the Cu-7 may also be indicated in the event of heavy or persistent bleeding.

The physician should become thoroughly familiar with the instructions for use before attempting insertion or removal of the Cu-7.

Clinical Efficacy: In clinical trials of the Cu-7 conducted by Searle Laboratories, use effectiveness was determined as follows for parous and nulliparous women, as tabulated by the life table method. (Rates are expressed as cumulative events per 100 women through 12, 24, and 36 months of use.)

This experience encompasses 387,131 woman-months of use, including 12 months for 11,517 women, 24 months for 7,895, and 36 months for 3,661.

	12 Months		24 Months		36 Months	
	Parous	Nulliparous	Parous	Nulliparous	Parous	Nulliparous
Pregnancy	1.9	1.7	2.9	2.6	3.4	3.4

How Supplied

Available in cartons of 6, 30 and 100 sterile units (Cu-7 with an inserter) and sufficient patient leaflets and identification cards.

Please see complete product labeling for additional information, including insertion and removal instructions.

Cu-7® intrauterine copper contraceptive

—the leading IUD

A lot less than everyone once thought. Just a few years ago, a 50-mcg dosage was considered low. Today, there's an effective combination oral contraceptive containing 30 mcg of estrogen: Loestrin 1.5/30.

In spite of a 40% reduction in the dose of estrogen, efficacy of Loestrin 1.5/30 is considered comparable to that of combination oral contraceptives containing higher levels of estrogen.

Irregular bleeding is somewhat more frequent with Loestrin 1.5/30 than with combinations containing larger doses of estrogen. With continued use, however, the frequency decreases.

And if you're concerned about your patients' intake of estrogen over an extended period of time, Loestrin 1.5/30 contains 30 mcg of ethinyl estradiol, so patient exposure to estrogen is reduced.

LOESTRIN® 1.5/30

(1.5 mg norethindrone acetate and
30 mcg ethinyl estradiol tablets, USP)

a 30-mcg alternative to higher estrogen

ualization of

Brief Summary of Prescribing Information
LOESTRIN® 1.5/30
(1.5 mg norethindrone acetate and 30 mcg ethinyl estradiol tablets, USP) See section under Special Notes on Administration and How Supplied.

DESCRIPTION
Loestrin 1.5/30 Products are progestogen-estrogen combinations.

INDICATION AND USAGE
Loestrin 1.5/30 Products are indicated for the prevention of pregnancy in women who elect to use oral contraceptives.

In clinical trials with Loestrin 1.5/30 involving 17,139 therapy cycles, there was a pregnancy rate of 0.49 per 100 woman years.

Dose-related risk of thromboembolism from oral contraceptives: Studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. It is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance.

CONTRAINDICATIONS
1. Thrombophlebitis or thromboembolic disorders
2. A past history of deep-vein thrombophlebitis or thromboembolic disorders
3. Cerebral vascular or coronary artery disease
4. Known or suspected carcinoma of the breast
5. Known or suspected estrogen-dependent neoplasia
6. Undiagnosed abnormal genital bleeding
7. Known or suspected pregnancy (See No. 5 under WARNINGS.)

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, and hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well-established. Studies have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic.

Cerebrovascular disorders: In a collaborative study in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers, and the risk of thrombotic stroke was 4.0 to 9.5 times greater.

Myocardial infarction: An increased risk of myocardial infarction associated with oral contraceptives has been reported confirming a previously suspected association. These studies found that the greater the number of underlying risk factors (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) for coronary artery disease, the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor.

It has been estimated that users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are smokers have about a fivefold increased risk of fatal infarction compared to users who do not smoke, but about a tenfold to twelvefold increased risk compared to nonusers who do not smoke. The amount of smoking is also an important factor.

Risk of dose: In an analysis of data, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives; however, the quantity of estrogen may not be the sole factor involved.

Estimate of excess mortality from circulatory diseases: The risk of diseases of the circulatory system is concentrated in older women, in those with a long duration of use, and in cigarette smokers.

A study of available data from a variety of sources concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke.

The risk of thromboembolic and thrombotic diseases associated with oral contraceptives increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia, and especially by cigarette smoking.

The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders. Should any occur or be suspected, the drug should be discontinued immediately.

A fourfold to sixfold increased risk of postsurgery thromboembolic complications has been reported in users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

2. *Ocular lesions:* Neuro-ocular lesions, such as optic neuritis or retinal thrombosis, have been associated with the use of oral contraceptives. Discontinue the oral contraceptive if there is unexplained sudden or gradual, partial, or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions.

3. *Carcinoma:* Long-term continuous administration of estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver.

In humans, an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women has been reported. However, there is no evidence suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only oral contraceptives.

Studies found no evidence of increase in breast cancer in women taking oral contraceptives; however, an excess risk in users with documented benign breast disease was reported.

There is no confirmed evidence of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of users is, nevertheless, essential. In cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer, or who have breast nodules, fibrocystic disease, or abnormal mammograms, should be monitored with particular care.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with oral contraceptives. Because hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage, they should be considered in women presenting abdominal pain and tenderness, abdominal mass, or shock.

A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Usage in or Immediately Preceding Pregnancy; Birth Defects in Offspring, and Malignancy in Female Offspring:* During early pregnancy, female sex hormones may seriously damage the offspring.

An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of oral contraceptives in pregnancy.

There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives.

Pregnancy should be ruled out before continuing an oral contraceptive in any patient who has missed two consecutive menstrual periods. If the patient has not adhered to the schedule, the possibility of pregnancy should be considered at the time of the first missed period, and oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed.

Women who discontinue oral contraceptives with the intent of becoming pregnant should use an alternate form of contraception for a period of time before attempting to conceive.

Administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives.

7. *Carbohydrate and Lipid Metabolic Effects:* Because decreased glucose tolerance has been observed in a significant percentage of patients, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives.

An increase in triglycerides and total phospholipids has been observed.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving oral contraceptives. The prevalence in users increases with longer exposure. Age is also strongly correlated with development of hypertension. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure.

9. *Headache:* Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of oral contraceptiv

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, nonfunctio causes should be borne in mind. In undiagnosed abnormal bleeding from the vagina, adequa diagnostic measures are indicated to rule out pregnancy or malignancy.

Women with a past history of oligomenorrhea or secondary amenorrhea, or young women without regular cycles should be advised that they may have a tendency to remain anovulatc or to become amenorrheic after discontinuation of oral contraceptives.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contracept failures.

12. *Breast Feeding:* Oral contraceptives may interfere with lactation. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of moth receiving these drugs.

PRECAUTIONS
1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include specia reference to blood pressure, breasts, abdomen, and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another examination.
2. Preexisting uterine leiomyomata may increase in size.
3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree.
4. Oral contraceptives may cause fluid retention and should be prescribed with caution, ar only with careful monitoring, in patients with conditions which might be aggravated.
5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice. If jaundice develops, the medication should be discontinued.
6. Steroid hormones may be poorly metabolized and should be administered with caution i patients with impaired liver function.
7. Users may have disturbances in normal tryptophan metabolism, which may result in a relative pyridoxine deficiency.
8. Serum folate levels may be depressed.
9. The pathologist should be advised of oral contraceptive therapy when relevant specime are submitted.
10. Certain endocrine and liver function tests and blood components may be affected. (a) Increased sulfobromophthalein retention. (b) Increased prothrombin and factors VII, VI IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregabili (c) Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone. (d) Decreased pregnanediol excretion. (e) Reduced response to metyrapone test.

Drug interactions: Reduced efficacy and increased incidence of breakthrough bleeding ha been associated with concomitant use of rifampin and an association has been suggested w barbiturates, phenylbutazone, phenytoin sodium, and ampicillin.

ADVERSE REACTIONS
An increased risk of the following serious adverse reactions has been associated with oral contraceptives.

Thrombophlebitis; Pulmonary embolism; Coronary thrombosis; Cerebral thrombosis; Cerebral hemorrhage; Hypertension; Gallbladder disease; Benign hepatomas; Congenital anomalies.

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed. Mesenteric thrombosi Neuro-ocular lesions, eg, retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving oral contraceptiv and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle Other reactions, as a general rule, are seen much less frequently or only occasionally: gastro testinal symptoms; breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma; breast changes; change in weight; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately post partum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; r (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature; intolerance to contact lenses.

The following adverse reactions have been reported and the association has been neither confirmed nor refuted.

Premenstrual-like syndrome; cataracts; changes in libido; chorea; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; vaginitis; porphyria.

Special Notes on Administration
Loestrin 21 1.5/30 (1.5 mg norethindrone acetate and 30 mcg ethinyl estradiol tablets, USP)—Menstruation usually begins two or three days, but may begin as late as the fourth or fifth day, after discontinuing medication.

Loestrin Fe 1.5/30—Menstruation usually begins two or three days, but may begin as late the fourth or fifth day, after the brown ferrous fumarate tablets have been started.

Because of the relatively low estrogenic content, Loestrin 1.5/30 is not a good cyclic regula tor. There are patients whose inherent hormone balance will require larger amounts of estrog than that contained in Loestrin 1.5/30 to achieve cyclic regularity. These patients experience altered bleeding patterns, which do not conform to treatment schedules.

The physician should be alert to the fact that the irregular bleeding patterns could mask bleeding from organic cause, and appropriate diagnostic measures should be taken if the bleeding persists or continues after changing to a higher estrogen-content product.

After several months, bleeding may be reduced to a virtual absence; reduced flow may be a result of medication and not indicative of pregnancy.

HOW SUPPLIED
Loestrin Fe 1.5/30 is available in compacts each containing 21 green tablets and 7 brown tablets. Each green tablet contains 1.5 mg of norethindrone acetate and 30 mcg of ethinyl estradiol. Each brown tablet contains 75 mg of ferrous fumarate. Available in packages of five compacts and packages of five refills.

Loestrin 21 1.5/30 is available in compacts each containing 21 tablets. Each green tablet contains 1.5 mg of norethindrone acetate and 30 mcg of ethinyl estradiol. Available in packages of five compacts and packages of five refills.

95% of American women of child-bearing age have inadequate iron intake.[1] About 50% have laboratory evidence of iron depletion.[2]

Just any iron may not solve the problem.

Any iron may cause GI irritation and constipation. To avoid patient resistance—especially during pregnancy when iron requirements are greater than ever—be specific. Recommend FERRO-SEQUELS.® Its delayed release avoids absorption of iron in the stomach. Instead, most of the iron is released gradually in the duodenum for optimum absorption and minimum irritation. And FERRO-SEQUELS contains a stool softener to help prevent constipation.

An iron that encourages compliance is an iron worth being specific about.

FERRO·SEQUELS®

Sustained Release Iron Capsules

Each capsule contains:	
Ferrous Fumarate (equivalent to approx. 50 mg. of elemental iron)	150 mg.
Dioctyl Sodium Sulfosuccinate	100 mg.

New Formula Dermoplast®

AEROSOL ■ TOPICAL ANESTHETIC SPRAY

For improved relief of postpartum discomfort

Enhanced analgesia...20% benzocaine concentration relieves discomfort and itching of postepisiotomy and of postpartum hemorrhoids.

Soothing menthol...contains 0.5% menthol for a cooling, soothing effect.

Water-soluble...won't affect sutures...will not dry out or macerate skin...washes off easily with soap and water.

Environmentally acceptable propellant...provides the suitable delivery mode for postepisiotomy and postpartum hemorrhoidal care.

In convenient 6 oz aerosol for individual patient use. Also available in 3 oz. Aerosols spray from any angle.

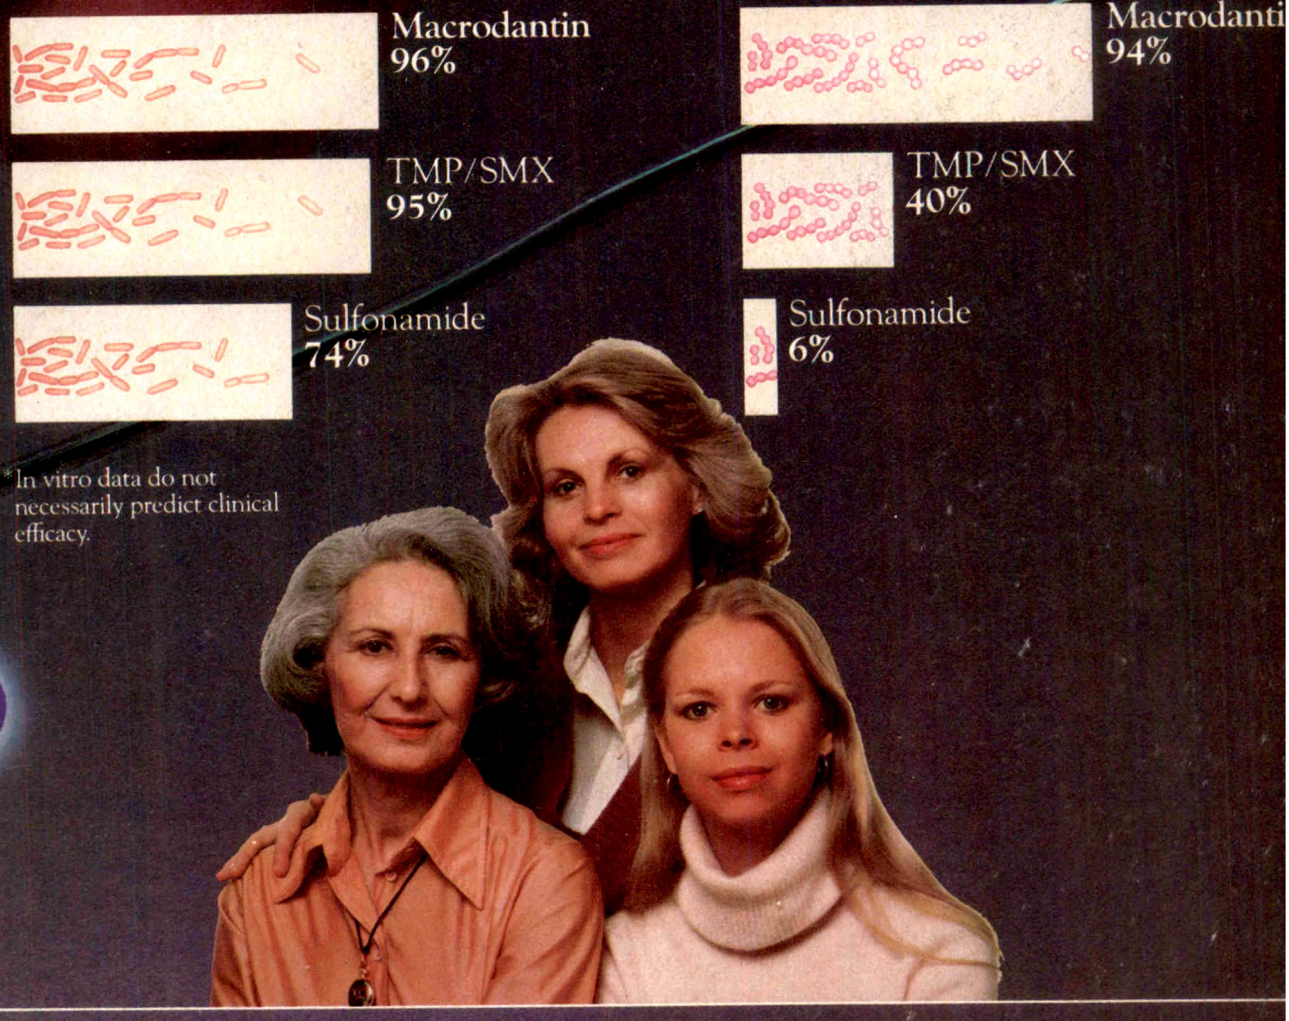
Enterococcus:



One reason for failure...

It is well known that *Escherichia coli* causes most cases of UTI. Enterococcus (also called *Streptococcus faecalis* and *Streptococcus*, group D) has become the *second* most prevalent uropathogen[1,2]— particularly in sexually active women.[3]

...reason enough to prescribe Macrodantin

Superior in vitro* efficacy against the two most common uropathogens[1]
(PMR Bacteriologic Report, Summer Series 1978)

*In vitro data do not necessarily predict clinical efficacy.

For UTI in their sexually active years...

Capsules: 25 mg, 50 mg, 100 mg

Macrodantin®
(nitrofurantoin macrocrystals)

See next page for brief summary of prescribing information including susceptible organisms.

Norwich-Ea
PHARMACEUTI

For UTI in their sexually active years...

Macrodantin®
(nitrofurantoin macrocrystals)

Capsules: 25 mg, 50 mg, 100 mg

INDICATIONS: Macrodantin is indicated for the treatment of urinary tract infections when due to susceptible strains of *Escherichia coli*, enterococci, *Staphylococcus aureus* (it is not indicated for the treatment of associated renal cortical or perinephric abscesses), and certain susceptible strains of *Klebsiella* species, *Enterobacter* species, and *Proteus* species.
NOTE: Specimens for culture and susceptibility testing should be obtained prior to and during drug administration.
CONTRAINDICATIONS: Anuria, oliguria, or significant impairment of renal function (creatinine clearance under 40 ml per minute) are contraindications to therapy with this drug. Treatment of this type of patient carries an increased risk of toxicity because of impaired excretion of the drug. For the same reason, this drug is much less effective under these circumstances.

The drug is contraindicated in pregnant patients at term as well as in infants under one month of age because of the possibility of hemolytic anemia due to immature enzyme systems (glutathione instability).

The drug is also contraindicated in those patients with known hypersensitivity to Macrodantin, Furadantin® (nitrofurantoin), and other nitrofurantoin preparations.
WARNINGS: Acute, subacute and chronic pulmonary reactions have been observed in patients treated with nitrofurantoin products. If these reactions occur, the drug should be withdrawn and appropriate measures should be taken.

An insidious onset of pulmonary reactions (diffuse interstitial pneumonitis or pulmonary fibrosis, or both) in patients on long-term therapy warrants close monitoring of these patients.

There have been isolated reports giving pulmonary reactions as a contributing cause of death. (See Hypersensitivity reactions.)

Cases of hemolytic anemia of the primaquine sensitivity type have been induced by Macrodantin. The hemolysis appears to be linked to a glucose-6-phosphate dehydrogenase deficiency in the red blood cells of the affected patients. This deficiency is found in 10 percent of Negroes and a small percentage of ethnic groups of Mediterranean and Near-Eastern origin. Any sign of hemolysis is an indication to discontinue the drug. Hemolysis ceases when the drug is withdrawn.

Pseudomonas is the organism most commonly implicated in superinfections in patients treated with Macrodantin.
PRECAUTIONS: Peripheral neuropathy may occur with Macrodantin therapy; this may become severe or irreversible. Fatalities have been reported. Predisposing conditions such as renal impairment (creatinine clearance under 40 ml per minute), anemia, diabetes, electrolyte imbalance, vitamin B deficiency, and debilitating disease may enhance such occurrence.
Usage in Pregnancy: The safety of Macrodantin during pregnancy and lactation has not been established. Use of this drug in women of childbearing potential requires that the anticipated benefit be weighed against the possible risks.
ADVERSE REACTIONS: Gastrointestinal reactions: Anorexia, nausea and emesis are the most frequent reactions; abdominal pain and diarrhea occur less frequently. These dose-related toxicity reactions can be minimized by reduction of dosage, especially in the female patient. Hepatitis occurs rarely.
Hypersensitivity reactions: Pulmonary sensitivity reactions may occur, which can be acute, subacute, or chronic.

Acute reactions are commonly manifested by fever, chills, cough, chest pain, dyspnea, pulmonary infiltration with consolidation or pleural effusion on x-ray, and eosinophilia. The acute reactions usually occur within the first week of treatment and are reversible with cessation of therapy. Resolution may be dramatic.

In subacute reactions, fever and eosinophilia are observed less often. Recovery is somewhat slower, perhaps as long as several months. If the symptoms are not recognized as being drug related and nitrofurantoin is not withdrawn, symptoms may become more severe.

Chronic pulmonary reactions are more likely to occur in patients who have been on continuous nitrofurantoin therapy for six months or longer. The insidious onset of malaise, dyspnea on exertion, cough, and altered pulmonary function are common manifestations. Roentgenographic and histologic findings of diffuse interstitial pneumonitis or fibrosis, or both, are also common manifestations. Fever is rarely prominent.

The severity of these chronic pulmonary reactions and the degree of their resolution appear to be related to the duration of therapy after the first clinical signs appear. Pulmonary function may be permanently impaired even after cessation of nitrofurantoin therapy. This risk is greater when pulmonary reactions are not recognized early.
Dermatologic reactions: Maculopapular, erythematous, or eczematous eruption, pruritus, urticaria, and angioedema.
Other sensitivity reactions: Anaphylaxis, asthmatic attack in patients with history of asthma, cholestatic jaundice, drug fever, and arthralgia.
Hematologic reactions: Hemolytic anemia, granulocytopenia, leukopenia, eosinophilia, and megaloblastic anemia. Return of the blood picture to normal has followed cessation of therapy.
Neurological reactions: Peripheral neuropathy, headache, dizziness, nystagmus, and drowsiness.
Miscellaneous reactions: Transient alopecia. As with other antimicrobial agents, superinfections by resistant organisms may occur. With Macrodantin, however, these are limited to the genitourinary tract because suppression of normal bacterial flora elsewhere in the body does not occur.

The Department of Obstetrics and Gynecology at The University of Michigan School of Medicine in Ann Arbor is undergoing a major rebuilding program and is seeking applicants who have an MD degree and postdoctoral training in perinatal medicine, endocrinology, psychosomatic medicine, infertility with expertise in microsurgery, and oncology. Positions at any academic level will be considered. Send curriculum vitae, brief summary of present and future research, and names and addresses of three references to Alan E. Beer, MD, Professor and Chairman of the Department of Obstetrics and Gynecology, Women's Hospital, University of Michigan Medical School, Ann Arbor, Michigan 48109. The University of Michigan is a non-discriminatory, affirmative action employer.

APPLICATIONS ARE BEING ACCEPTED FOR SUBSPECIALITY FELLOWSHIPS TO BEGIN JULY 1, 1980.

IN THE SURGICAL MENOPAUSE:

Possibly the most convincing reasons for using Premarin®

...are the years after surgery.

Severe vasomotor symptoms following surgical menopause: in the patient without contraindications, estrogen replacement is clearly indicated now...and to prevent the progressive debilitating effects of prolonged estrogen deficiency.

For the younger, oophorectomized woman, the deferred symptoms of postmenopausal bone loss* and its painful sequelae may appear at a needlessly early age. PREMARIN may retard this loss and avert the accompanying pain, muscle contracture, and kyphosis.

Although endometrial stimulation is not a concern in the hysterectomized patient, PREMARIN should still be administered cyclically at the lowest effective dose.

PREMARIN. Frequently indicated after surgery...a growing part of the routine.

PREMARIN®
(CONJUGATED ESTROGENS TABLETS, U.S.P.)
0.3 mg/0.625 mg/1.25 mg/2.5 mg

FOR THE SHORT- AND LONG-TERM CONSEQUENCES OF SURGICAL MENOPAUSE

*Conjugated Estrogens Tablets have been evaluated as probably effective for postmenopausal osteoporosis.

See last page of this advertisement for prescribing information.

TERIOR FLA PAINT

BRIEF SUMMARY
(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULAR)

PREMARIN® Brand of Conjugated Estrogens Tablets, U.S.P.

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.

Three independent case control studies have reported an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for more than one year.[1-3] This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade.[4] The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment[1] and on estrogen dose.[3] In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration;[3] it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.

The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a non-steroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare.[5,6] This risk has been estimated as not greater than 4 per 1000 exposures.[7] Furthermore, a high percentage of such exposed women (from 30 to 90 percent) have been found to have vaginal adenosis,[8-12] epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb reduction defects.[13-16] One case control study[16] estimated a 4.7-fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 per 1000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well controlled studies that progestogens are effective for these uses. If PREMARIN is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the advisability of pregnancy continuation.

DESCRIPTION: PREMARIN (Conjugated Estrogens Tablets, U.S.P.) for oral administration contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters.

INDICATIONS: Based on a review of PREMARIN Tablets by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications for use as follows:

Effective:

1. Moderate to severe *vasomotor* symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression without associated vasomotor symptoms, and they should not be used to treat such conditions.)
2. Atrophic vaginitis.
3. Kraurosis vulvae.
4. Female hypogonadism.
5. Female castration.
6. Primary ovarian failure.
7. Breast cancer (for palliation only) in appropriately selected women and men with metastatic disease.
8. Prostatic carcinoma—palliative therapy of advanced disease.
9. Postpartum breast engorgement—Although estrogens have been widely used for the prevention of postpartum breast engorgement, controlled studies have demonstrated that the incidence of significant painful engorgement in patients not receiving such hormonal therapy is low and usually responsive to appropriate analgesic or other supportive therapy. Consequently, the benefit to be derived from estrogen therapy for this indication must be carefully weighed against the potential increased risk of puerperal thromboembolism associated with the use of large doses of estrogens.[19]

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

"Probably" effective: For estrogen deficiency-induced osteoporosis, and only when used in conjunction with other important therapeutic measures such as diet, calcium, physiotherapy, and good general health-promoting measures. Final classification of this indication requires further investigation.

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 2. Known or suspected estrogen-dependent neoplasia. 3. Known or suspected pregnancy (See Boxed Warning). 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. A past history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

WARNINGS: At the present time there is no satisfactory evidence that estrogens given to postmenopausal women increase the risk of cancer of the breast,[17] although a recent study has raised this possibility.[18] There is a need for caution in prescribing estrogens for women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease, or abnormal mammograms. A recent study has reported a 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease in women receiving postmenopausal estrogens.[17]

Adverse effects of oral contraceptives may be expected at the larger doses of estrogen used to treat prostatic or breast cancer or postpartum breast engorgement; it has been shown that there is an increased risk of thrombosis in men receiving estrogens for prostatic cancer and women for postpartum breast engorgement.[19-22] Users of oral contraceptives have an increased risk of diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction.[23-30] Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users.[31,32] An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives.[33,34] If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization. Estrogens should not be used in persons with active thrombophlebitis, thromboembolic disorders, or in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease. Large doses (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown[35] to increase the risk of nonfatal myccardial infarction, pulmonary embolism and thrombophlebitis. When doses of this size are used, any of the thromboembolic and thrombotic adverse effects should be considered a clear risk.

Benign hepatic adenomas should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Hepatocellular carcinoma has been reported in women taking estrogen-containing oral contraceptives.[36] Increased blood pressure may occur with use of estrogens in the menopause[37] and blood pressure should be monitored with estrogen use. A worsening of glucose tolerance has been observed in patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolau smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc. Oral contraceptives appear to be associated with an increased incidence of mental depression.[23a] Patients with a history of depression should be carefully observed. Preexisting uterine leiomyomata may increase in size during estrogen use. The pathologist should be advised of estrogen therapy when relevant specimens are submitted. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, metabolic bone diseases associated with hypercalcemia, or in young patients in whom bone growth is not complete.

The following changes may be expected with larger doses of estrogen:

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered.

d. Impaired glucose tolerance.

e. Decreased pregnanediol excretion.

f. Reduced response to metyrapone test.

g. Reduced serum folate concentration.

h. Increased serum triglyceride and phospholipid concentration.

As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy, including oral contraceptives: breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea; premenstrual-like syndrome, amenorrhea during and after treatment; increase in size of uterine fibromyomata; vaginal candidiasis, change in cervical erosion and in degree of cervical secretion; cystitis-like syndrome; tenderness, enlargement, secretion (of breasts); nausea, vomiting, abdominal cramps, bloating; cholestatic jaundice; chloasma or melasma which may persist when drug is discontinued; erythema multiforme; erythema nodosum; hemorrhagic eruption; loss of scalp hair, hirsutism; steepening of corneal curvature; intolerance to contact lenses; headache, migraine, dizziness, mental depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea, and withdrawal bleeding may occur in females.

DOSAGE AND ADMINISTRATION: 1. *Given cyclically for short term use only:* For treatment of moderate to severe *vasomotor* symptoms, atrophic vaginitis, or kraurosis vulvae associated with the menopause (0.3 to 1.25 mg or more daily).

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Administration should be cyclic (*e.g.*, three weeks on and one week off).

Attempts to discontinue or taper medication should be made at three to six month intervals.

2. *Given cyclically:* Female hypogonadism. Female castration. Primary ovarian failure. Osteoporosis.

Female hypogonadism—2.5 to 7.5 mg daily, in divided doses for 20 days, followed by a rest period of 10 days' duration. If bleeding does not occur by the end of this period, the same dosage schedule is repeated. The number of courses of estrogen therapy necessary to produce bleeding may vary depending on the responsiveness of the endometrium.

If bleeding occurs before the end of the 10 day period, begin a 20 day estrogen-progestin cyclic regimen with PREMARIN (Conjugated Estrogens Tablets, U.S.P.), 2.5 to 7.5 mg daily in divided doses, for 20 days. During the last five days of estrogen therapy, give an oral progestin. If bleeding occurs before this regimen is concluded, therapy is discontinued and may be resumed on the fifth day of bleeding.

Female castration and primary ovarian failure—1.25 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Osteoporosis (to retard progression)—1.25 mg daily, cyclically.

3. *Given for a few days:* Prevention of postpartum breast engorgement—3.75 mg every four hours for five doses, or 1.25 mg every four hours for five days.

4. *Given chronically:* Inoperable progressing prostatic cancer—1.25 to 2.5 mg three times daily.

Inoperable progressing breast cancer in appropriately selected men and postmenopausal women—10 mg three times daily for a period of at least three months.

Patients with an intact uterus should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

HOW SUPPLIED: PREMARIN (Conjugated Estrogens Tablets, U.S.P.) No. 865—Each *purple* tablet contains 2.5 mg in bottles of 100 and 1,000. No. 866—Each *yellow* tablet contains 1.25 mg in bottles of 100 and 1,000. Also in unit dose package of 100. No. 867—Each *red* tablet contains 0.625 mg in bottles of 100 and 1,000. Also in unit dose package of 100. No. 868—Each *green* tablet contains 0.3 mg in bottles of 100 and 1,000.

"Nonspecific" vaginitis is often masked
"Nonspecific" vaginitis
...Often masked by previsit and routine douches, candidiasis and trichomoniasis.[1]
...Often chronic—in a recent clinical study of 5,000 consecutive cases of chronic vaginitis, the chief cause was undiagnosed H. vaginalis vaginitis, followed by candidiasis and trichomoniasis.[1]
1. Fleury, F.J.: Obstet. Gynecol. News 12:1,25, Aug. 15, 1977.
2. Gardner, H.L., and Kaufman, R.H.: Benign Diseases of the Vulva and Vagina, St. Louis, The C.V. Mosby Company, 1969, p. 191.

When you unmask "nonspecific" vaginitis you may find H. vaginalis

Sultrin
TRADEMARK

Triple Sulfa Cream/Vaginal Tablets

effective against H.vaginalis— the cause of over 90% of "nonspecific" vaginitis[2]

Effective
Based on a review by the National Academy of Sciences/National Research Council, SULTRIN was rated as "effective" against *H. vaginalis.*

Prompt symptomatic relief
Patients can experience relief of embarrassing itching and malodorous discharge. Within the same time, most patients can also achieve marked clinical improvement.

Versatile adjunct in other vaginitides
SULTRIN is also effective in treating H.V. vaginitis concomitant with trichomoniasis and candidiasis.

Convenient choice of dosage forms
SULTRIN comes as a soothing, nonstaining and esthetically pleasing cream or convenient vaginal tablets.

Composition: SULTRIN Cream contains sulfathiazole 3.42%, sulfacetamide 2.86%, sulfabenzamide 3.7%, and urea 0.64%. Each SULTRIN Tablet contains sulfathiazole 172.5 mg, sulfacetamide 143.75 mg, and sulfabenzamide 184.0 mg.

Indications: SULTRIN Cream and Tablets are indicated for treatment of *Haemophilus vaginalis* vaginitis. They may also be used as a deodorant for saprophytic infection following radiation therapy.

Contraindications: Sulfonamide sensitivity and kidney disease.

Dosage: SULTRIN Cream: One applicatorful intravaginally twice daily for 4 to 6 days. The dosage may then be reduced one-half to one-quarter.
SULTRIN Tablets: One tablet intravaginally before retiring and again in the morning for ten days. This course may be repeated if necessary.

Supplied: SULTRIN Cream is available in 2.75 oz. (78 g) tubes with the ORTHO* Measured-Dose Applicator.
SULTRIN Tablets are available in packages of 20 foil-wrapped tablets with vaginal applicator.

CHAIRMAN
OBSTETRICS & GYNECOLOGY
UNIVERSITY OF TENNESSEE

Clinical Education Center—Chattanooga

Position available as Chairman for the Department of Obstetrics and Gynecology in the Clinical Education Center at Chattanooga. Direct Obstetrics and Gynecology Residency Program in a University Affiliated Hospital. Approval Program with nine residents. Rotation of Medical Students for Core Clerkships and Electives. Faculty appointment. Must be Board Certified Obstetrics and Gynecology. Please direct inquiries and C. V. to:

Colman C. Keane
Staff—Search Committee
Suite 400—921 East Third Street
Chattanooga, Tennessee 37403
Phone (615) 756-3370

The University of Tennessee is an Affirmative Action and Equal Employment Opportunity Employer.

GROUP PRACTICE OPPORTUNITIES
PACIFIC NORTHWEST

Rapid growth in the metropolitan area of Portland, Oregon has created immediate openings in the Department of Obstetrics and Gynecology. We are seeking obstetrician/gynecologists and/or perinatologists to join an active service with over 3,700 deliveries per year, a high risk intensive care nursery and complete fetal monitoring equipment.

Northwest Permanente, P.C. is a professional medical corporation which provides health care services to the 220,000 members of the Kaiser Foundation Health Plan of Oregon. Through its association with Kaiser Foundation Health Plan, a federally qualified HMO, Northwest permanente, P.C. operates nine outpatient clinics and two full service hospitals.

The medical practice is varied and professionally stimulating offering the physician a pure practice free of business and administrative concerns. A comprehensive salary and benefits package including a sabbatical program, malpractice coverage, three weeks vacation and one week educational leave to start, life, medical/dental and disability insurance along with two excellent retirement programs is provided. The physician is eligible for ownership participation after two years of service.

Portland, Oregon, on the Columbia and Willamette Rivers, is a city with a moderate climate located in a stable, prosperous economic region of the beautiful Northwest. Outdoor recreational facilities are superb and include excellent skiing, backpacking, fishing and boating opportunities. The Environmental Protection Agency, in a recent study, selected Portland as the "most livable city" in the United States.

Please send a curriculum vitae with your initial response to Marvin P. Goldberg, M.D., President, Northwest Permanente, P.C., 1500 S. W. 1st Avenue, 11th Floor, Portland, Oregon, 97201.

NORTHWEST PERMANENTE, P.C.-
PHYSICIANS & SURGEONS

EDITORS! REVIEWERS! AUTHORS!

For you . . . a new book that contains virtually everything you want to know about

THE SCIENTIFIC JOURNAL: EDITORIAL POLICIES AND PRACTICES

Guidelines for Editors, Reviewers, and Authors

In 1665 the first scholarly journal was published in France. Since that time, there has been no one source of editorial guidelines for journal editors. This new book now provides you with such a source.

YOU DECIDE YOUR OWN APPROACH!

Presenting the advantages and disadvantages of each specific decision, eminent editors offer you various recommendations, discussions, and opinions concerning the problems you may encounter:

"Because we are aware that there is no 'right' policy on most editorial matters, we have tried not to prescribe rules, but have, instead, explored various facets of the problems that confront the editor in his daily work."

The book is divided into two general sections: editorial policies, which usually require major decisions; and editorial practices, which involve minor decisions, often about format or mechanical style. You'll find essays exploring: the manuscript reviewing system; special types of manuscripts (abstracts, transactions, solicited manuscripts, book reviews). You'll value chapters which cover: information for authors; copyright; errata; references cited; copy-editing; journal cover; etc.

From "the purpose of scientific journals" to "binding practices," this new book contains virtually everything you want to know as editor, reviewer, or author. See for yourself!

By Lois DeBakey, Ph.D. In collaboration with: Paul F. Cranefield, M.D., Ph.D.; Ayodhya P. Gupta, M.D.; Franz J. Ingelfinger, M.D.; Robert J. Levine, M.D.; Robert H. Moser, M.D.; J. Roger Porter, Ph.D.; and F. Peter Woodford, Ph.D. August, 1976. 128 pages, 6″ × 9″. Price, $12.50.

Information for authors

Submission of contributions. Manuscripts should in general be sent to a particular Editor according to the following plan: If it is from the southeastern quadrant of the United States or from Canada, or if it has been presented before one of the official sponsoring societies, to Dr. Brewer; if from the northeastern quadrant (including Ohio), or if it is a Clinical Opinion or a Letter to the Editors, to Dr. Zuspan; if from the north central states, any of the United States west of the Mississippi, Hawaii, Alaska, or abroad, to Dr. Quilligan.

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. Therefore, all manuscripts must be accompanied by the following written statement, signed by one author: "The undersigned author transfers all copyright ownership of the manuscript (title of article) to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

All articles published in this JOURNAL must be contributed to it exclusively. Articles previously published in another language are not acceptable.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority.

Articles dealing with human experimentation cannot be accepted unless the experiment was approved by the author's local Human Experimentation Committee.

Statements and opinions expressed in the articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantee, warrant, or endorse any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

Manuscripts. Manuscripts should be typewritten on one side of the paper only, with double spacing and liberal margins. The original and one copy of the manuscript are required. References should be placed at the end of the article. They should include name of author(s), article title, name of periodical, volume, page, and year. Name of periodical should conform to that shown in latest *List of Journals Indexed in Index Medicus*. For reference style see current issue of JOURNAL. Authors are encouraged to limit references to *16, except* for Communications in Brief, limited to *2*, Current Investigation and Clinical Opinion, limited to *6*, and Current Developments, for which there is *no* limit. Illustrations accompanying manuscripts should be numbered, provided with suitable legends, and marked lightly on the back with the author's name. Authors should indicate on the manuscript the approximate position of tables and text figures.

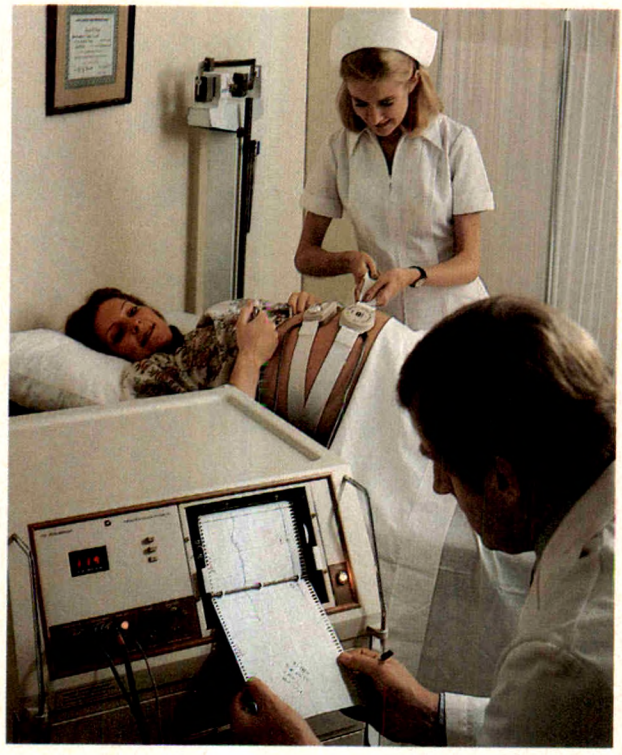
Tables should be typed on separate sheets of paper, not in the text, with one table to a page. They should be numbered in sequence and each must be referred to at an appropriate point in the text. Captions of the tables should be brief, yet indicate clearly the purpose or content of each table. Rows and columns in the table should precisely define the nature of the data in each. Abbreviations in tables should be used as little as possible and if abbreviations are used they should be explained in a footnote to the table.

An abstract of 50 to 150 words, to be published as an introduction, should accompany each manuscript and should be typed on a separate sheet of paper.

A footnote should be included which gives the name and complete mailing address of the person to whom reprint requests and correspondence should be sent.

A Guide to Writing for the American Journal of Obstetrics and Gynecology may be obtained from the Publisher on request.

Illustrations. A reasonable number of halftone illustrations will be reproduced free of cost to the author, but special arrangements must be made with the Editors for color plates, elaborate tables, or extra illustrations. Original drawings or graphs should be drawn with black India ink. Typewritten or freehand lettering is not acceptable. All lettering must be done professionally. **Do not send original art work, x-ray films, or ECG tracings.** Glossy print photographs are preferred, for good black and white contrast is essential.



Announcements. Announcements of meetings must be received by Dr. Brewer at least 2½ months prior to the time of the meeting. Such announcements should concern major meetings and other significant activities. Announcements of symposia or seminars for which fees are charged are not published in the scientific pages of the JOURNAL but may be submitted for paid advertisements, if desired.

Letters to the Editors. A brief Letter to the Editors commenting upon some article which has appeared in the JOURNAL will be considered for publication. The writer of the original article will have an opportunity to reply to unfavorable comments. A brief case presentation of special interest in the form of a Letter to the Editors will also be considered for publication. All such letters should be sent to Dr. Zuspan.

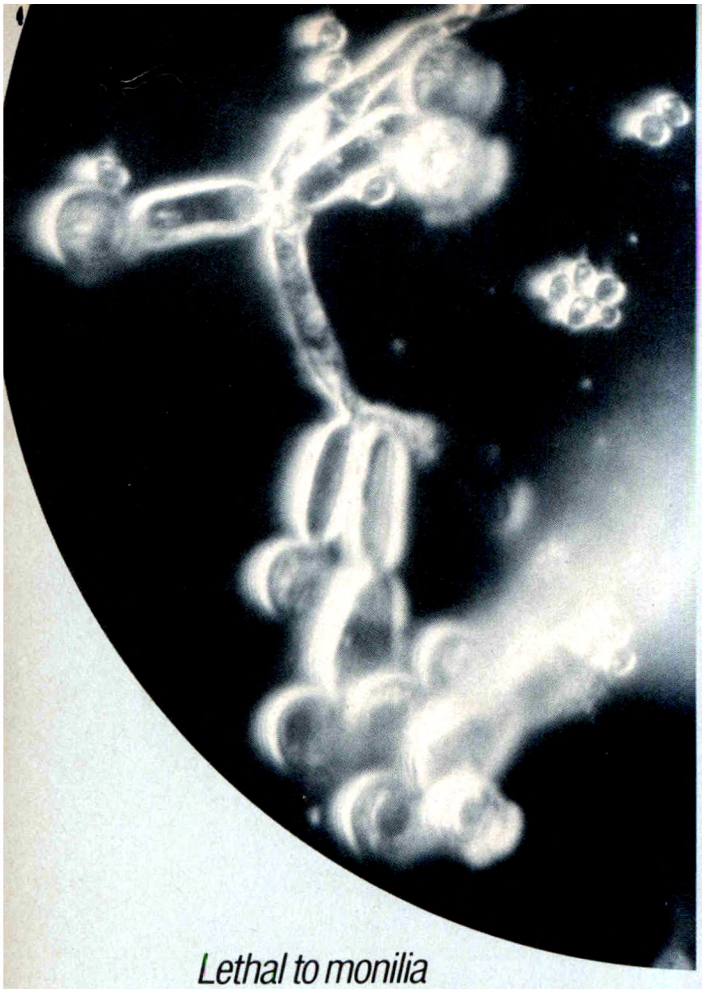
Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie.

Reprints. Reprints of articles must be ordered from the Publishers, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63141, who will send their schedule of prices. Individual reprints of an article must be obtained through the author.

How to determine fetal well-being, accurately, in your office.

For the first time, you can perform fetal non-stress testing (NST) conveniently and safely in the privacy of your office, with the Corometrics 110 Antepartum Monitor. Think of it—a test location reassuring to your patient and a modality far easier and less costly than the oxytocin challenge test.

Convenience for you and your patient. The 110 frees you from battling testing schedules and eliminates waiting for data to arrive—the average test lasts 12 minutes. Included as a regular part of your prenatal care program, the 110 can economically and reliably help you provide better patient care.



NST—a noninvasive, efficient and reliable test method. The Corometrics 110 monitors FHR accelerations, associated with fetal movement, which indicate fetal well-being. Non-stress testing is comfortable for both mother and fetus. A reactive NST pattern demonstrates fetal well-being more reliably than any other test.*

The Corometrics 110 Antepartum Monitor. It adds a more personal touch to your practice. For more information, contact: Corometrics Medical Systems, Inc., 61 Barnes Park Road North, Wallingford, Connecticut U.S.A. 06492, (203) 265-5631.

COROMETRICS MEDICAL SYSTEMS, INC.

**Routine Fetal Heart Rate Monitoring in the Antepartum Period*—Barry S. Schifrin, Gerard Foye, Jack Amato, Richard Kates & Jarleth McKenna. Presented at the District VIII Meeting ACOG, Honolulu, October 10, 1978. Accepted for publication—Obstetrics and Gynecology.

Lethal to monilia

Gentle to patients

IN MONILIASIS

BETADINE® Microbicides Vaginitis Regimen

High cure rate... rapid symptomatic relief

High cure rate is achieved in monilial vaginitis with the topical regimen employing BETADINE Microbicides:

BETADINE® SOLUTION
BETADINE® VAGINAL GEL*
(povidone-iodine)
BETADINE® DOUCHE

Easy-to-follow regimen

In the office, swab the cervix and vulvovaginal area with BETADINE Solution which is promptly and decisively microbicidal. Prescribe BETADINE Vaginal Gel (povidone-iodine), one applicatorful of which is to be inserted each night, followed the next morning by BETADINE Douche in therapeutic concentration.

After 2 weeks

The patient returns for an office visit after two weeks of therapy. In more resistant cases, the regimen may have to be continued through 1 or 2 cycles. BETADINE Microbicides are virtually nonirritating to vaginal mucosa and do not stain skin and natural fabrics.

Lethal to other vaginal pathogens too

The broad-spectrum microbicidal action of BETADINE Microbicides kills not only monilia, but also *Trichomonas* and *Hemophilus vaginalis*. Unlike exclusively antimonilial agents, the BETADINE MICROBICIDES VAGINITIS REGIMEN is not contraindicated when *Trichomonas* or *H. vaginalis* is present.

BETADINE Microbicides kill both gram-positive and gram-negative bacteria (including antibiotic-resistant strains), fungi, viruses, protozoa and yeasts. Their microbicidal action is maintained in the presence of blood, serum, and vaginal secretions.

*BETADINE Vaginal Gel (povidone-iodine) has been evaluated as possibly effective for use in the management of *Trichomonas vaginalis* vaginitis, monilial vaginitis and nonspecific vaginitis.

Purdue Frederick

See adjoining page for brief summary.

A8795 189777

Now available... BETADINE® Douche Kit

For douching in the BETADINE Microbicides Vaginitis Regimen, you can now prescribe BETADINE Douche Kit for a complete douching system, or BETADINE Douche 8 oz. for use with a gravity-flow douche bag or bulb syringe.

BETADINE Douche Kit contains:

(1) BETADINE Douche concentrate for making the douche solution
(2) Comfortable-to-use, squeezable, plastic syringe bottle
(3) Anatomically-correct cannula
(4) Instruction booklet
— Complete, ultra-modern, convenient douching system
— Provides the benefits of microbicidal BETADINE Douche

For a therapeutic concentration using BETADINE Douche Kit, instruct the patient to: Pour one (1) tablespoonful of BETADINE Douche concentrate into the syringe bottle provided in the kit. Add lukewarm water up *to the top of the syringe bottle.* Attach nozzle and shake gently to mix. Douche, *then repeat the procedure.*

For a therapeutic concentration using BETADINE Douche 8 oz., instruct the patient to: Add two (2) tablespoonfuls to a quart of lukewarm water, for use with a gravity-flow douche bag or bulb syringe.

BETADINE® Vaginal Gel (povidone-iodine)
Brief Summary

For use in the treatment of Trichomonas vaginalis vaginitis, monilial vaginitis and nonspecific vaginitis.

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows: possibly effective for use in the management of trichomonas vaginalis vaginitis, monilial vaginitis and nonspecific vaginitis. Final classification of the less-than-effective indications requires further investigation.

Precaution

If irritation, redness or swelling develops, discontinue use. The rare individual with history of iodine sensitization should not use this product, pending further investigation.

Saf-T-Coil®— in use for over 10 years

Saf-T-Coil is an IUD found comparable to the "pill" in use effectiveness.[1-2]

Five-year study[2]—27,712 insertions—541,248 women/months of use:

- a low 0.8% *in situ* pregnancy rate
- high 80% continuation rate
- 11.9% expulsion rate
- 8.0% removal rate

Subsequently, the investigators made Saf-T-Coil their "device of first choice."

1. Caraway, A.F.: Florida's Experience with an Intrauterine Device for the Nulliparous Patient. Presented at the International Family Planning Research Association Meeting, Palm Springs, California, October 21, 1974.
2. Caraway, A.F. and Vaughn, B.J.: J. Reprod. Med. *10*:170, April 1973.

Life table data—46,721 women/months

Clinical trials were conducted with Saf-T-Coil in which use effectiveness was determined as follows for parous women, as tabulated by the life table method.[3-7] This experience is based on 46,721 women/months of use including 4,231 women who completed 12 months of use and 1,842 women who completed 24 months of use. Rates are expressed as events per 100 women through 12 and 24 months of use.

	12 Months	24 Months
Pregnancy	2.4 (0.42-2.8)	3.1 (0.42-3.8)
Expulsion	18.3 (7.8-29.0)	18.8 (9.0-21.5)
Medical Removal	15.6 (4.8-18.7)	23.2 (9.0-27.0)
Continuation Rate	70.4 (55.2-88.0)	59.8 (57.0-81.5)

7. Tietze, C.: Report of a New IUD: The Double Coil. Advances in Planned Parenthood, III:85, 1967.

Three Saf-T-Coil sizes ensure contraceptive effectiveness throughout her reproductive years: Saf-T-Coil Nullip 25-S for the nulliparous and young woman, Saf-T-Coil 32-S for the primiparous woman and Saf-T-Coil 33-S for the multiparous woman.

Every Saf-T-Coil is made of inert plastic with no copper additives. And with every Saf-T-Coil—Saf-T-Sound®—the sterile, disposable intrauterine probe that helps make fitting easier and more accurate.

Caution: Federal law restricts this product to sale by or on the order of a physician.
Contraindications: Should not be used in: pregnancy or suspicion of pregnancy; abnormalities of the uterus resulting in distortion of the uterine cavity; acute pelvic inflammatory disease or a history of repeated pelvic inflammatory disease; postpartum endometritis or infected abortion in the past three months; known or suspected uterine or cervical malignancy including unresolved, abnormal "Pap" smear; genital bleeding of unknown etiology; untreated acute cervicitis until infection is controlled.

EDITORIAL

Transfusion therapy in pregnant sickle cell disease patients

A CONSENSUS DEVELOPMENT CONFERENCE on Transfusion Therapy in Pregnant Sickle Cell Disease Patients was held at the National Institutes of Health on April 23-24, 1979.

In general, four consensus work groups explored the question of whether there was sufficient evidence about transfusion therapy to advocate its use to treat pregnant patients with sickle cell disease. Other aspects of treatment of sickle cell disease addressed included the need for further research, including clinical research, perinatal considerations, and sociomedical issues. The work groups were divided into four subject areas—the need for further research, clinical research approaches, perinatal considerations, and sociomedical issues. Each group then reached conclusions on its subject.

Work Group I

Further research in transfusion therapy for pregnant patients with sickle cell disease is needed, but the question must be approached in a systematic fashion.

In transfusion therapy, patients are divided into two major groups for management. Group 1 is treated symptomatically, but the majority of these patients still receive blood components. Blood transfusions are used whenever judged to be necessary but are not given prophylactically. Group 2 is treated with prophylactic blood transfusions. Transfusion in this group is used to elevate the hemoglobin (Hgb) and hematocrit (Hct) significantly and to suppress Hgb S–containing cells, while replacing them with Hgb A cells. Other patients in Group 2 are managed with exchange transfusions.

The following question was posed: Have the positive effects of transfusion therapy been satisfactorily proved? The consensus of the group is that the value of transfusion therapy has not been proved. Although most studies regarding transfusion therapy have examined effects on maternal infection, toxemia, jaundice, anemia, sickle cell crisis, and hospitalization and on fetal growth retardation, perinatal mortality, and premature delivery, there is no consensus as to the effects of transfusion on these parameters. Some of the reasons for neither proving nor refuting the value of transfusion therapy are that the problems associated with sickle cell disease and pregnancy are not well defined, previously reported data are retrospective, there are no controls for gathering information about pregnancies in sickle cell disease patients, data regarding patients are not comparable among institutions, and pathophysiologic mechanisms leading to poor outcome in sickle cell disease patients are not understood.

The problems of the pregnant sickle cell disease patient must be defined before there can be an attempt to solve them. Which parameters to study and modify must be determined before the best outcome for both mother and infant can be sought. Because some of the pregnant sickle cell patients seem to be at low risk, a method must be found to determine which mothers need, and which do not need, transfusion therapy.

Studies of pregnant sickle cell patients may shed light on reasons for intrauterine growth retardation, reasons for and management of fetal stress and distress, and the importance of various parameters in determining

Sponsored by the National Heart, Lung, and Blood Institute. Assisted by the Office for Medical Applications of Research, National Institutes of Health.

U.S. DEPT. OF HEALTH, EDUCATION & WELFARE LIBRARY

the degree of risk for individual pregnant sickle cell patients.

Since the positive effects of transfusion therapy have been neither proved nor refuted, a task force for study design should be formed. The task force would develop a protocol for a prospective randomized study to determine the benefits and risks of transfusions in the pregnant sickle cell disease patient. To provide for an adequate data base, The National Cooperative Study of the Clinical Course of Sickle Cell Disease should be expanded to include additional perinatal information decided upon by a task force. Further input should come from interested perinatal centers. This "natural history" study has been funded by the National Institutes of Health for 5 years and involves 15 medical centers and 23 hospitals.

Studying the problem further indicates that the management of the pregnant sickle cell disease patient is not well established. The impact on the lay population and decisions of the sickle cell disease patient regarding future pregnancies should be carefully considered.

Work Group II

Further research is necessary to define the relationship between outcome and transfusion therapy during pregnancy. To be definitive, this research must be prospective and randomized. Since it is apparent that no one hospital or city has a sufficient patient population to perform such a study within a reasonable interval, a national cooperative multicenter approach should be utilized. The study should be integrated with the ongoing "natural history" study. To be well conducted, such an expensive and extensive task must be given priority, organized through mechanisms of the National Heart, Lung, and Blood Institute, and adequately funded.

Patients should not be excluded from the study on the basis of genotype, but criteria must be developed for those who will be included. For example, is the patient's history helpful? Should sickle B+ thalassemia and patients with $\geq 10\%$ hemoglobin F be included in the study?

Data must be accumulated to determine more fully the risks of transfusion, and methods must be defined for reducing transfusion risks to the minimum. Follow-up data are mandatory and must include careful collaboration among obstetricians, hematologists, pediatricians, pathologists, and blood banking personnel. In addition, blood-typing and blood-processing requirements must be carefully defined.

Patients should be randomized to transfusion or no-transfusion therapy in a prospective way after informed consent has been given. However, patients randomized to "no-transfusion" therapy may be transfused for specifically defined indications.

Data collection must start as early as possible, and the benefit and timing must be determined by the study design analysis group. Following initial therapy, frequent monitoring of high hemoglobin S levels must be performed and an upper limit defined (possibly from data from the natural history study) which, when exceeded, warrants repeat transfusion. Additionally, maximum hemoglobin levels not to be exceeded must be defined.

Work Group III

Perinatal considerations for transfusion therapy in sickle cell patients should address these questions: (1) How should patient monitoring be considered? (2) What are the challenges of intrapartum management? (3) What is the approach to infant follow-up?

A detailed series of clinical and laboratory procedures could be used to evaluate patients during the antepartum, intrapartum, and postpartum periods and to establish a data base. The comprehensive nature of the outline recommended reflects the importance of gathering complete data during pregnancy. Important retrospective information might be obtained from these data and prospective therapeutic guidelines developed.

Regardless of the specific guidelines followed for pregnant sickle cell patients, medical care should be provided in a tertiary center, with a joint effort among obstetricians, hematologists, and pediatricians. It should involve awareness of the clinical course of the disease process during pregnancy as well as therapeutic modalities that may modify the course and outcome of pregnancy. Infants born to sickle cell disease patients, who may or may not have had transfusion therapy during pregnancy, should be observed for a minimum of 2 years.

Since an appropriate study has not been performed to document its value, the detailed list of procedures prepared by the group should not be considered as recommendations for patient management.

Work Group IV

The data are insufficient to advocate a large-scale, nationwide policy of transfusion therapy or to reach definitive conclusions about ethical considerations. However, a study to determine (within 1 to 2 years) in a limited number of centers the value of therapeutic versus prophylactic transfusion in management should be undertaken. Justification would appear to be the marked difference in opinion as regards the value of various treatment modalities.

Any study design must consider psychological considerations, including patient and physician levels of awareness and knowledge, and must allow for prejudice or feelings concerning fear of transfusion, possible intimidation from the community regarding transfusion needle marks (confused with addiction), pressure on family for repeated blood donations, convenience factors favoring time of transfusion for physician versus patient, overprotectiveness of patient's family, and possible "addiction" of patient to transfusion. Economic, geographic, and educational data relating to patient and physician must be considered, and continual updating of information about the progress of the study for all concerned must be planned. Counseling should be available both before and after conception. Information about the value of amniocentesis in selected instances should be made available to patients. Any study design should take all of the psychosocial aspects into account.

Access to the study must be available to all patients who wish to become involved, but patients should not be coerced.

Informed consent should be obtained from all participants. Innovative methods, such as audiovisual presentations with subsequent question-and-answer sessions, should be developed to avoid coercion of patients. Patient feedback mechanisms to test levels of comprehension need to be developed. Paramedical personnel may need to be included.

Funding for patient care in such a study should be through private or public means and not by grant support. Analysis of data and reporting can be related to National Institutes of Health support, but patient-care funding cannot.

The presence of hemoglobin SS, SC, or sickle thalassemia, which constitute sickle cell disease, should not be the sole justification for either abortion or sterilization. These procedures should be performed on the basis of medical indications and/or patient desire. The medical and legal communities need to be apprised of this consensus.

The conference was supported by the National Heart, Lung, and Blood Institute, National Institutes of Health. At the National Institutes of Health, consensus development conferences bring together biomedical research scientists, practicing physicians, consumers, and others, as appropriate, in an effort to reach general agreement on the efficacy and safety of a medical technology.

Cochairmen for the consensus meeting were John C. Morrison, M.D., University of Tennessee, Memphis; and Henry Foster, M.D., Meharry Medical College, Nashville.

Transactions of the Forty-first Annual Meeting of the South Atlantic Association of Obstetricians and Gynecologists

The points of Osler's compass

Presidential address

CARROLL H. LIPPARD, M.D.
Lynchburg, Virginia

WHILE THERE HAVE BEEN notable advances and accomplishments during our professional lifetime, many of us are uneasy about the direction medicine has taken. The forces that control our professional lives seem to have passed out of our control.

At the heart of the problem is a deterioration in the rapport of the physician-patient relationship which was so salutary for all concerned in the past, but which is now threatened by increasing intrusion of the federal government, by a growing technological influence on the practice of medicine, and by an increasing emphasis on the business aspects of our practices. In such an atmosphere there is the risk that our sense of mission and satisfaction in our work may fade and that our respect for ourselves as physicians in the time-honored sense may be weakened. In the midst of plenty, anxiety stalks among us with velvet step.

It has long been permissible and customary for presidential remarks to follow a philosophical bent, often fortified by quotes from notable historic figures or the classic philosophers. But I want to call upon the wisdom of that famous contemporary American philosopher Satchel Paige. You may remember one of Satchel's famous aphorisms: "Don't look back! Somethin' may be gaining on you."

At a time when we wonder if we may have taken a wrong turn somewhere and may have lost our bearings, perhaps we should ignore Satchel's admonition and look back to an earlier age of medicine for a new compass course, adjusting our sextant to focus on the values and precepts of William Osler as he trod the halls of the University of Pennsylvania almost a century ago.

The attraction of the University of Pennsylvania School of Medicine for Southerners has been remarkable and of long duration. Prior to the Civil War there were 5,501 graduates of that institution.[1] More than three fourths were from the South. Twenty-five percent of the entire corps of Confederate Army surgeons were graduates of that single institution contrasted with only six percent of Union Army surgeons.[2]

Such traditions do not fade easily in the South. In our own generation many a young product of the postdepression, small-town South moved northward in annual migratory waves after completing the first two medical school years in southern institutions, a significant number heading for the University of Pennsylvania School of Medicine.

Wards B and D at the University Hospital were Osler's wards. The first medical students in the United States to go to the patient's bedside with their teacher for ward rounds did so with him on those wards.

Osler would never have left Canada to come to Philadelphia had not the University of Pennsylvania been going through one of its periodic power struggles. After the Chair of Clinical Medicine was vacated in 1884, the Board of Trustees was deadlocked between two candidates from within the institution. Compromising, they went outside and chose Osler.[3]

Presented at the Forty-first Annual Meeting of the South Atlantic Association of Obstetricians and Gynecologists, Hot Springs, Virginia, January 28-31, 1979.

Reprint requests: Dr. Carroll H. Lippard, 1910 Thomson Dr., Lynchburg, Virginia 24501.

0002-9378/79/160854+06$00.60/0 © 1979 The C. V. Mosby Co.

He really was not too impressive at first. His teaching colleague, William Pepper, was an outstanding lecturer, silver-tongued, facile with words. Not so with Osler. The lecture platform was not his favorite forum. He was halting in his speech, usually sitting on the edge of a table, swinging his feet and twisting his ear. When standing, he shifted his weight from one leg to the other. His wife remarked, "I wish Willie would not rub the calf of his leg with his other foot to stir up his ideas."[4]

On the wards it was a different matter. Since Pepper rarely appeared except for lectures, Osler had the wards almost to himself, spending most of each morning with the medical students examining patients. An ever-growing number of students followed him about. It was in this setting that Osler developed a unique chemistry with his patients and with his students at the bedside. Any reservations the students had about Osler's performance in the lecture hall were soon dispelled as they worked side by side with him in the wards.

There was no microscope at the University Hospital when Osler arrived.[5] He brought his own and within a month had set up shop under the hospital amphitheater seats, where he introduced this revolutionary diagnostic tool to his students.

An eclectic scholar, Osler seemed to have time for whatever interested him or wherever he was needed. An accomplished pathologist, he made himself available for autopsies at the Blockley dead house, next door to the hospital, leading his omnipresent student disciples through the gate in the old wall like the Pied Piper. He taught them to respect the autopsy room as medicine's temple of truth, where fact was separated from conjecture.

In 1889, Johns Hopkins, a Baltimore merchant, died a bachelor, leaving $7 million to be divided equally between a new university and a new hospital, each to bear his name. The Johns Hopkins Hospital was about to be born. After five years at the University of Pennsylvania, Osler accepted the position of professor of medicine and physician in chief at The Johns Hopkins Hospital. He brought with him his Philadelphia friend, Howard A. Kelly, of Kelly stitch fame, as professor of obstetrics and gynecology. In Osler's sixteen years at Johns Hopkins, the "Hopkins Four"—Welch, Kelly, Halstead, and Osler—created an institution and teaching program that became the model for present-day medical education.

Osler's final move came in 1905, when he left Johns Hopkins to become Regius Professor of Medicine at Oxford University in England. There he spent the final fourteen years of his life, acclaimed worldwide as the outstanding clinician and teacher of his era.

Scope of influence

The scope of Osler's influence was enormous. At the time of his arrival on the medical scene in the United States, most medical schools were proprietary in nature, operated for profit, and medicine was taught primarily in the lecture hall. By general custom the hall was rented by the professor, the student paying his tuition directly to the instructor. For the most part, bedside instruction was neither expected nor provided.

At the University of Pennsylvania and Johns Hopkins, Osler revolutionized medical education by bringing the medical student to the patient's bedside on the wards, using the patient himself as the primary vehicle for teaching. Lectures and textbooks became secondary. As he put it, "To study the phenomena of disease without books is to sail an uncharted sea, while to study books without patients is not to go to sea at all."[6]

The importance Osler accorded the change he wrought in medical education is manifest in his comment, "I desire no other epitaph than the statement that I taught medical students in the wards."[7] The traditions of ward rounds, clinical clerkships, and house officer–residency programs were his creations and our legacy.

He introduced and popularized some of the medical technology new to his era. In addition to initiating the use of the microscope in the University of Pennsylvania Hospital, he introduced into the United States in 1884 the binaural stethoscope which is still in universal use.[8]

His writing ability became apparent early in his career. In addition to more than 1,200 medical articles in his lifetime, he wrote extensively on natural history, the history of medicine, and the history of English literature.[9] The bibliography of his published works spans 132 pages.[10] His influence became worldwide with publication of *The Principles and Practice of Medicine* in 1892, which rapidly became the premier texbook of medicine. Sixteen editions were published, the last in 1947, appearing not only in English but in French, German, Spanish, Portugese, and Chinese translations.

Osler's most lasting influence was the degree to which he humanized medicine. He taught by word and example that clinical excellence and skill in the technologies of medicine are important prerequisites for medical practice, but to be a physician in the true sense of the word, there must be a genuine interest in and commitment to the patient above and beyond the disease itself—a higher obligation to serve as the patient's advocate, counselor, and protector. The assertion of

such a humanitarian requirement was particularly impressive coming, as it did, from the man who was universally viewed as the consummate clinician, educator, and medical author of his era.

Relevance for today

Osler has been gone for sixty years, but our generation, as those before us, seems drawn to him as to no other historical figure. A computer search of the past five years revealed fifty-four articles in the English language medical literature that referred to him in their titles. His was a lovely flame, whose smoke still gets in our eyes. He reminds us of what we could be, of what the noblest traditions of our profession are.

His world was not easy, medical or otherwise. Yet he possessed a set of inner directed principles that provided safe transit for him and the generation who relied on his guidance through the rocky narrows of his day. Might the compass that proved so reliable in providing direction for Osler still work? Might it point out the way we should go to heal the breach that disturbs our relationship with our patients, to restore our sense of mission as physicians? Let us take a closer look at some of Osler's guiding principles, the key points of the compass by which he traveled through life.

The points of Osler's compass

True North for Osler was his conception of the ethical and philosophic precepts which should govern our lives as physicians.

The son of a minister, he grew up in an atmosphere that gave high priority to making one's life of service to others. He viewed medicine as a calling whose real reward lay in helping others. In 1906 he addressed a group of his favorite people, medical students: "Get your relationship clearly defined. You are in this profession as a calling, not a business. . . .Once get down to a purely business level, your influence is gone and the true light of your life is dimmed."[11] On another occasion: "More than any other, the practitioner of medicine may illustrate the . . . great lesson that we are here not to get all we can out of life for ourselves but to try to make the lives of others happier. . . . The practice of medicine is an art, not a trade; a calling, not a business; a calling in which your heart will be exercised equally with your head."[12]

At the South point of Osler's North-South axis was the patient himself.

For Osler, the management of the medical problem proceeded only in the context of working for the welfare of the patient as a total human being. As advocate and counselor for his patient, he was concerned not only with his patient's disease, but with his family, economic security, and any other factor of importance to his patient.

According to his Johns Hopkins associate, J. M. T. Finney, "There was developed in him . . . the capacity of making each individual patient feel that he was personally interested in his or her case, not by number, but as an individual. This was not merely assumed interest with him, either; it was genuine. . . . One of his special characteristics was optimism; not of the foolish sort which . . . says all is well when it surely is not, but which grasps every opportunity . . . to turn the . . . patient's thought from self and gloomy forebodings. . . . Hope was the bright star to which he was constantly pointing."[13] But if the patient was beyond cure and on desperate ground, Osler was there to comfort and to counsel.

He viewed this type of relationship as the "art of medicine." If absent, no matter how skilled and well documented the clinical handling of the patient, he viewed that physician as a technician, not a true physician in the best sense of the word.

The East point of Osler's compass refers to his lifelong interest in education.

In addition to the transformation he effected in medical school education, he was one of the earliest proponents of continuing education for physicians. He cautioned the graduating students at McGill University in 1905 that the body of knowledge they carried with them would be current for five years at most. He urged a systematic program to remain current or, ten years later, be "dead mentally, . . . fit to do a routine practice, . . . but without any deep convictions and probably more interested in stocks or horses than in diagnosis or therapeutics."[14]

He recognized the obstacles that success may throw into our paths. "The ever-increasing demands of practice leave less and less time for study, and a first class man may lose touch with his subject through no fault of his own, but through an entanglement from outside affairs which he deeply regrets but which he cannot control."[15]

Osler held firm opinions about qualifications for teachers. First, they should have a high level of clinical competence in their field. While stressing the "art of medicine," he did not view it in any sense as a substitute for thorough scientific competence. Second, they should teach by example traits of gentleness, forbearance, and courtesy in dealing with patients. Third, they should demonstrate a sense of obligation to put something back into the profession, to pass on to those who follow some of the benefits which the profession had provided them. Fourth, Osler felt it essential that teachers be involved in some degree with private prac-

tice, not for the sake of additional income, but to make them more aware of the actual conditions under which the student would be practicing in the future. Thus, he opposed the full-time teaching concept. "I cannot imagine anything more subversive to the highest ideal of a clinical school than to turn over young men who are to be our best practitioners to a group of teachers who are . . . out of touch with the conditions under which these young men will live."[16]

Osler's final compass point, West, was his way of life.

Osler related that while a junior in medical school in Montreal he was in a period of considerable anxiety. "Much worried as to the future, partly about final examinations, partly about what I should do afterwards, I picked up a volume of Carlyle, and on the page I opened there was the sentence, 'Our main business is not to see what lies dimly at a distance, but to do what lies clearly at hand'."[17] It seemd to Osler that life suddenly came into clear focus. He resolved to dismiss every anxiety from his mind and concentrate solely on putting his best into the next twenty-four hours. It was the starting point of a life attitude. He divided his life into "daytight" compartments, concentrating on doing justice to that twenty-four hour unit, not allowing himself to be distracted by concerns of past or future.

Osler speaks of the past: "Shut out the yesterdays—the petty annoyances, the real and fancied slights, the trivial mistakes, the disappointments, the sins, the sorrows, even the joys—bury them deep in the oblivion of each night. . . . Undress your soul at night . . . by shedding, as you do your garments, the daily sins, whether of omission or commission, and you will wake a free man with a new life."[18]

Osler bids us wall out the future as well. "The load of tomorrow, added to that of yesterday, carried today, makes the strongest falter. Shut off the future as tightly as the past. No dreams, no visions, no delicious fantasies, no castles in the air. . . . Nervous worries dog the steps of the man who is anxious about the future."[18] It was Osler's conviction that the only real influence we have on tomorrow hinges on how well we take care of today.

As for the day itself, he treated it as a precious thing, a slice of eternity given him by his Maker to be lived carefully and fully. "Join the whole creation of animate things in a deep heartfelt joy that you are alive, that you see the sun, that you are on this glorious earth which Nature has made so beautiful and which is yours to conquer and enjoy. . . . Realize that you have sixteen waking hours in which to accomplish the . . . objectives of that day. . . . Let each hour have its allotted duty, and cultivate that power of concentration which grows with its exercise so that the attention neither flags nor wavers, but settles with a bulldog tenacity on the subject before you. . . . No matter how trifling the matter at hand, do it with a feeling that it demands the best that is in you."[19]

He cautioned physicians against losing interest in everything but work and becoming one of the "bovine brethern who think of nothing but the treadmill and the corn."[20] His emphasis was on the balanced day and the balanced life.

He commented on the importance of a hobby, a happy marriage, and communion with the best minds of the ages through reading. "You will be a better man and not a worse practitioner for an avocation. I care not what it may be: gardening or farming, literature or history."[21] As for marriage, Osler wrote a former student who was contemplating matrimony, "You have a career ahead of you which the right woman will help, the wrong woman wreck. A level headed fellow can do anything he wishes with a wife if love blossom into trust, gentleness and consideration. A doctor needs a woman who will look after his house and rear his children, . . . whose first care will be for the home. Make her feel that she is your partner. . . . Consult her and take her advice about the house and children, but keep to yourself, as far as possible, the outside affairs relating to the practice."[22] Osler was happily married himself. At age 43 he married the great-granddaughter of Paul Revere, the widow of Dr. Samuel W. Gross, his longtime friend from Philadelphia days. Their only child, a son, they named Revere.

There was one further time allotment which Osler viewed as essential—a time reserved for reading the thoughts of the authors of the world's great literature. The final hour of his waking day, from ten to eleven o'clock, was spent in this fashion. It was from this hour that his broad sweep of interest in the humanities was continually recharged.

He urged us to meet the inevitable moments of stress and frustration with imperturbability and coolness under fire. He deliberately avoided strife from whatever quarter. "I have striven with none, not . . . because none was worth the strife, but because I have had a deep conviction of the hatefulness of strife, of its uselessness, of its disastrous effects, and a still deeper conviction of the blessings that come with . . . peace and concord."[23]

He was moved by the patience and forbearance with which the average man endured suffering. "Nothing will sustain you more . . . than the power to recognize in your humdrum routine . . . the true poetry of life—the poetry of the commonplace, of the ordinary man, of the plain toil-worn woman, with their loves and their joys, their sorrows and their griefs."[24]

Osler recognized that some of us will be called upon to face disappointment, failure, and even disaster. He expressed the hope that he himself might "cultivate such a measure of equanimity as . . . to be ready, when the day of sorrow and grief comes, to meet it with the courage befitting a man."[25] "You cannot hope . . . to escape from the cares and anxieties incident to . . . life. Stand up bravely, even against the worst. Your very hopes may have passed out of sight. . . . You may be left to struggle in the night alone. There is a struggle with defeat which some of you will have to bear. . . . Even with disaster ahead and ruin imminent, it is better to face them with a smile and with the head erect, than to crouch at their approach."[26]

Such a moment came to Osler himself. His only child, Revere, was killed in France in 1917. There was private heartbreak but no public grief. He wrote a friend, "Grief is a hard companion, particularly to an optimist and to one who has been a stranger to it for so many years. We decided to keep the flag flying, and let no outward action demonstrate . . . the aching hearts."[27]

In July, 1919, in his seventieth year, Osler developed a respiratory tract infection which was to be his terminal illness. It progressed to pneumonia and empyema. In the last days, before he became too ill to write, he sent brief notes to many of his close friends. His last note, six days before his death, contained the following sentence: "The harbour is not far off. And such a happy voyage! And such dear companions all the way. And the future does not worry."[28]

On December 29, 1919, this remarkable man passed from life into history, remaining true in the ordeal of his final illness and death to the qualities that made him an authentic hero to his generation. Our generation has not been fertile soil for heroes, medical or otherwise, but we could do worse than look to William Osler.

Comment

There are three areas that offer us the opportunity to claim some of Osler's ideals for our own.

First, we should adjust our personal compass to whatever degree may be necessary to ensure that our true North, as Osler's, is the welfare of each patient as a whole human being.

Our greatest professional fulfillment should come from our relationship with him as a total person rather than with his disease alone. We should endeavor to protect him from threats from any quarter, including from the marvels of our own specialty when this involves major financial expenditures in quest of technological data of interest but uncertain practical importance. We must recognize that the patient has a spectrum of aims and aspirations, of which his medical care is only one. Depletion of his economic resources by medical expense might severely impair his ability to achieve other of his life's objectives of exceeding importance to him. When this possibility exists, whatever our final recommendation to the patient, if it is made with full consideration given to all of his interests and responsibilities, Osler would be in accord with the decision as having been made on the right grounds.

Second, we, as private practitioners, should reclaim a central role in medical education.

Many medical teaching centers now find themselves under pressure from several directions. First, there has been widespread dispersion of the population away from university medical centers into suburbs and outlying communities. The population base from which clinical material was drawn for teaching purposes is no longer there. Second, university teaching centers are no longer the referral centers they once were. The residents whom they have trained so well over the past two decades are now located in those outlying communities, have excellent hospital facilities at their command, and encounter few medical problems which now require referral away from community hospitals into university centers. Third, medical schools are now faced with larger classes at the very time that the clinical material has dispersed. Fourth, capitation grants and other federal funds for medical education are falling increasingly into question, and funds to build additional beds at university centers are falling afoul of certificate-of-need requirements and constraints of federal and state budgets.

In the face of such changing conditions, patterns of medical education must change with them if our students and residents are to receive adequate clinical instruction. A fundamental prerequisite for any system of medical education has always been the availability of clinical material for teaching purposes. Willie Sutton, the bank robber of note, expressed the appropriate concept when asked why he robbed all those banks. His reply was, "Because that's where the money is." Medical education should occur where the patients are.

Those of us in private practice who have benefited so greatly from the teaching provided us by others in our training days should take note of our own developing opportunity to do the same for a new wave of medical students and residents in our community hospitals. At the same time, we must be aware of our responsibility to the student, the resident, and the medical school to ensure continuing quality of the teaching provided.

This process must be a two-way street. Departments of obstetrics and gynecology within our medical schools must reciprocally recognize their need to enter an educational partnership with community hospitals. There are obviously many problems and adjustments to be

worked out by all concerned, but our overriding priority should be to provide upcoming classes of students and residents exposure to a full range of clinical material under the best teachers and conditions possible, taking advantage of the strong points and assets of both university hospital and community hospital.

Third, we need to declare for ourselves an ethical tithe.

We live in an era when medicine is big business. Our offices hum with automated equipment. Our desks sag under stacks of third-party forms, reports, and regulations. We have had to devise a system dedicated to efficient delivery of medical care per unit of practice time.

This poses a dilemma. From its beginnings our profession has fostered a tradition of caring for those in genuine need without regard to time expended or financial reward, yet our system leans toward the impersonal and rewards efficiency.

To preserve the humanitarian side of medicine we must reserve a time to work outside the system, to disregard efficiency, and to treat ourselves to the pleasure of giving to some poor soul all the time he needs and the best of our skills in a thoroughly unbusinesslike way. To practice medicine with the expectation of compensation all along the way is to run the risk of extinguishing that fragile flame that lights our inner being and gives meaning to our lives. We must grasp the opportunity to exercise this ethical tithe, to give part of ourselves away, not so much for the patient and his welfare as for the nuturing of our own professional souls.

Conclusion

I have attempted to bring before you an outline of the life, attitudes, and values of William Osler. I do so with convictions born of twenty-five years of laboring with you in the medical vineyards that his beliefs and ideals remain realistic and practical and can restore a measure of peace and sense of mission to our lives. We will not always succeed, but in making the effort we will establish company with Osler in those ancient virtues he sought to exalt and preserve. The important thing for us is to claim those ideals for our own and attempt to incorporate them in a practical way into our individual lives. Osler realized that we would not always be successful in doing so. Even knowing this to be true, he tells us that we will be better men and truer physicians for the effort. In Osler's own words, "To have striven, to have made an effort, to have been true to certain ideals—this alone is worth the struggle."[29]

Six years' experience with screening of a diethylstilbestrol-exposed population

Philadelphia, Pennsylvania

The physician population delivering obstetric care in Philadelphia between 1950 and 1970 was contacted to ascertain their use of diethylstilbestrol (DES) during pregnancy. Of the 31.8% of the physicians who responded to the questionnaire, 71.3% used DES during pregnancy and 12.7% desired assistance in review of their records. During the 6 years from the initial survey, 830 young women exposed to DES in utero were periodically screened for cervicovaginal abnormalities and clear cell adenocarcinoma. Of these 830 patients 67.7% were found to have cervicovaginal abnormalities, and 65.9% of the patients showed either adenosis or evidence of the prior existence of vaginal adenosis. Eight patients were treated for clear cell adenocarcinoma. Two cases were detected while asymptomatic. Seven of the patients are living with no evidence of cancer, and two of these have survived over 5 years. (AM. J. OBSTET. GYNECOL. 134:860, 1979.)

AFTER THE INITIAL REPORTS in 1972 by Herbst and associates[1, 2] describing the association of the maternal use during pregnancy of the synthetic steroid diethylstilbestrol (DES) with clear cell adenocarcinoma, adenosis, and other related vaginal abnormalities in female offspring, it became increasingly evident that many young women in the Philadelphia area were demonstrating these findings. In addition, because of the increased publicity devoted to this association by the lay press, a significant number of these women were seeking pelvic evaluation. In many of these patients a history of maternal DES therapy was confirmed by information from the patient's mother or from the mother's obstetrician. The Gynecologic Oncology Division of the Department of Obstetrics and Gynecology at the Hospital of the University of Pennsylvania felt it was important to locate and examine as many of the DES-exposed women as possible. A project was designed to locate the population at risk to DES exposure in utero in the greater Philadelphia area by contacting area physicians who might have used the drug in their practices and providing for them information and seminars aimed at locating the patients involved.

From the Department of Obstetrics and Gynecology, Division of Gynecologic Oncology, and the Department of Research Medicine, The University of Pennsylvania School of Medicine.

Presented as Official Guest at the Forty-first Annual Meeting of the South Atlantic Association of Obstetricians and Gynecologists, Hot Springs, Virginia, January 28-31 1979.

Funded in part by the United Fund of Philadelphia, 1974.

Junior Faculty Clinical Fellow, American Cancer Society.

Material and methods

Reaching the DES-exposed population. Dorland's Medical Directory between the years 1949 and 1970[3] was utilized to identify those physicians in the Philadelphia area who were cited as practicing obstetrics during those years. These physicians were then contacted by letter, which outlined the DES problem, provided information and a bibliography on exposure to DES in utero, and offered to them the services of trained personnel to try to locate the population at risk by review-

0002-9378/79/160860+06$00.60/0 © 1979 The C. V. Mosby Co.

ing their own practice files. In the initial letter, which was mailed to all these physicians, two questions were asked: (1) Did you use DES in your obstetric practice? (2) If you did use DES in your practice, would you avail yourself of the services that could be provided by the Hospital of the University of Pennsylvania? A list of gynecologists in the Philadelphia area familiar with DES-exposed women, as well as proficient in colposcopic examination of these patients, was provided.

Results

Between 1951 and 1970, a total of 718 obstetricians, gynecologists, and general practitioners delivered obstetric care in the Philadelphia area. Six hundred and seventy-eight (94.5%) of these physicians were located and 40 (5.5%) of these physicians could not be located. Of the 678 physicians in the Philadelphia area to whom the letters of information were mailed, 216 (31.8%) responded to the letter and 462 (68.2%) did not respond. Of those 216 physicians who responded to the questionnaire, 155 (71.8%) answered that they had used DES; 13 physicians (6%) were deceased and no information was available pertaining to their practices. One physician responded to the questionnaire but provided no information on his practice. Of the 47 physicians who used DES, 24 (59.1%) did not desire assistance, 15 (31.9%) informed us that they either had reviewed or were in the process of reviewing their own records, six (12.7%) desired assistance, and two (4.2%) declared that there were no records available for review.

The DES Evaluation Center. As of December, 1978, 830 young women had registered for examination and evaluation at the DES Center of the Hospital of the University of Pennsylvania. Six hundred and thirty-five were evaluated on two or more occasions. This paper will focus upon data from the initial visits of 830 patients. Twenty-six states were represented but the vast majority of the patients were born in the Delaware Valley area, representing Pennsylvania, New Jersey, and Delaware.

Although the initial referrals were generated primarily via the lay media (179 patients, 21.6%) family (70, 8.5%), or friends (50, 6.0%), the greatest number of referrals came from private physicians (470, 56.6%).

The age of the study population ranged from 7 to 35 years of age with 612 (73.5%) falling between the ages of 20 and 29. The population was 99.5% white (825 of 830).

Patient evaluation. At the time of the initial visit, a detailed medical history of the DES-exposed offspring was taken by a registered nurse. The data collected included a gynecologic history along with a record of any other pertinent medical information. The mother's gynecologic and obstetric history, especially with the pregnancy in question, as well as any drug dosage information was secured when possible. Since the three main sources for securing data are the delivering obstetrician's record, the pharmacy where the drug was purchased, and the hospital records where the patient was born, the patient was encouraged in the preliminary letter to exhaust all sources of information concerning the drug data.

The details of the examination were reviewed with the patient prior to entering the examination room. Depending on the age of the patient, more emphasis might have been placed on the details of her first gynecologic examination rather than the colposcopic examination.

Only rarely was it necessary to hospitalize the virginal DES-exposed patient for examination with anesthesia. Any patient presenting with complaints of irregular bleeding who could not be adequately evaluated in the outpatient center was admitted without delay for further evaluation with anesthesia. The actual gynecologic examination and colposcopic examination were performed as described by Townsend.[4]

Structural abnormalities. Gross structural cervicovaginal abnormalities were found in 512 (61.7%) of the individuals evaluated. One hundred eighty-seven (22.5%) patients were observed to have complete cervical collars; 96 (11.6%) were observed to have incomplete cervical collars; 185 (22.3%) were noted to have a "cock's comb" formation, and nine (1.1%) were observed to have transverse vaginal septa. Thirty-seven (4.5%) were lacking vaginal pars or fornices, and 45 patients (5.4%) had various other minor structural changes. Forty-seven (5.3%) had combinations of two or more structural changes in the cervix or vagina and forty-five (5.4%) had abnormalities that defied description.

Adenosis. Vaginal adenosis is the presence of glandular tissue similar to that found in other glandular müllerian elements. When the DES Study Center was initially opened, all patients had biopsies taken to prove the presence or absence of vaginal adenosis. As more and more individuals were examined, the necessity to take biopsies in order to prove the presence of vaginal adenosis was abandoned, and colposcopic identification of columnar epithelium in the vagina was considered adequate to document vaginal adenosis. In addition, a presumptive method of documenting vaginal adenosis, or the prior existence of vaginal adenosis, was the colposcopic identification of metaplastic squamous epithelium in the vagina. In 38 patients, vaginal adenosis existing alone was documented. In another 279 pa-

tients metaplasia existing alone was noted in the vagina and in another 230 patients both metaplasia and adenosis coexisting in varying degrees were found. Thus 547 (65.9%) showed either adenosis or evidence of the prior existence of vaginal adenosis.

Abnormal Papanicolaou smears. Papanicolaou smears of the cervix, endocervix, and vaginal walls were obtained on all visits. One hundred fifty-nine (19.1%) patients had abnormal cytologic findings (Table I). Forty-nine of these patients had cytologic interpretations consistent with mild (43), moderate (five), and severe (one) dysplasia. There were no patients with cytology suggestive of carcinoma in situ (Table II).

Colposcopic findings. Colposcopic evaluation similarly showed disturbing results. The frequency of the abnormal colposcopic findings is noted in Table III. Over 35% of our patient population had one or more colposcopic abnormalities normally associated with dysplastic epithelium. The results of directed biopsies from colposcopically abnormal areas were much less disturbing. Colposcopically directed biopsies in 154 patients revealed dysplastic epithelium in only 31 patients. The majority of these patients (22) showed only mild dysplasia. When the results of the colposcopic findings were compared to the histologic results of biopsies taken from the areas of colposcopic abnormalities, it was obvious that the common colposcopic abnormalities used to identify abnormal epithelial changes, particularly white epithelium, punctation, and mosaic patterns, were unreliable in discerning areas of dysplastic epithelial changes in the DES-exposed population (Table IV).

Clear cell adenocarcinoma. Eight patients with clear cell adenocarcinoma of the vagina or cervix were seen. They ranged in age from 14 to 25, with a mean of 19.9. Each of the individuals was born during the decade of the 1950's (Table V).

Symptoms. Two of the patients were asymptomatic and were undergoing examination because of a known history of DES exposure in utero. Two of the patients had an abnormal vaginal discharge and four of the patients had irregular bleeding. Except for the two patients who were asymptomatic, the duration of symptoms in five of the other patients varied between 1 and 5 months, and in the last patient there was a history of postcoital bleeding for 2 years (Table VI). It should be noted that this latter patient had seen at least two gynecologists for examination, at which time "severe inflammation" of the cervix was noted, and because of normal cytologic findings nothing further was recommended. In seven of the eight patients, therefore, the

delay in diagnosis was felt to be insignificant. Seven of the eight patients had never had sexual intercourse.

Papanicolaou smears. Papanicolaou smears were not obtained in three of the patients since initial examination by the referring physician revealed an abnormality from which a direct biopsy was performed, which showed cancer. The patient who had the 2 year delay in diagnosis had negative cervical cytologic findings on several occasions. Of the remaining four patients, two had Class III cytologic smears, designated as "suspicious" or "rule out adenocarcinoma," while two of the patients had Class V vaginocervical cytologic findings consistent with adenocarcinoma.

Location and stage of carcinoma. Seven of the eight patients had carcinomas which were classified as clear cell adenocarcinoma of the cervix and one as clear cell adenocarcinoma of the vagina. Of the patients with cervical cancer one had a Stage IB lesion clinically, five had Stage IIA, and one patient had a Stage IIIB lesion. The last patient had celiotomy for surgical staging and was found at that time to have only an inflammatory process causing the parametrial induration. The patient with the vaginal carcinoma, Stage II, had a 1.5 cm polypoid lesion attached by a narrow stalk to the upper left lateral vagina, below the cervix, with minimal induration of the underlying vaginal tissues.

Treatment. Seven of the patients were treated by radical hysterectomy and bilateral para-aortic and pelvic lymphadenectomy. Two of the patients were found to have nodes involved with tumor and were given postoperative total pelvic radiation. The extent of the dissection of the vagina was based on the degree to which the vagina was involved with either the tumor or areas of adenosis. Total vaginectomy was never performed primarily and in no instance was grafting of the vaginal tract necessary. The technique of vaginal closure as described by Welch and colleagues[5] was carried out to increase the vaginal depth when radical hysterectomy was done. The one patient who was originally classified as having a Stage IIIB carcinoma of the cervix, prior to staging celiotomy, was treated by total pelvic radiation followed by total abdominal hysterectomy and bilateral salpingo-oophorectomy.

Survival. One of the patients who was treated by radical hysterectomy and pelvic lymphadenectomy developed fatal postoperative hepatic necrosis which was thought to be related to the use of halothane.* The other seven patients are all living and well, from 1 to 7 years, with a mean of 41.1 months. Two of the survivors have lived over 5 years. The longest survivor had two tumor-bearing nodes and received postoperative radiation.

One patient developed a limited focus of recurrence in the upper vagina 6 months following radical surgery, which was discovered on colposcopically directed biopsy. This was followed by resection of the upper half of the vagina and replacement of the area by a split-thickness skin graft. There has been no evidence of further recurrence in this patient 3 years after resection.

Associated DES changes. An evaluation of the associated DES changes found in these patients with clear cell adenocarcinoma of the cervix or vagina shows that all of the seven patients who were initially examined had evidence of adenosis on gross or colposcopic examination. In all seven, the gross lesions were also obvious. In addition, four had a partial or complete cervical collar, one had a "cock's comb," and one had a pseudopolyp of the cervix. The patient who had Stage IIIB disease could not be properly examined and therefore is not included in this evaluation.

In reviewing the DES background of the mothers of the patients with clear cell adenocarcinoma, there was a definite maternal DES history in six of the eight patients. In one there was a questionable history and in another no history of any type of medication could be ascertained. Only three of the eight mothers had a history of bleeding during pregnancy.

Comment

The 30% response to the questionnaire sent to the physician population was disappointing. The nature of

the questions might have been interpreted by some to be threatening, since the maternal ingestion of DES and its subsequent association with adenocarcinoma of the vagina have resulted in a significant number of lawsuits. Although physicians are apparently not legally culpable for possible DES-induced sequelae a pointed inquiry as to the physicians' use of DES to preserve pregnancy may have discouraged a significant number of physicians from answering this question.

Another interesting finding was the fact that those physicians who used DES over half (51.1%) did not wish any assistance in reviewing their records. It is presumed that patient privacy was the primary reason for this response. It had been expected that such a tedious task as review of patient charts would have prompted a more positive response, especially since the review would have been performed by professional personnel. A review of the charts of those six physicians who used DES and desired our assistance in review of their charts located 563 young women exposed to DES in utero. An interesting question that will remain unanswered is whether our letter and questionnaire served to stimulate some physicians to review their own records. Since 31.9% of the physicians either had screened, were screening, or planned to screen their own records it can be presumed that this questionnaire was a positive force in this direction. Subsequent review of the records of 563 DES-exposed female subjects seen in our clinic has shown that 51.8% of the patients were sent to us by physicians.

The total number of structural abnormalities of the cervix and vagina (61.7%) was consistent with the findings of other investigators but our estimate of the presence of vaginal adenosis was greater than that first described by Sandberg[6] (43%) in a normal population and by Herbst and associates[2] in their initial report (33%) and similar to the findings of Burke and associates[7] (64% ± 5%).

These results, which are similar to those of other authors (Ng,[8] Burke and associates,[7] and Robboy and colleagues,[9] and Bibbo and co-workers[10]) show a much lower incidence of significant dysplastic squamous changes (1.1%) than that of earlier reports, which predicted a significant degree of squamous neoplasia (Fetherston[11] and Mattingly and Stafl[12]). The subjective element of these earlier, more alarming reports is evident. These data are also consistent with those of Burke and associates in emphasizing the lack of correlation between colposcopic abnormalities of the vaginal mucosa and the eventual histologic interpretation. White epithelium, punctation, and mosaic patterns are unreliable indicators of abnormal epithelial growth when found in the vaginal mucosa of the DES offspring.

The experience with clear cell adenocarcinoma and DES exposure in utero is consistent with the report by Herbst and Cole[13] of 333 young women with clear cell adenocarcinoma. An interesting finding is the higher incidence of carcinoma of the cervix in our patients, with only one being strictly vaginal. A total of 59.7% of the cases of clear cell adenocarcinoma reported to the Registry for Research on Hormonal Transplacental Carcinogenesis were confined to the vagina. The relatively short duration from the onset of symptoms to diagnosis is also striking since two of the patients had no symptoms and the cancer was discovered on routine examination because of DES exposure and since two had only increased nonbloody vaginal discharge. The value of screening of the DES-exposed population is reaffirmed.

Two of the patients were found to have pelvic lymph nodes involved with tumor, and postoperative radiation therapy was given to each patient. At present all seven of the patients who survived the operation are living and free of disease.

Each patient who had clear cell adenocarcinoma also had associated adenosis. The relation of these lesions suggests that the misplaced müllerian epithelium may have, because of its abnormal anatomic location, a tendency for malignant change. It does not, however, explain the development of clear cell adenocarcinoma in the cervix, where glandular epithelium is a normal component.

Quality of life for the gynecologic oncology patient

MICHAEL NEWTON, M.D.
Chicago, Illinois

An attempt is made to define the quality of life in terms of the patient with gynecologic cancer. The effect of the diagnosis of cancer and its recurrence or its terminal state on the quality of life is considered. Possible methods of assessing the patient's individual feelings about the quality of her life are reviewed and suggestions made for incorporating these into plans of management at all stages of the disease. (AM. J. OBSTET. GYNECOL. 134:866, 1979.)

"QUALITY OF LIFE" is an intriguing and puzzling term. It is mentioned frequently in connection with gynecologic oncology patients, but if I asked for a definition of it I might get as many answers as there are people in the audience. This widespread use of the phrase without precise agreement on its meaning reminds me of what Dr. Dale Coman, Professor of Pathology at the University of Pennsylvania School of Medicine, told me many years ago. He said that if you want a subject for research you should take a generally accepted statement from a standard textbook and try to find out if it is true. Very often you will discover that it is only an opinion and is not supported by good data. The purpose of this paper, then, is to define what "quality of life" means, how it is affected by gynecologic cancer and its therapy, and how it may be included in the overall plans for patient care.

The life whose quality we are considering is composed of certain basic components (Table I). Body functions include the essentials of eating, excreting, activity, sexuality, and the presence or absence of pain. The worst thing that can happen to some people is to have one or another of these functions go wrong. For example, even the relatively minor nausea and vomiting which occasionally accompany the use of melphalan after operation in advanced cancer of the ovary may be almost intolerable to one woman. On the other hand, the severe vomiting which is often associated with the use of cis-platinum in the same condition may be acceptable to another.

From the Department of Obstetrics and Gynecology, Northwestern University Medical School.

Presented as Guest Speaker at the Forty-first Annual Meeting of the South Atlantic Association of Obstetricians and Gynecologists, Hot Springs, Virginia, January 28-31, 1979.

Reprint requests: Dr. Michael Newton, 333 E. Superior, Suite 482, Chicago, Illinois 60611.

The ability to work, to earn money, and to be active outside the home is extremely important. Absence from work is one of the worst things that can happen to some women. Another woman may regard it as an opportunity to do something she had always wanted. Staying at home may be a disaster for one but a boon for another.

Family relationships, whether with a husband, son, daughter, or other relative, can be the most important thing in a woman's life. Another woman may not be so concerned about closeness to her family members. Such family ties may not always be loving ones. Some years ago a middle-aged man brought his wife into the hospital. She had had an exploratory laparotomy at another hospital for Stage III carcinoma of the ovary and had then been treated by abdominal radiation therapy. On admission she appeared to have extensive and almost terminal recurrent disease. It was clear, however, even from her few words, that she and her husband had a relationship in which she was the dominant figure and he the submissive one. We gave her chemotherapy—we were using Thiotepa at the time—and much to our surprise she had a remarkable remission which persisted for 6 months. As soon as she began to recover, the argumentative dominant-submissive relationship between her and her husband became obvious to everyone on the floor. And our perceptive social worker remarked that for this patient, perhaps, one part of the quality of her life lay in this antagonistic relationship.

The discovery of cancer or, indeed, of any serious disease adds a new and usually unpleasant dimension to an individual's concept of the good life. First, the symptoms of the disease itself, although often minor at the beginning, may affect various organs and functions. Kuebler-Ross[1] has pointed out that knowledge of approaching death results in a series of emotional responses—denial, anger, bargaining, depression, and

0002-9378/79/160866+04$00.40/0 © 1979 The C. V. Mosby Co.

resignation. Similar reactions occur when a diagnosis of cancer is first made, with possible substitution of the word "acceptance" for "resignation" (Table II).[2] These responses, it should be noted, do not necessarily occur consecutively or in the order listed. One may be predominant and more than one may occur at the same time. But whatever the reactions, they effect an underlying change in the individual's understanding of the quality of her life.

Primary treatment for cancer of the female genital tract alters function, activity, and family relationships in different but specific ways. The effect of surgical treatment depends on the type of cancer and the extent of the procedure. Relatively minor and temporary changes usually result from such procedures as a simple hysterectomy with or without removal of the ovaries or from local excision of a vulvar lesion. However, concern about unnecessary operations and about the possible ill-effects of removing the ovaries makes some women unduly apprehensive about oophorectomy even when it is done for cancer. Radical hysterectomy for Stage I cancer of the cervix is somewhat different. There are immediate changes in the urinary tract, consisting of bladder atony, and long-term changes in bladder sensation and micturition. Because of the shortness of the vagina there may be changes in the response to coitus, although the distensibility of that organ usually permits these to be surmounted. Radical vulvectomy as primary treatment for cancer of the vulva produces a major change in the sexual life of a woman particularly if sexual stimulation and activity has been largely confined to the pelvic area and the external genitalia. The notorious tendency of radical vulvectomy incisions to heal by secondary intention sometimes has the unexpected effect of making a woman dependent on her family for care when she had always cared for them in the past.

The effects of primary radiation therapy for cancer of the cervix or corpus uteri are often of a temporary nature. However, after the usual dose of external radiation many women note persistent changes in their intestinal tract, which alter food intake and bowel function. Years later they may say that there are certain foods that they cannot eat or that give them diarrhea. These effects are exaggerated if radiation is given to the para-aortic nodes or to the whole abdomen. Also, the shortening and stenosis of the upper vagina, primarily due to the internal application of radioactive sources, may adversely affect sexual relationships for the rest of a woman's life.

Until recently, chemotherapy has not been part of the primary treatment of gynecologic cancer. Now, however, single-drug chemotherapy, usually with an alkylating agent such as melphalan, is often employed after operation in all stages of ovarian cancer. Of more importance is multiple-drug chemotherapy. For example, such regimens as hexamethylmelamine, cyclophosphamide, methotrexate, and 5-fluorouracil[3] or doxorubicin and cyclophosphamide[4] have been used with considerable success and are being suggested as standard treatment after reductive surgery for carcinoma of the ovary, Stages III and IV. Chemotherapy affects the whole body and its side effects may involve many organ systems (Table III). It is easy to underestimate the cumulative impact of single-drug and especially multiple-drug chemotherapy on the whole patient.

Recurrent cancer places a much heavier burden on the patient's life. She may have disabling symptoms, and the knowledge that she still has disease despite her primary treatment recreates the denial, anger, bargaining, depression, and acceptance response. Also the treatment is likely to affect her more adversely. Secondary surgical treatment has typically been thought of as some type of exenteration. This results in a major change in the intestinal and urinary tracts and in the sexual apparatus. Recently, in persistent ovarian cancer, second-look procedures and operations for removal of bulky tumors or to relieve intestinal obstruction have been performed more frequently. All of these run the risk of affecting the patient's life by the formation of abdominal stomas such as colostomy, ileostomy, and mucous fistulas.

If radiation is given for recurrent gynecologic cancer, it is often localized treatment which may disturb the patient very little. One exception is radiation to the perineum, whether by internal or external therapy. This can have a long-term effect on urinary and bowel function, as well as a continuing skin reaction.

Chemotherapy is commonly used for recurrent ovarian carcinoma, now more frequently for carcinoma of the corpus uteri, and occasionally for carcinoma of the cervix and vulva. The effects of chemotherapy mentioned previously are more than ever applicable in recurrent cancer.

It seems hardly appropriate to use the words "quality of life" in relation to the management of the patient terminally ill from cancer for whom all curative treatment has been exhausted. This has led some to use phrases such as "dying with dignity." Yet that is hardly appropriate, since it is life, even though it is finite, and its quality that are in question. With diminishing functions and activity, the quality of the remaining life is set at a different level from what a healthy person expects. Recognizing that vital physiologic functions are deteriorating and that work and even activity become difficult and eventually impossible, the patient's pain, the comfort of her surroundings, and her family relationships become increasingly important.

It is evident that some assessment of what a woman regards as important in her life is desirable if she is to be wisely counseled in the treatment of gynecologic cancer. Unfortunately, there is no good instrument for doing this. Experienced clinicians may say that such an assessment is a matter of clinical judgment, and I am sure that this is often the case with a sensitive and intuitive physician. However, the management of the patient with gynecologic cancer is often shared between many people, so that an organized approach to assessment of an individual's feelings about the quality of her life is important. There are four ways in which this can be done (Table IV). For some years performance scales have been used to assess function in the cancer patient and to evaluate the effects of therapy. One variety of this is shown in Table V. However, even more important is an attempt to evaluate the patient's feelings in regard to the physiologic functions of eating, urinating, defecating, sleeping, and sex. For a busy clinician who is taking her history this may be accomplished by asking how any disorder of these functions has affected her in the past; if it appears to have greatly disturbed her, then that function is important to the quality of her life. A psychosocial history can be obtained as part of the general history, but it is even more helpful to have a social worker see all patients, because additional relevant data can often be obtained in this way (Table VI). The advantage of a patient care conference is that information on what the patient considers important to her life may come from a variety of different sources. For many years I have held weekly patient care conferences attended by nurses, social workers, dietitians, home care nursing personnel, and physicians from different services. On occasion, a hospital chaplain has been a valuable asset to the group. Finally, it is helpful to indicate in some way on the patient's record, as part of her management plan, areas of concern in maintaining the quality of her life as she perceives it. Such an evaluation and management plan may require revision on several occasions during the patient's course.

The significance of the patient's quality of life, as she and her attendants understand it, varies according to whether she is to receive treatment for primary, recurrent, or terminal disease. In each category, the extent of the disease and its symptoms are important and must be balanced with the proposed treatment in regard to the overall effects on the patient's life. Although each patient with gynecologic cancer is an individual with her own special situation and problems, some guidelines can be drawn up.

1. In primary treatment, unless the cancer is too far advanced, the benefits of treatment, i.e., the likelihood of cure, generally outweigh the possible effects on the quality of the patient's life. This does not mean that the patient's concerns should be ignored. The task of all the health team concerned with her care is to help her to accept the functional changes that necessary treatment brings.

2. Recurrent cancer often involves more difficult decisions in regard to treatment, decisions in which the quality of life for the patient becomes crucially important. For example, an exenteration for recurrent carcinoma of the cervix is much more difficult therapy for a patient who is alone and has no near relatives than for a woman with an accepting, supportive family. Also, second-line chemotherapy for ovarian carcinoma with its attendant intestinal symptoms, hair loss, and weakness may be unacceptable to the patient, in comparison with the uncertain benefits offered.

3. The care of the terminal cancer patient may require the hardest decisions. Two questions have come under much discussion in recent years—the use of ordinary or extraordinary means to maintain life and the appropriateness of cardiopulmonary resuscitation. Granted that the relief of pain and provision of comfort are essential, it is often difficult to determine whether a given medication or treatment is ordinary or extraordinary. One of the hardest problems in the hospital setting, at least for me, is the continued use of intravenous fluids. The possible prolonged use of intravenous hyperalimentation further complicates this issue. From a philosophic and ethical point of view I think the term "reasonable or unreasonable" is more helpful than "ordinary or extraordinary."[5] On the practical side, the introduction and spread in this country of the hospice concept may make the transition period between life and death easier for the cancer patient.[6] The question of resuscitation offers many legal snags. It is very sensitively handled from a nonlegal point of view in a recent *New England Journal of Medicine* Editorial by Spencer.[7] He points out that in this area, where legal issues are unclear, where neither the patient nor the family can make a fully informed and objective decision, the physician is in a position in which he has to use his best judgment in the interests of all involved and "in which there is no escape from making such decisions."

Ectopic pregnancy: Current clinical trends

JAMES D. KITCHIN III, M.D.
ROBERT M. WEIN, M.D.
WALLACE C. NUNLEY, JR., M.D.
SIVA THIAGARAJAH, M.B.B.S.(SRI LANKA)
W. NORMAN THORNTON, JR., M.D.
Charlottesville, Virginia

During the 16 year period ending in November, 1978, 191 cases of ectopic pregnancy were managed at the University of Virginia Hospital. The overall incidence was 1/126 deliveries but during the last 3 years of the study the incidence was 1/60 deliveries. Only 56 patients have had a subsequent conception. Thirteen have had a recurrent ectopic implantation. Only 36 women (23.7% of those available for follow-up) have had subsequent term pregnancies. Ectopic pregnancy continues to be a major gynecologic problem and the potential for subsequent fertility is poor.
(AM. J. OBSTET. GYNECOL. 134:870, 1979.)

THE DIAGNOSIS and managment of ectopic pregnancy continues to be a major problem in gynecology. The Committee on Maternal Health of the Medical Society of Virginia has determined that during the 8 year period from 1970 through 1977, 14 of the 31 maternal deaths (15.4%) attributable to maternal causes were related to complications of ectopic pregnancy. In addition, considerable evidence indicates that the incidence of this disorder may be increasing.[1-6] There is remarkable uniformity in the reported potential for successful subsequent pregnancy in these patients. The outlook is generally bleak in that less than half are likely to conceive again and only about one third can expect to produce a living child.[2, 4, 7-18]

In 1961, Thornton and associates[19] reviewed 89 cases of ectopic pregnancy managed at the University of Virginia Hospital. The purpose of this report is to present an additional 16 years' experience with this problem at the same institution and to review some of the current clinical trends with particular emphasis on available evidence regarding subsequent fertility.

Material and methods

Between July 1, 1962, and November 1, 1978, there were 23,987 deliveries at the University of Virginia Hospital. During this period, 191 ectopic pregnancies were treated in 178 women, an incidence of 0.80% or 1/126 deliveries. However, during the most recent 10 years of this study, the incidence has increased to 1.12% or 1 per 90 deliveries, and since 1975 there has been one ectopic pregnancy for every 60 deliveries (1.69%).

An intrauterine contraceptive device (IUD) was in place at the time of ectopic implantation in 20 cases (10.5%).

In 36 cases there had been no previous pregnancies and in 48 there had been only one prior pregnancy. However, in 107 (56%) pregnancy had occurred two or more times before (Table I). Among the IUD wearers, 75% had more than 1 prior pregnancy.

The majority of information included in this report was obtained from retrospective analysis of hospital records, operating room records, and pathology files. Of the 178 patients under consideration recent documentation of their subsequent medical history was available in 123. In an effort to extend the follow-up in the others, a questionnaire primarily directed toward establishing subsequent fertility was sent to 55 women. Twenty-six of these were not returned. Thus, adequate follow-up is limited to 152 patients.

Results

Menstrual history (Table II). In most cases (53.4%) patients described a normal menstrual period 4 to 8 weeks prior to admission. However, in 20.4% (including 30% of those wearing an IUD) there was no history of a missed period. In 60 (31.4%) cases there was no vaginal bleeding or "spotting" since the most recent

From the Department of Obstetrics and Gynecology, University of Virginia School of Medicine.

Presented at the Forty-first Annual Meeting of the South Atlantic Association of Obstetricians and Gynecologists, Hot Springs, Virginia, January 28-31, 1979.

period and there was no difference in the incidence of this symptom among the IUD users.

Pain. Lower abdominal or pelvic pain was present in 189 cases and in 84 (44%) was less than 24 hours in duration. In 55 cases (28.8%) pain had been present for 1 to 7 days, and in 50 (26.2%) pain had existed for more than 1 week. The IUD group did not differ from the other patients with regard to either the incidence of pain or its duration.

Physical findings (Table III). Adnexal tenderness was present in 180 cases (94.2%), and in 71 cases it was bilateral. A palpable adnexal mass was present in less than half of cases (43%) and in 16 of 82 (19.5%) was noted on the side opposite to that of the gestation. A palpable mass was slightly more common in the IUD group. An enlarged uterus was infrequent in both groups. Clinical shock, present in 33 cases (17.3%) overall, was twice as common in the IUD group (30%). None of the IUD patients presented with fever. Culdocentesis was performed in 42 cases and yielded nonclotting blood in all but three.

Laboratory tests. Preoperative hematocrits ranged from 15% to greater than 40% and correlated poorly with clinical shock. Of those patients with initial hematocrits less than 26%, 10 of 26 (38.5%) were in shock, but seven of 75 women (9.3%) with hematocrits greater than 35% were in clinical shock as well. Erythrocyte sedimentation rate and leukocyte counts were variable and of no diagnostic value. Pregnancy tests were performed in 70 cases and were positive in 50. Cervical mucus was examined in relatively few patients but showed ferning in 80%.

Operative findings. The anatomic distribution of the ectopic implantations is detailed in Table IV. There were three ovarian pregnancies in this series (all in IUD users) for an incidence of 1 in 63.7 ectopic pregnancies, or 1 in 6.7 ectopic pregnancies in women with an IUD.

The location of the corpus luteum was recorded in 84 of the 191 cases and was noted to be on the same side as the ectopic implantation in 57 and on the opposite side in 27. The corpus luteum was ipsilateral to the pregnancy in all nine cases in IUD users in whom this observation was made.

Twenty-eight patients had anatomic changes consistent with prior inflammatory disease in both the affected and contralateral fallopian tube.

Operative procedure. Immediate celiotomy was performed in 153 cases. Diagnostic laparoscopy preceded celiotomy in 27 cases and in another 11 cases diagnostic posterior colpotomy preceded celiotomy. Salpingectomy was performed in all cases of tubal implantation except one in which the products of conception were "stripped out." (This patient had a subsequent ectopic pregnancy in the same tube 3 months later.) Two of the ovarian pregnancies were managed by oophorectomy and one by partial oophorectomy.

Course in hospital. One patient had a wound dehiscence, and two had febrile complications associated with coexistent pelvic inflammatory disease. The latter were the only two patients in this series with significant postoperative febrile morbidity.

There was one postoperative death. A 35-year-old multiparous woman was admitted with a mistaken diagnosis of incomplete abortion. Curettage was performed and she was discharged the next day. Four days later she returned with a ruptured ampullary ectopic pregnancy. Postoperatively, she developed pulmonary edema, congestive heart failure, and arrhythmia and died a few hours later. The cause of death was thought

Recurrent ectopic pregnancy	13	8.6
Abortion	7	4.6
Lost to follow-up	26	—

*Four patients are included in two categories: One had therapeutic abortion followed by term pregnancy; two had a term pregnancy and a subsequent ectopic pregnancy; one had a spontaneous abortion followed by a term pregnancy with twins.

†Based on 152 patients available for follow-up.

‡These 36 women had 45 pregnancies including one set of twins.

to be related to aspiration. The pathology report from the curettage revealed only decidua.

Blood transfusions were not required in 73 cases (38.2%) including 11 of 20 (55%) in IUD wearers. One hundred twelve patients were given 1 to 6 U of blood and six others required more.

Subsequent fertility. The duration of follow-up is relatively short in 44 patients (2 years or less). Of 152 women available for review 65.8% have failed to achieve a subsequent pregnancy and in 27% there is no apparent reason.

In 56 cases (36.8% of those available to follow-up) there has been a subsequent conception, but only 36 (64.3% of those conceiving) have carried pregnancies to term. Ectopic pregnancy has recurred in 13 women (23.7% of those conceiving) and all of these have been subsequently infertile as a result of the second operative procedure.

Of the 43 patients who have not achieved a subsequent pregnancy (and who have not been sterilized or used contraception) one is now postmenopausal and two have died (one postoperatively and one of an unrelated illness). Forty remain involuntarily infertile.

Only five of the 36 women who were nulliparous at the time of the initial ectopic surgery have experienced a later term pregnancy (13.9%).

Comment

Although the overall incidence of ectopic pregnancy in this report (1/126 deliveries) is comparable to that in the earlier series from this clinic (1/149 deliveries), the trend in the most recent 3 years is markedly different (1/60 deliveries). It is possible that the increase in incidence may be, in part, apparent rather than real and related to a decrease in the number of normal term deliveries with no concomitant decrease in patients admitted for gynecologic emergencies. It has been suggested by one group that factors which may have been expected to increase the incidence of ectopic pregnancy in recent years include an increased incidence of gonorrhea as well as various family planning methods which reduce intrauterine pregnancy more effectively than ectopic pregnancy (induced abortion, IUDs, tubal sterilization). However, the same authors[17] cited a stable incidence of ectopic pregnancy in their clinic since 1950 (1 per 123 deliveries). A detailed epidemiologic study from England and Wales[1] indicates an increasing incidence in the late 1950's and a sharp increase since 1970. It is obvious that the incidence will vary with the population group under study, but the weight of the evidence appears to indicate an increase and in no case has any author presented evidence for a decrease.

The clinical features of the patients in this report with regard to demographic data, symptoms, and physical findings are not notably different from those described earlier by Thornton and associates and are consistent with generally accepted information.[17] Lower abdominal or pelvic pain is by far the most frequent symptom. Although almost half reported acute pain of less than 1 day's duration, a significant number (26.2%) had pain for more than a week, an observation which may reflect a persistent low index of suspicion for this disorder. Similarly the menstrual pattern was variable, with 20.4% of women reporting no abnormal menstrual history at all. The more common incidence of "normal" menstrual histories in IUD wearers may be

attributable in part to the tendency of such patients to consider vaginal bleeding and pelvic pain as "normal" side effects of the IUD and to the fact that some of these patients sought interruption of pregnancy before symptoms of ectopic gestation developed.

Adnexal tenderness and signs of peritoneal irritation were the most common physical findings. Although an adnexal mass was detected in 43% of cases, it was on the side opposite to that of the gestation in 19.5%, a finding consistent with that in our earlier series. This observation may be related to coincident pelvic inflammatory changes, accumulation of blood and clot in the pelvis, or palpation of a contralateral corpus luteum. The latter was present in 32% of patients in whom the location of the corpus luteum was noted and has been reported in 15% to 50% of cases in other reports.[18]

Accurate diagnosis and prompt management of ectopic pregnancy depend on clinical suspicion and careful assessment of symptoms and physical findings. Laboratory tests are of negligible value in diagnosis. Information obtained from diagnostic maneuvers such as culdocentesis and diagnostic ultrasound should be interpreted within the context of careful clinical assessment and must not be allowed to delay operative intervention if clinical suspicion exists. Diagnostic laparoscopy may be useful but is contraindicated if obvious clinical evidence of an abdominal emergency exists.

An association between ectopic pregnancy and the use of IUDs was recognized by Gräfenberg in 1929. A detailed analysis of this correlation by Lehfeldt and associates[6] in 1970 suggested that 4.3% of accidental pregnancies occurring in IUD users are likely to be ectopic and that one ectopic pregnancy will occur per 1,000 IUD users per year. It was further concluded that an IUD reduces uterine implantation far more effectively than it reduces either tubal or ovarian implantation. They and others[5, 18] point out that the IUD is probably not causal but is simply not protective against ectopic implantation in predisposed patients. Barron and associates[20] concluded that the overall incidence of ectopic pregnancy may be slightly lower in women using the IUD but that the relative risk in those women who conceive is (using Lehfeldt's data) increased 2.5-fold to ten-fold. Although this association is generally regarded as evidence of a mode of action of the IUD,[6, 18, 21] Weekes and Sutherst[22] pointed out that the relationship of the IUD and ectopic pregnancy may be indirect, in that IUD users are at increased risk of pelvic inflammatory disease. Soderstrom[23] has presented data indicating that 47% of women using the IUD who undergo laparoscopic sterilization have visual evidence of "salpingitis" (although cultures may be sterile).

Regardless of the exact role of the IUD, it is apparent that patients using the device are at risk and if pregnancy occurs it will be ectopic in 1 of 23 cases.[6] Thus a high index of suspicion is required especially in view of the frequency of lower abdominal pain and abnormal bleeding in these women. Seward and associates[24] have succinctly summarized the appropriate management of IUD wearers when pregnancy is confirmed. If the pregnancy is to be allowed to continue, careful examination and removal of the IUD are done, warning given regarding symptoms of ectopic pregnancy, and close follow-up provided until the pregnancy is established to be intrauterine. If therapeutic abortion is requested (or spontaneous abortion ensues), examination with anesthesia, culdocentesis, and careful examination of the tissue obtained from the uterus are recommended. We believe that frozen-section examination of curettage specimens is advisable in these cases. In the present series five patients (including the one maternal death) were found to have an ectopic pregnancy after an initial diagnosis of either spontaneous or induced abortion.

The occurrence of three ovarian pregnancies among the IUD group in this series (15%) is consistent with that of other reports.[21] This is presumably related to the relative ineffectiveness of the device in preventing ovarian implantation as compared with both tubal and intrauterine implantation.[6] Coustan and colleagues[25] suggested that diagnostic laparoscopy may be misleading in cases of suspected ectopic gestation if ovarian pregnancy is not seriously considered, as the superficial appearance may resemble that of an ovarian cyst.

Women who have experienced an ectopic pregnancy have a higher subsequent incidence of persistent infertility, recurrent ectopic pregnancy, and pregnancy wastage. Swolin and Fall[4] reviewed the literature in 1972 and found that 38% to 70% of patients were infertile after surgery, 25% to 69% had a subsequent normal intrauterine pregnancy, and recurrent ectopic pregnancy occurred in 4% to 25%. These figures will obviously be influenced by differences in the population under study, desire for subsequent pregnancy, coexistent pelvic disease, type of operation performed, other fertility factors, and duration of follow-up. Regardless of such differences the fact remains that no more than half are likely to conceive again, only one third will have a successful term pregnancy, and the risk of another ectopic gestation is increased thirtyfold to fiftyfold.[2-4, 7-10, 11-13, 14-15, 18] The results of the current study are in accordance with these rather discouraging observations and there is little evidence in

the recent literature to suggest any improvement in he outlook for future fertility.

Jeffcoate's[26] proposal in 1955 that concomitant ipsilateral oophorectomy be considered in women subjected to salpingectomy in order that the remaining tube be provided with as many ova as possible has been both supported[9] and refuted.[7, 10, 16] Available evidence does not clearly establish an advantage in removing a normal ovary and it appears that preservation of such ovaries is indicated in these women who already have low fertility potential.

The current availability of improved techniques for tubal reconstructive surgery may provide better opportunities for successful subsequent fertility in the future. Timonen and Nieminen[8] found similar rates of successful pregnancy after radical (anything more than tubal reconstruction) and conservative surgery but the recurrence rate of ectopic pregnancy was greater in the conservatively treated group. Others[16] have found no difference. Despite the clear risk of recurrent ectopic pregnancy it must be re-emphasized that successful pregnancies do occur in about one third of women and that this is a highly significant proportion when it is recognized that many have not had a prior successful gestation. We should be realistic about the prospects for future pregnancy but is is possible that too many salvageable tubes are sacrificed because of defeatism and unwillingness to assume reasonable risks. Bender[9] suggested that the uninvolved tube should be carefully inspected before the affected tube is excised so that salpingotomy may be considered if the uninvolved tube is rudimentary or hopelessly damaged. He and others[10, 12] stressed the importance of removing clot and blood (in an effort to decrease the incidence of adhesions and infection) as well as the use of prophylactic antibiotics. McElin and Iffy[18] in a recent detailed review presented cogent arguments in favor of such measures and further recommended that intraoperative hydrotubation as well as immediate postoperative hysterosalpingography be considered. They concluded that any reasonable management concept which might enhance future fertility is desirable.

The current clinical trends in ectopic pregnancy are depressingly similar to those of earlier reports. Women still die of this disease and despite the availability of appropriate antibiotic treatment for one of its major recognized predisposing conditions (pelvic inflammatory disease) the incidence is apparently not decreasing. A high index of suspicion is necessary, especially in women with prior pelvic infections or ectopic pregnancies, those wearing an IUD, and those with histories of primary infertility. An understanding of the implications regarding future fertility should be provided to the patient. Serious consideration should be given to management methods that may offer better potential for future reproduction. Aggressive extirpative surgery may not be required in all cases and skilled application of the principles of tubal reconstructive surgery may offer a brighter fertility future to selected women.

Discussion

DR. LOUIS KEFFER (Official Guest), Newport News, Virginia. It is refreshing to hear a paper dealing with a problem that all of us face in our day-to-day practice. Extrauterine pregnancy not only is not declining in frequency, as many medical problems are, but is actually on the increase, when expressed as a ratio of ectopic pregnancies per delivery. In the authors' series, over a 16 year period, the incidence was one ectopic pregnancy for each 126 deliveries. In the more recent years of the series it has been 1 in 60. The incidence in my hospital is presently 1 in 80. When Dr. Ware wrote a paper on this subject approximately 30 years ago, the figure was 1 in 300.

The increased incidence, at least as related to one factor, the IUD, may be more apparent than real. The relatively large number of ectopic pregnancies among IUD users, due to selective suppression of intrauterine but not extrauterine pregnancies, introduces an interesting concept. This same selectivity is true in regard to elective abortions.

The tremendous increase in gonococcal infections, particularly in teenagers, has produced and undoubtedly will produce a very real rise in the number of ectopic pregnancies.

In the authors' series 20.4% of the patients reported no missed menstrual periods. Perhaps it is more to the point that 68.6% did report missed periods. It is possible that a very persistent history taker could raise that percentage even higher. Many patients who at first deny missed menses will later admit that the last one or two were not altogether normal.

Pain is virtually always the most prominent feature and nearly always the symptom that first causes the patient to seek medical assistance. The laboratory is usually of little value in making a correct diagnosis. An exception is when the rupture is not so explosive and the blood loss not as sudden and massive as in the classical textbook example of ectopic pregnancy. In cases where the blood loss is gradual, serial hematocrit and hemoglobin determinations are of great value. Pregnancy tests may well be misleading. A positive test may occur with intrauterine pregnancy and hemoperitoneum due to a bleeding corpus luteum, and a negative test may be found in an ectopic pregnancy with a conceptus no longer living.

Invasive diagnostic techniques should be limited to those cases not easily diagnosed by history and physical findings. Laparoscopy is definitely preferable to culdocentesis. In the latter, both false positive and false negative findings are frequent. The laparoscope, however, not only confirms the presence of hemoperitoneum but usually identifies its source as well.

The prevalence of low fertility both before and after an ectopic pregnancy and the risk of a repeat extopic gestation has long been known and is well documented by the paper presented.

In a small series of 27 ectopic pregnancies, during 1978, at Riverside Hospital, 18, or 67%, had no or one previous delivery. The age distribution was predictable. Fifteen patients were between 20 and 24 years of age. Nine were between 25 and 30, and only three were between 31 and 40. Fifteen of the 27 patients required no transfusions and of those who did 11 patients needed 1 to 4 U. All of our patients reported missed or abnormal menses. Twenty-two (all but five) had missed only one or two menses. Three of the 27 were IUD users (11%). One had had a laparoscopic sterilization by cautery. One patient had endometriosis, and one had active gonorrhea, diagnosed by cervical culture

The authors' paper re-emphasized the importance of early diagnosis and prompt surgical intervention. It also reminds us of the importance of having a high degree of suspicion, particularly with women at risk, namely, those with a history of infertility, IUD use, pelvic inflammatory disease, and prior ectopic pregnancy. This paper also reminds us that although we will not be able to lower the incidence of ectopics gestation we can surely decrease the morbidity and mortality rates by diagnostic acumen and surgical skill.

DR. JAMES EDWIN CLEMENT, Greenville, North Carolina. Dr. Kitchin and his associates have again brought to our attention the importance of an entity which is not only protean but common enough to cause loss of sleep by all physicians who care for young women.

The clear-cut case of "ectopic" pregnancy still exists. In addition, Dr. Kitchin has pointed out the increased incidence of the problem in the "uncharacteristic" patient, who, as well, must be carefully scrutinized when she comes in with a history of pain, spotting, and a missed menstrual period, with a pelvic mass. The reported increased incidence of 1 in 60 pregnancies in the last three years at the University of Virginia should alert every physician who cares for women, because, as it has been pointed out, ectopic pregnancies still account for 50% of all maternally related maternal deaths in the United States, with less than 50% of those who survive ever conceiving again; of these, 23% will be ectopic pregnancies. Perhaps as important as any fact which he has brought to our attention, however, is the fact that in this study only five of 37 nulliparous patients ever became pregnant again.

The review of such a report from a university hospital allows one to review one's own situation and, hopefully, by review to improve upon patient care.

In looking over the statistics of our own community hospital for the years 1967 to 1977, we have found, in a hospital service of comparable size, that the occurrence rate has been 1:164 in the first five years of our review and 1:120 in the last six years. We have also noted a decrease in incidence to 1:187 in 1977. It is interesting to note that in our county, with a 46% black population, there was an almost equal distribution between the

races. The surgical approach at laparotomy was similar, with 55% having salpingectomy and 20% to 25% having elective bilateral tubal ligation. A similar number received transfusion (44% compared to 38% at the University of Virginia). Nontubal (ovarian, cornual, and abdominal) pregnancies occurred in three of 104 of the patients in our hospital, while at the University of Virginia one of 63 ectopic pregnancies was ovarian.

The difficulty in classical diagnosis has been compounded by the IUD-ectopic question. In the early years of observation of this entity, there undoubtedly existed the problem of disbelief that extrauterine (or intrauterine) pregnancy often occurred with an IUD. Surely the fact that 17% of the University of Virginia group with IUDs–ectopic pregnancies were in shock was due to this factor. In the early years of recognition of this problem (10 to 15 years ago), I kept a careful personal account of each patient with an IUD who developed an ectopic pregnancy and could account for practically each one from memory. But recently the occurrences have been commonplace. I agree with the report of Dr. Kitchin and colleagues that probably one of 23 pregnancies associated with an IUD is ectopic.

The use of pregnancy tests, which were done in 37% of the University of Virginia patients (and were positive in 50 of 70), has also many times clouded the picture and caused delay. Perhaps the newer, more refined evaluations of human chorionic gonadotropin will be more reliable and useful when they become more accessible and when more physicians use them.

Abdominal pain in young women, particularly in patients with pelvic inflamation, IUD's, and endometriosis, is very common and cannot often in itself be very helpful in diagnosis. All but two of the patients reported in the University of Virginia study had this symptom. In addition, as every gynecologist knows, a pelvic mass in a patient with an acute process is very hard and often impossible to palpate, particularly in young girls who are prime candidates for extrauterine gestation.

So I will make a plea for the early use of culdocentesis in all patients in whom the diagnosis of ectopic pregnancy is suspected. While it is true that diagnostic laparoscopy is helpful in patients with so-called "mild" ectopic pregnancy, as is ultrasound, a positive culdocentesis with a syringe full of nonclotting blood gives information which cannot be denied. It can be obtained in minutes and before the patient becomes involved in the hospital delay-mill. Certainly an unyielding tap is not informative. But every gynecologist (and especially those in training) should be prepared not only to perform it in every patient, not in shock, who has the characteristic pelvic-abdominal findings which make one suspect ectopic pregnancy.

Bilateral Paget's disease of the nipple: Case report

W. RICHARD ANDERSON, M.D.
St. Petersburg, Florida

Paget's disease of the breast accounts for 1% to 4.1% of all cancers; however, bilateral Paget's disease is extremely rare. A case of bilateral Paget's disease is presented and treatment is described. (AM. J. OBSTET. GYNECOL. 134:877, 1979.)

DIAGNOSIS OF LESIONS of the breast has become a major responsibility of the gynecologist. Although Paget's disease of the breast is not rare, accounting for 1% to 4.1% of all cancers, bilateral Paget's disease is extremely rare. In the literature of the past ten years I found no cases of bilateral Paget's disease. In a personal communication, Henry J. Norris, of the Air Force Institute of Pathology, confirmed the rarity of this disease. Lever[4] stated in *Histopathology of the Skin* that the lesion is always unilateral. This case is reported to remind the gynecologist of the clinical presentation of Paget's disease and to add to the literature a case of bilateral Paget's disease of the nipple.

Case presentation

A 53-year-old woman, gravida 2, para 2, was seen for her yearly physical examination; she had no complaints. On examination a scaly, pinkish lesion was found on both nipples of the breasts. With local analgesia and using a Keyes punch biopsy a small portion of the right nipple was taken. The impression was Paget's disease of the right nipple but since it appeared to be bilateral the pathologist requested a larger sample. A wedge of both nipples was taken following general anesthesia. Again, our pathologist felt that this was Paget's disease, but since it was bilateral he referred the slides to the Armed Forces Institute of Pathology, which confirmed the diagnosis of Paget's disease of the nipple. No masses could be palpated and xeromammography proved to be negative. Bilateral modified radical mastectomy was performed. A small focus of intraductal carcinoma was found deep within the left breast, but despite repeated serial sections of the right breast no further malignancy was observed. All nodes from both the right and left axilla were negative. The patient did well postoperatively and was free of obvious disease when last seen in September, 1978.

Comment

Paget's disease of the nipple occurs in middle-aged women. In a series of 159 cases reported by Kister and Haagensen,[2] the range in age was 26 to 81 with a mean age of 54. The lesion is characterized by an inflammatory response which has the appearance of chronic eczema. There is usually a sharply demarcated area around the nipple, involving all or part of the nipple and areola. The superficial epithelium may be denuded. It is moist and soft and may be covered with a crust or a scab. In 10% of cases there is no visible clinical lesion.

Differential diagnosis of Paget's disease of the nipple should include: (1) benign intraductal papillomas, which extend out onto the surface of the nipple; (2) benign dermatologic lesions; (3) secondary invasion of the nipple by carcinoma elsewhere. When benign intraductal papillomas are present there is a firm nodule which can be easily felt in the nipple, and there is oozing of serum and blood, not a true discharge. In benign dermatologic lesions the spread of the disease is usually rapid and involves not only the areola but the surrounding skin. In invasive cancer of the nipple the contour of the breast is usually destroyed.

In 50% of cases no palpable lesion is present. In patients with a palpable lesion two thirds will have positive axillary lymph nodes. One third of the patients without palpable lesions will have positive lymph nodes. There have been several reports of positive lymph nodes when no breast tumor was found in the surgical specimen.

Few cancers are so easily seen and give the opportunity for easy biopsy and diagnosis. Any lesion of the nipple should be biopsied prior to treatment. The delay in making the diagnosis many times is 15 to 18 months. With a high index of suspicion the diagnosis of

Paget's disease of the nipple can be made early and treatment instituted. Biopsy is the only way of establishing a diagnosis. Biopsy of the nipple can be done very simply as an office procedure with local anesthesia and a dermal Keye's punch biopsy.

Treatment of choice is modified radical mastectomy. Since there have been reports of positive nodes without a palpable lesion and without presence of a carcinoma deep within the breast, simple mastectomy is insufficient treatment. Kister and Haagensen[2] reported a 10 year survival rate of 79% with no axillary spread. There was a 29% survival rate in women with axillary spread. Other series gave similar cure rates.

Identical twins with twisted benign cystic teratoma of the ovary

ERNEST H. BROWN, JR., M.D.
Lumberton, North Carolina

THE TWO CASES reported here represent, for your consideration, some aspects of the diagnosis of complications of benign cystic teratoma of the ovary, the origin of benign cystic teratoma of the ovary, and the treatment thereof.

Case reports

Case 1. T. L., a 24-year-old, Lumbee Indian, nulliparous woman, presented with a 2 week history of lower abdominal pain. She had been treated elsewhere for pelvic inflammatory disease with antibiotics and no improvement. Surgery had been recommended for her "infection." When initially seen, she was afebrile. Physical findings were limited to the abdomen and pelvis. The abdomen was slightly protuberant with normal peristalsis and minimal spasm and guarding. There was some low abdominal tenderness without rebound. The uterus was of normal size. A left adnexal, irregular cystic mass extended from the anterior surface of the uterus to the left pelvic side wall. A right adnexal, exquisitely tender mass extended posteriorly to the uterus and into the cul-de-sac. Outpatient therapy of suspected pelvic inflammatory disease was continued with tetracycline. One week later, she was essentially asymptomatic and had been afebrile throughout the past week. Examination revealed the left adnexal mass to be mobile. The right mass was less tender but was fixed. One week subsequent to this, the left mass was interpreted as being completely mobile and cystic. Pelvic laparotomy for pelvic inflammatory disease or twisted ovarian cyst was performed on November 25, 1964, and revealed a twisted, infarcted, hemorrhagic, 12 cm, benign cystic teratoma of the right ovary. The left ovary was quite large and contained five separate benign cystic teratomas measuring from 1 to 8 cm in diameter. The right adnexa were removed, and multiple cystectomies were performed on the left ovary with preservation of ovarian tissue. In 1969, a 6 cm cystic teratoma of the ovary was removed. In 1971, at the time of elective repeat cesarean section, a 1.5 by 1.5 cm benign cystic teratoma of the ovary was removed, for a total of seven benign cystic teratomas of the left ovary. The patient continues to be examined at regular intervals and is completely asymptomatic.

Case 2. V. E., a 25-year-old twin sister of T. L., gravida 4, para 4. was seen in 1966, when she was acutely ill with a chief complaint of the sudden onset of rather severe, right–lower quadrant abdominal pain which was becoming progressively worse. Abdominal examination revealed low abdominal tenderness without rebound or referred tenderness. Bowel sounds were normal. The uterus was anterior, of normal size, and freely movable. There was some pain referable to the right lower quadrant upon manipulation, and there was a questionable "doughy" mass on the right. The left adnexa were not delineated. Antibiotics were administered. Twelve hours later, examination revealed a 6 to 8 cm cyst on the right ovary. An irregular mass was also palpated on the left ovary. Laparotomy revealed a 14 cm, twisted, infarcted, hemorrhagic, benign cystic teratoma of the right ovary. The left ovary was four times normal size with three benign cystic teratomas. The right adnexa were removed, and left ovarian cystectomies were performed with preservation of ovarian tissue.

Comment

Review of the literature failed to demonstrate the incidence of benign cystic teratomas in twins to be different than that in offspring of single births. The etiology of benign cystic teratomas, which is discussed below, lends only speculative reasons as to why they occur.

Benign cystic teratomas of the ovaries are the most common of all ovarian neoplasms, representing approximately 20% of all ovarian neoplasia.[1] Various authors[1, 2] have stated that from 12% to 25% occur bilaterally. Many neoplasms of the ovary are so small they are not recognized unless the ovary is bisected.

Today, the etiology of benign cystic teratomas remains speculative. One theory is that totipotent cells

(blastomeres) are segregated at an early state in the development of the morula. Such cells would be capable of forming derivatives of all three germinal cell layers. Why such cells concentrate in the ovary is difficult to explain.

A more widely accepted theory is that of parthenogenesis or asexual development. The spark that stimulates such imperfect development is unknown. The first case presented (Patient T. L.) promotes speculation of a continuing stimulus for such development.

The most common complication of benign cystic teratoma of the ovary is torsion, which may occur as often as 15% of the time.[3] The mechanism of torsion is unknown. Other complications include rupture of the benign cystic teratoma, malignant degeneration, and adherence to and erosion into the intestinal tract and bladder.[4]

Torsion of the ovarian pedicle pres
abdomen." The differential diagnosi
pelvic inflammatory disease, appe
schmerz, and other acute abdominal
cases demonstrate the difficulty in n
nosis at the outset of the castastroph
later date.

The treatment of benign cystic t
ovaries consists of resection of the neo
ian conservation. Adequate functioni
can and should be preserved. The co
should be inspected and generally
complications are encountered, they
separately.

ENDO LABORATORIES TAMES THE POPPY—
TO BRING YOU
new NUBAIN®
nalbuphine HCl
ANALGESIA COMPARABLE TO MORPHINE,
WITH IMPORTANT DIFFERENCES

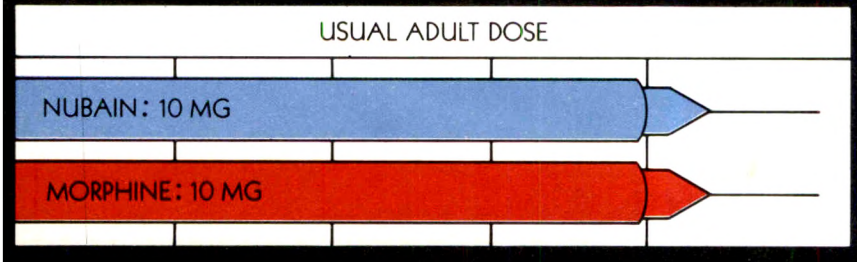
new

NUBAIN®

AMPULS AND VIAL

nalbuphine HCl

ANALGESIA COMPARABLE TO MORPHINE

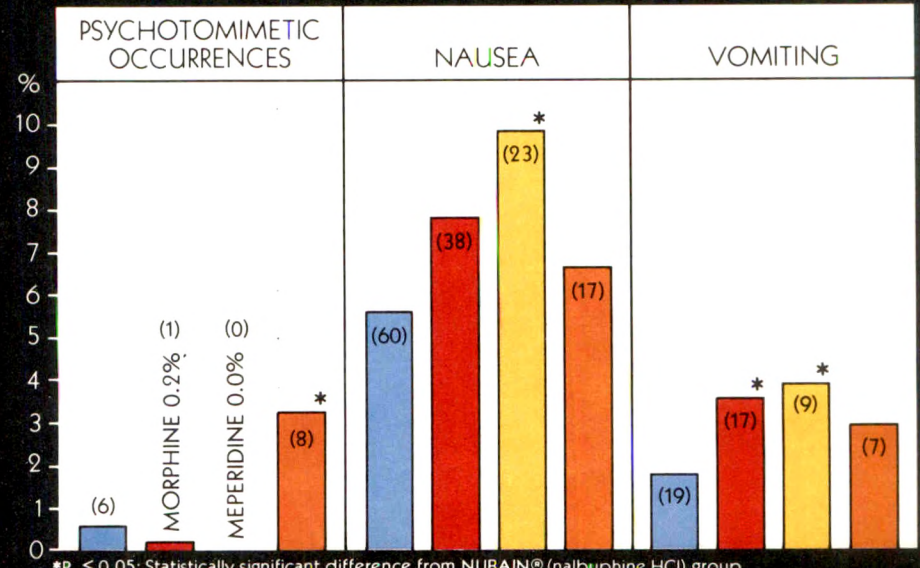


NUBAIN offers:
- Onset, peak and duration
- Comparable to morphine

10 mg of NUBAIN is comparable in analgesic effect to 10 mg of morphine

Onset of action with NUBAIN begins within 2 to 3 minutes I.V., and less than 15 minutes I.M. or S.C.

Analgesic effect of NUBAIN lasts from 3 to 6 hours



NUBAIN is an Endo registered U.S. trademark.

WITH A LOW INCIDENCE OF SIDE EFFECTS

Clinical studies show: low incidence of nausea, vomiting and psychotomimetic effects

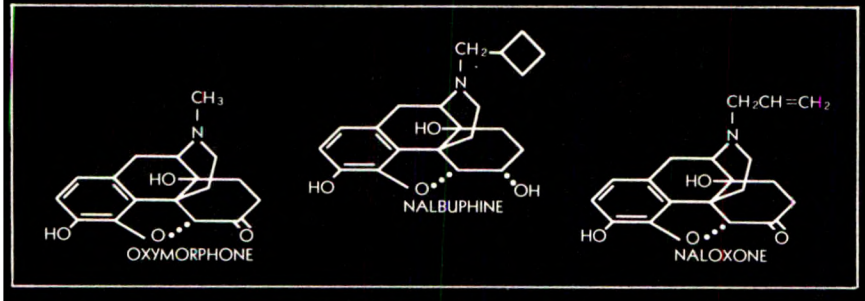
IN 27 SINGLE OR CROSS-OVER CLINICAL STUDIES (2,038 DRUG EVALUATIONS) THESE SIDE EFFECTS WERE OBSERVED:[1]

*P ≤ 0.05: Statistically significant difference from NUBAIN® (nalbuphine HCl) group.

Key
- NUBAIN (1,066 patients)
- MORPHINE (486 patients)
- MEPERIDINE (234 patients)
- TALWIN® (252 patients)

1. These clinical studies involved patients with pain from a variety of medical causes, including labor, cancer, and orthopedic and general surgical procedures. Actual number of patients experiencing each side effect is shown in parentheses on the bar

Endo DUPONT



new NUBAIN®
nalbuphine HCl

OFFERS LOW POTENTIAL FOR ABUSE

NUBAIN requires no special storage or additional paperwork beyond your normal order or prescription.

The unique properties of NUBAIN may be found in its molecular structure.

Certain substances, such as NARCAN® (naloxone HCl), counteract or antagonize the effects and side effects of potent narcotics, such as morphine or NUMORPHAN® (oxymorphone HCl). NUBAIN was designed to incorporate important molecular features of the antagonist NARCAN and the potent analgesic NUMORPHAN, resulting in a drug with strong analgesia but limited abuse potential.

And a lower respiratory effect

At dosages of 10 mg/70 kg, NUBAIN causes respiratory depression comparable to that of morphine. In contrast to morphine, higher doses of NUBAIN do not increase respiratory depression appreciably (see Precautions).

NARCAN is an Endo registered U.S. trademark.

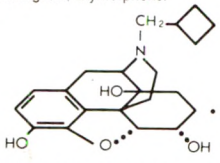
NUMORPHAN is an Endo registered U.S. trademark.

Please see complete prescribing information on last page of this advertisement.

A clinical summary:

27 investigations evaluated more than 1,000 medical and surgical patients in regard to the effect of NUBAIN upon acute or chronic pain. Among these studies are the following, which highlight important areas of analgesic use:

- ORTHOPEDICS—this study encompassed 52 patients and compared NUBAIN to meperidine. Treatment varied from 1 to 40 days. NUBAIN was found to deliver satisfactory analgesia with no overt evidence of physical tolerance.
- CANCER—this study encompassed 37 patients treated for 1 to 186 days. Many of the patients stabilized on I.M. NUBAIN received dosages every 6-8 hours.
- OBSTETRICS—four double-blind studies were conducted encompassing 159 patients in labor. I.M. NUBAIN was compared to I.M. meperidine. Analgesically, both drugs were deemed similar (10-15 mg NUBAIN equal to 75-113 mg meperidine). Neonates did equally well on both drugs, but there is a possibility that either drug can produce depressive effects in the fetus or neonate. Mothers treated with NUBAIN had fewer side effects, and hospital personnel liked NUBAIN.
- Please see full prescribing information, including a complete discussion of adverse reactions, on following page.



NUBAIN® (nalbuphine HCl)

Analgesia comparable to morphine, with important differences

new NUBAIN®
nalbuphine HCl

DESCRIPTION

NUBAIN (nalbuphine hydrochloride) is a synthetic narcotic agonist-antagonist analgesic of the phenanthrene series. It is chemically related to both the widely used narcotic antagonist, naloxone, and the potent narcotic analgesic, oxymorphone.

NALBUPHINE HYDROCHLORIDE

(-)-17-(cyclobutylmethyl)-4, 5α-epoxy-morphinan-3, 6α, 14-triol, hydrochloride • HCl

Each ml of the injectable aqueous solution of NUBAIN contains 10 mg of nalbuphine hydrochloride.

ACTIONS

NUBAIN is a potent analgesic. Its analgesic potency is essentially equivalent to that of morphine on a milligram basis.

Its onset of action occurs within 2 to 3 minutes after intravenous administration, and in less than 15 minutes following subcutaneous or intramuscular injection. The plasma half-life of nalbuphine is 5 hours and in clinical studies the duration of analgesic activity has been reported to range from 3 to 6 hours.

The narcotic antagonist activity of NUBAIN is one-fourth as potent as nalorphine and 10 times that of pentazocine.

INDICATIONS

For the relief of moderate to severe pain. NUBAIN can also be used for preoperative analgesia, as a supplement to surgical anesthesia, and for obstetrical analgesia during labor.

CONTRAINDICATIONS

NUBAIN should not be administered to patients who are hypersensitive to it.

WARNINGS

Drug Dependence NUBAIN has been shown to have a low abuse potential which is approximate to that of pentazocine. When compared with drugs which are not mixed agonist-antagonists, it has been reported that nalbuphine's potential for abuse would be less than that of codeine and propoxyphene. Psychological and physical dependence and tolerance may follow the abuse or misuse of nalbuphine. Therefore, caution should be observed in prescribing it for emotionally unstable patients, or for individuals with a history of narcotic abuse. Such patients should be closely supervised when long-term therapy is contemplated.

Care should be taken to avoid increases in dosage or frequency of administration which in susceptible individuals might result in physical dependence.

Abrupt discontinuation of NUBAIN following prolonged use has been followed by symptoms of narcotic withdrawal, i.e., abdominal cramps, nausea and vomiting, rhinorrhea, lacrimation, restlessness, anxiety, elevated temperature and piloerection.

Use in Ambulatory Patients NUBAIN may impair the mental or physical abilities required for the performance of potentially dangerous tasks such as driving a car or operating machinery. Therefore, NUBAIN should be administered with caution to ambulatory patients who should be warned to avoid such hazards.

Use in Emergency Procedures Maintain patient under observation until recovered from NUBAIN effects that would affect driving or other potentially dangerous tasks.

Use in Children Clinical experience to support administration to patients under 18 years is not available at present.

Use in Pregnancy (other than labor) Safe use of NUBAIN in pregnancy has not been established. Although animal reproductive studies have not revealed teratogenic or embryotoxic effects, nalbuphine should only be administered to pregnant women when, in the judgement of the physician, the potential benefits outweigh the possible hazards.

Use During Labor and Delivery NUBAIN can produce respiratory depression in the neonate. It should be used with caution in women delivering premature infants.

Head Injury and Increased Intracranial Pressure The possible respiratory depressant effects and the potential of potent analgesics to elevate cerebrospinal fluid pressure (resulting from vasodilation following CO_2 retention) may be markedly exaggerated in the presence of head injury, intracranial lesions or a pre-existing increase in intracranial pressure. Furthermore, potent analgesics can produce effects which may obscure the clinical course of patients with head injuries. Therefore, NUBAIN should be used in these circumstances only when essential, and then should be administered with extreme caution.

Interaction With Other Central Nervous System Depressants Although NUBAIN possesses narcotic antagonist activity, there is evidence that in nondependent patients it will not antagonize a narcotic analgesic administered just before, concurrently, or just after an injection of NUBAIN. Therefore, patients receiving a narcotic analgesic, general anesthetics, phenothiazines, or other tranquilizers, sedatives, hypnotics, or other CNS depressants (including alcohol) concomitantly with NUBAIN may exhibit an additive effect. When such combined therapy is contemplated, the dose of one or both agents should be reduced.

PRECAUTIONS

Impaired Respiration At the usual adult dose of 10 mg/70 kg, NUBAIN causes some respiratory depression approximately equal to that produced by equal doses of morphine. However, in contrast to morphine, respiratory depression is not appreciably increased with higher doses of NUBAIN. Respiratory depression induced by NUBAIN can be reversed by NARCAN® (naloxone hydrochloride) when indicated. NUBAIN should be administered with caution at low doses to patients with impaired respiration (e.g., from other medication, uremia, bronchial asthma, severe infection, cyanosis or respiratory obstructions).

Impaired Renal or Hepatic Function Because NUBAIN is metabolized in the liver and excreted by the kidneys, patients with renal or liver dysfunction may overreact to customary doses. Therefore, in these individuals, NUBAIN should be used with caution and administered in reduced amounts.

Myocardial Infarction As with all potent analgesics, NUBAIN should be used with caution in patients with myocardial infarction who have nausea or vomiting.

Biliary Tract Surgery As with all narcotic analgesics, NUBAIN should be used with caution in patients about to undergo surgery of the biliary tract since it may cause spasm of the sphincter of Oddi.

ADVERSE REACTIONS

The most frequent adverse reaction in 1066 patients treated with NUBAIN is sedation (381, 36%). Less frequent reactions are: sweaty/clammy (99, 9%), nausea/vomiting (68, 6%), dizziness/vertigo (58, 5%), dry mouth (44, 4%), and headache (27, 3%).

Other adverse reactions which may occur (reported incidence of 1% or less) are:

CNS Effects nervousness, depression, restlessness, crying, euphoria, floating, hostility, unusual dreams, confusion, faintness, hallucinations, dysphoria, feeling of heaviness, numbness, tingling, unreality. The incidence of psychotomimetic effects, such as unreality, depersonalization, delusions, dysphoria and hallucinations has been shown to be less than that which occurs with pentazocine.

Cardiovascular Hypertension, hypotension, bradycardia, tachycardia.

Gastrointestinal Cramps, dyspepsia, bitter taste.

Respiration Depression, dyspnea, asthma.

Dermatological Itching, burning, urticaria.

Miscellaneous Speech difficulty, urinary urgency, blurred vision, flushing and warmth.

DOSAGE AND ADMINISTRATION

The usual recommended adult dose is 10 mg for a 70 kg individual, administered subcutaneously, intramuscularly or intravenously; this dose may be repeated every 3 to 6 hours as necessary. Dosage should be adjusted according to the severity of the pain, physical status of the patient, and other medications which the patient may be receiving. (See Interaction with Other Central Nervous System Depressants under WARNINGS.) In non-tolerant individuals, the recommended single maximum dose is 20 mg, with a maximum total daily dose of 160 mg.

Patients Dependent on Narcotics Patients who have been taking narcotics chronically may experience withdrawal symptoms upon the administration of NUBAIN. If unduly troublesome, narcotic withdrawal symptoms can be controlled by the slow intravenous administration of small increments of morphine, until relief occurs. If the previous analgesic was morphine, meperidine, codeine, or other narcotic with similar duration of activity, one-fourth of the anticipated dose of NUBAIN can be administered initially and the patient observed for signs of withdrawal, i.e., abdominal cramps, nausea and vomiting, lacrimation, rhinorrhea, anxiety, restlessness, elevation of temperature or piloerection. If untoward symptoms do not occur, progressively larger doses may be tried at appropriate intervals until the desired level of analgesia is obtained with NUBAIN.

Management of Overdosage The immediate intravenous administration of NARCAN® (naloxone hydrochloride) is a specific antidote. Oxygen, intravenous fluids, vasopressors and other supportive measures should be used as indicated.

The administration of single doses of 72 mg of NUBAIN intramuscularly to eight normal subjects has been reported to have resulted primarily in symptoms of sleepiness and mild dysphoria.

HOW SUPPLIED

NUBAIN® (nalbuphine hydrochloride) injection for intramuscular, subcutaneous, or intravenous use (10 mg/ml) is available in:

NDC #0056-0385 10 mg/ml, 1 ml ampuls (box of 10)
NDC #0056-0384 10 mg/ml, 2 ml ampuls (box of 10)
NDC #0056-0386 10 mg/ml, 10 ml vials

Each ml contains 10 mg nalbuphine hydrochloride, 0.1% sodium chloride, 0.94% sodium citrate, 1.26% citric acid anhydrous, 0.1% sodium metabisulfite, and 0.2% of a 9:1 mixture of methylparaben and propylparaben as preservative; pH is adjusted with hydrochloric acid.

Bicornuate uterus and partial atresia of the fallopian tube

MARTIN FARBER, M.D.
GEORGE W. MITCHELL, JR., M.D.
Boston, Massachusetts

Partial atresia of the fallopian tube was discovered in two patients with double uteri of the bicornuate variety. The abnormal tube in each case was ipsilateral to a noncommunicating, nonfunctioning, rudimentary uterine horn. A normal fimbriated end led to a short, patent ampullary portion that ended blindly in the mesosalpinx. Realization of the potential for the coexistence of congenital malformation of the fallopian tubes with various uterine malformations suggests that extreme caution be exercised during adnexal surgery in patients with anomalous development of the müllerian ducts. (AM. J. OBSTET. GYNECOL. 134:881, 1979.)

THE EMBRYOLOGIC EVENTS that result in the normal development of the fallopian tubes, uterus, cervix, and vagina in the woman are subtle and complex; although the past 50 years have yielded numerous descriptive treatises[1–3] no one is universally accepted.[4] The potential for varieties of malformations of the genital ducts is infinite but experientially certain patterns have emerged to permit their classification and to facilitate their diagnosis. Congenital anomalies of the müllerian (paramesonephric) ducts may be functionally categorized in those patients who present with: (1) amenorrhea, (2) amenorrhea and cryptomenorrhea, (3) cryptomenorrhea and menstrual egress per vagina, or (4) reproductive failure.[5] Alternatively these anomalies may be etiologically classified as those due to (1) complete unilateral failure of müllerian duct development, (2) partial unilateral or bilateral müllerian duct failure, or (3) failure of fusion of the müllerian ducts.[6] Often several etiologies must be invoked to explain a single functional result.

Anomalies of the paramesonephric ducts have been estimated to occur in 1/500 to 1/2,000 women.[7] Those resulting from unilateral partial müllerian duct maldevelopment or unilateral partial maldevelopment together with failure of fusion of the ducts are very unusual. Exemplary of the former are isolated reports of anomalous fallopian tube development. Unilateral duplication of the tube[8] and unilateral tubal ectopia have each been reported once.[9] In the case report of unilateral ovarian and fallopian tube absence with a stone in the cul-de-sac, it was concluded that the process was secondary to adnexal torsion and infarction.[10]

Bicornuate uterus with a noncommunicating rudimentary uterine horn exemplifies the latter type of maldevelopment. The rudimentary horn is almost always lined by functional endometrium and is in continuity with a patent fallopian tube. The diagnosis is usually made during pregnancy,[11] most commonly when the pregnant noncommunicating rudimentary horn ruptures with catastrophic intraperitoneal hemorrhage.[12] It may lead to a missed abortion[13] or be discovered at the time of resection of a chronic abdominal pregnancy.[14] Recently it was found by serendipity at the time of cesarean section which led to the delivery of a live fetus.[15] A high index of suspicion resulted in resection of the pregnant noncommunicating uterine horn in three cases prior to rupture.[16] Although it is an unusual cause of dysmenorrhea, the correct preoperative diagnosis will be inferred when hysterosalpingography demonstrates a unicornuate uterus contralateral to a significant pelvic mass.[17]

Only five cases have been reported of bicornuate uterus with a noncommunicating, rudimentary, noncanalized, functionless uterine horn associated with ipsilateral partial fallopian tube atresia.[18] Two additional

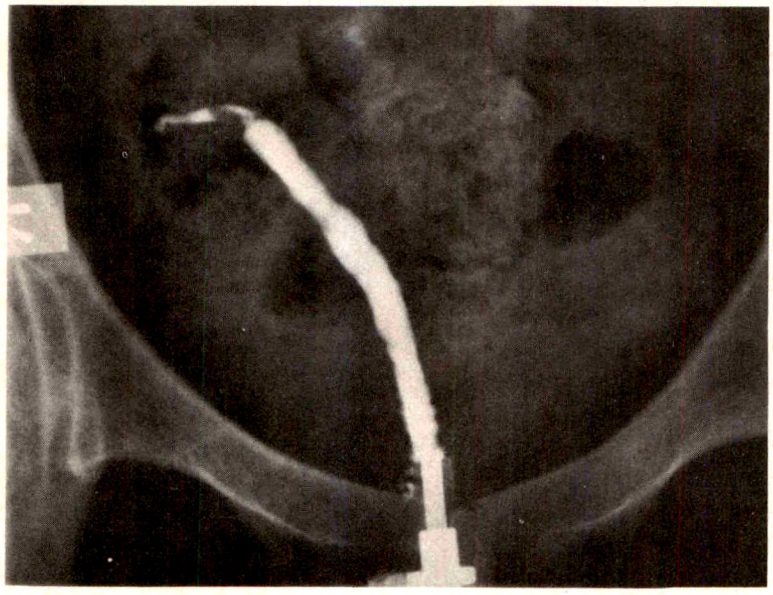

Fig. 1. Hysterosalpingogram demonstrating a right unicornuate uterus with an occluded tubal stump.

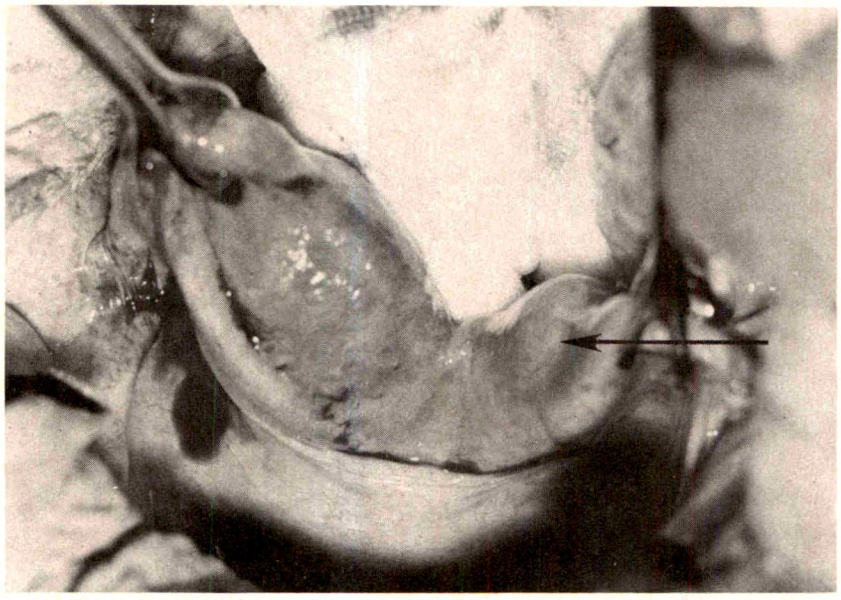

Fig. 2. Bicornuate uterus with a rudimentary left uterine horn (arrow).

cases are presented to effect an increased awareness of this anomaly and thus lead to intelligent clinical management.

Case reports

Case 1. A 23-year-old nulligravida woman who had undergone right salpingectomy and paraovarian cystectomy at age 18 was referred to the Division of Reproductive Endocrinology for primary infertility. At the time of initial laparotomy a bicornuate uterus was found with "bilaterally normally formed fallopian tubes." A hysterosalpingogram revealed a right unicornuate uterus with an occluded right tubal stump (Fig. 1). Hysteroscopy confirmed a lack of communication between the uterine horns. An intravenous pyelogram was normal.

Exploratory laparotomy revealed a bicornuate uterus but the left horn was rudimentary, measuring 3 cm in diameter (Fig. 2). It was situated in the folds of the left broad ligament, had no communication with the larger right horn, and was attached to the round ligament which exited through the internal inguinal ring.

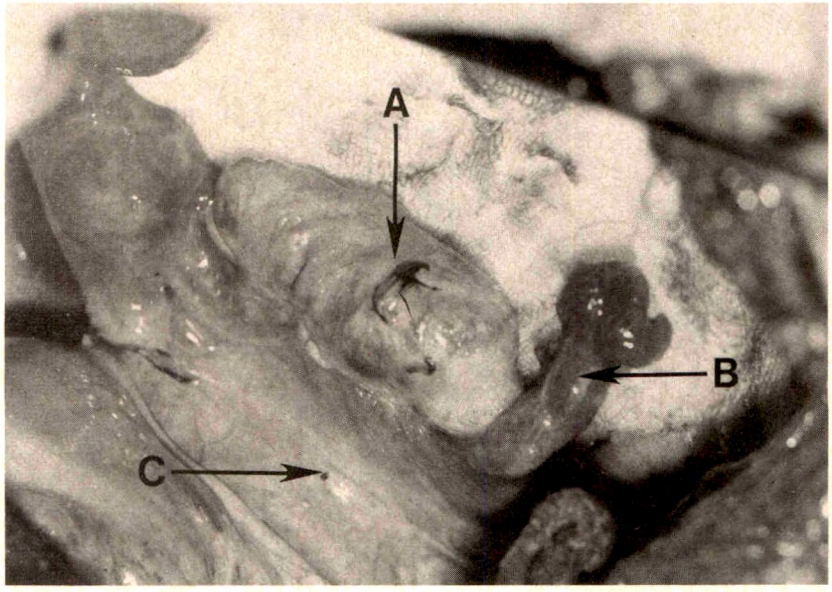

Fig. 3. The ovary *(A)* is interposed between the 1½ cm segment of left fallopian tube *(B)* which merges imperceptibly with the broad ligament *(C)* lateral to the rudimentary left uterine horn.

The right fallopian tube was absent. A 1½ cm canalized segment of left fallopian tube with a small, pale, fimbriated end was located 4 cm lateral to the rudimentary uterine horn (Fig. 3). Laterally it was contiguous with the left infundibulopelvic ligament and medially it merged imperceptibly with the broad ligament. The ovaries were grossly normal and there was no evidence of pelvic endometriosis. She was judged irreversibly sterile and the abdomen was closed.

Case 2. A 16-year-old nulligravid girl was referred to the Division of Reproductive Endocrinology for primary amenorrhea and cyclically recurrent pelvic pain of 3 months' duration. Secondary sexual characteristics were normal in chronologic and sequential appearance. Blood pressure was 140/90 mm Hg. Pelvic examination revealed the external genitalia to be normal. The vagina was 2 cm in depth and in the left posterior pelvis was a 10 cm fixed, firm, tender mass. An intravenous pyelogram demonstrated right renal hypogenesis; the vertical dimension of the right kidney was 6 cm and of the left kidney was 13.7 cm.

At laparotomy a bicornuate uterus with an atretic cervix was found (Fig. 4). The left horn was distended with blood and contiguous with a left hematosalpinx distally occluded by the left ovary. There was extensive pelvic endometriosis. The right uterine horn was rudimentary (2 cm in diameter), located in the leaves of the right broad ligament, and attached to the right round ligament which exited through the internal inguinal ring. A partially atretic fallopian tube canalized for 3 cm was located 4 cm lateral to the right horn. The left horn and ovary were excised and a neovagina was created utilizing Wharton's[19] technique.

Comment

The paired müllerian ducts arise as invaginations of coelomic epithelium opposite the third thoracic somite at the cephalic pole and lateral to the mesonephros. The ducts grow caudally in the mesenchyme and are intimately associated with the mesonephric ducts which they use as guides. At 8 weeks the paramesonephric ducts fuse at Müllers tubercle where they contact the posterior wall of the urogenital sinus (sinus tubercle). Fusion of the ducts proceeds in a craniad direction and dissolution of the resultant intervening septum to form a single genital canal is complete by 10½ weeks. The sinuvaginal bulbs, bilateral proliferations of cells at the region of the sinus tubercle, are augmented by a solid mass of cells of müllerian, mesonephric, or sinus origin that form the vaginal plate to completely occlude the vaginal tube. Ultimately the plate canalizes to form the vaginal lumen and by 21 weeks the entire genital canal has access to the exterior.[4]

A bicornuate uterus with a noncommunicating, nonfunctioning, rudimentary uterine horn associated with ipsilateral partial fallopian tube atresia represents very early failure in unilateral müllerian duct development and consequent failure of fusion. Because the rudimentary horn is functionless, in the absence of other associated anomalies to obstruct egress of the menstruum there is no pelvic pain and no abnormal mass. Although the potential exists for the nidation of an embryo in the partially atretic fallopian tube this has never been reported. The five reported cases were associated with normal vaginal development. There was

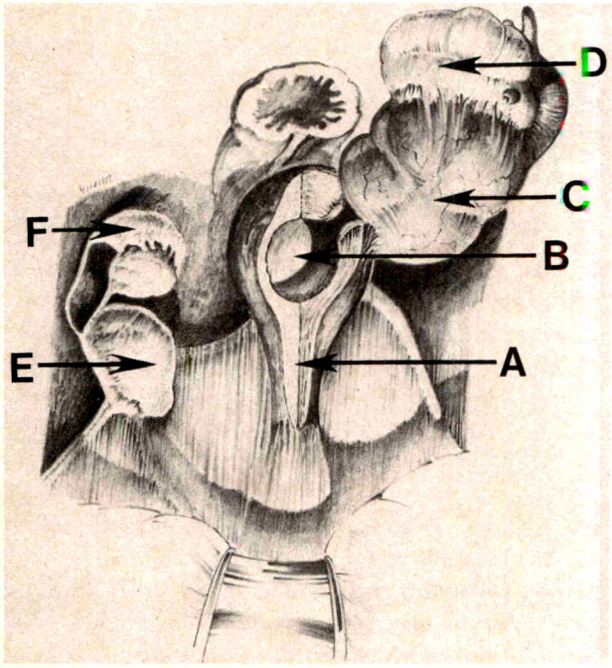

Fig. 4. The atretic cervix *(A)* has caused retrograde menstruation from the left uterine horn *(B)* to the resultant left hematosalpinx *(C)* distally occluded by the left ovary *(D)*. The right rudimentary uterine horn *(E)* is functionless and the right fallopian tube *(F)* only partially canalized.

no impairment of fertility and eight pregnancies were achieved in four patients. Two pregnancies terminated prematurely and four fetuses were small-for-dates.[17]

Knowledge of this anomaly suggests that extirpative adnexal surgery be performed with great caution in patients with double uteri and only after very careful assessment of the contralateral side. In our patients the short length of canalized fallopian tube precluded tubal implantation into the contralateral uterine horn, rendering the patients irreversibly sterile.

We are grateful for the technical assistance of Ms. Sarah Anderson in the preparation of this manuscript.

Tubal ligation by colpotomy incision

CECIL F. WHITAKER, JR., M.D., F.A.C.O.G.
Columbus, Georgia

A five-year review of colpotomy tubal ligation performed on 585 patients within a private-practice setting in Columbus, Georgia, is analyzed. Operative time averaged under 30 minutes, and average hospital stay was less than 3 days. The major postoperative complication rate was less than 2%. The patient population is reviewed as to age, parity, previous contraception, and medical indications for sterilization. Surgical technique is discussed, and several suggestions are made. A follow-up of subsequent gynecologic procedures and the interval following colpotomy is then presented. (AM. J. OBSTET. GYNECOL. 134:885, 1979.)

A REVIEW OF 585 cases of bilateral partial salpingectomy via colpotomy incision is presented. These operative procedures were performed by a professional association of four private physicians over a 5 year span (from June, 1973, through June, 1978). All surgical procedures were performed at either the Columbus Medical Center or Doctors' Hospital in Columbus, Georgia.

The patient population is analyzed as to age, parity, and medical indications for sterilization. Surgical technique is briefly reviewed, and several suggestions are made. Hospital stay is discussed, and immediate and long-term complications are presented. A review of subsequent gynecologic procedures is then conducted with emphasis on surgical indications and the time interval from tubal ligation.

Material and methods

Patient population. The patients ranged in age from 16 to 46. Mean age of patients was 31 years (Table I). Parity ranged from 0 to 6, with a mean parity of 2 (Table II).

Seventy-eight patients or 13% of the total were pregnant and underwent concomitant therapeutic abortion by suction curettage at the time of colpotomy.

Indications. The great majority of patients presented for elective sterilization; however, 69 patients or 11.7% presented for sterilization for medical reasons (Table III).

Contraception prior to tubal ligation. Contraceptive methods practiced prior to the operative procedure reflect the balance seen in our practice (Table IV).

Surgical technique. No prophylactic antibiotics were employed. Shaving of the perineal area was avoided, and surgical preparation with Betadine scrub and solution was performed. The posterior cul-de-sac was entered by sharp dissection with LeHey thyroid tenacula utilized for cervical traction. Care was taken not to extend the colpotomy incision lateral to the medial edge of the uterosacral ligaments.

A right-angled Haney retractor was placed in the open cul-de-sac, and the fallopian tube was grasped with a Babcock clamp and identified up to the fimbria. The tube was then ligated in a Pomeroy fashion utilizing 1-0 plain suture material, with the tubal segments submitted for evaluation.

The posterior peritoneum was closed in a nonlocking fashion, and the same suture material was then continued in a locking fashion for closure of the vaginal cuff. Careful attention was given to the lateral extent of both the peritoneal and the cuff incisions to ensure total hemostasis. Curettage performed in all patients with the use of sharp curettage technique. Suction curettage was carried out in those patients requiring therapeutic abortion. Early ambulation was encouraged. Except in surgically complicated cases, patients were returned to normal activity at the time of hospital discharge. Restraint from sexual intercourse was advised until office follow-up 2 weeks after surgery.

Results

Hospital stay. Hospital stay ranged from 2 to 7 days. Average hospital stay was 2.5 days per patient (Table V).

Surgical operative time (from colpotomy incision to conclusion of curettage). Surgical operative time

ranged from 15 to 60 minutes with an average time of 25.7 minutes.

Surgical complications. Laparotomy was required for ligation of tubes in eight patients or 1.37%. The reasons are shown in Table VI.

Nine patients experienced postoperative complications which contributed to prolongation of hospital stay and morbidity. Vaginal cuff hematoma and cuff abscess requiring incision and drainage were noticeably absent (Table VII).

Subsequent gynecologic procedures. The overall incidence of subsequent gynecologic procedures was 7.9% (Table VIII). It is of interest to note that the incidence in patients over 30 years of age was 18.08%.

Comment

Tubal ligation through vaginal colpotomy incision has proved to be an effective and efficient method of sterilization. Hospital stay and operative time have proved acceptably short.

Attention to surgical hemostasis, concomitant curettage, and early ambulation are believed to contribute to our low instance of operative complications.

The follow-up time of this patient population is

Discussion

DR. STEPHEN G. ANDERSON, Winston-Salem, North Carolina (Official Guest). Dr. Whitaker has presented one of the larger series of vaginal tubal ligations to date. His results with tubal ligation by colpotomy incision compare very favorably with those previously reported. Average operating time of 25.7 minutes, average hospital stay of 2.5 days, failed colpotomy rate of 1.37%, and postoperative complication rate of 1.53% all rank in the lower range when compared with those of other studies. In a thorough review of female sterilization, Shepard[1] reported a mean complication rate of 3.7% in 3,706 interval vaginal tubal ligations with a range of 0% to 26.3%.[1]

There are two problems in placing Dr. Whitaker's report in proper perspective. First, the follow-up period is admittedly short, prohibiting consideration of long-term effects of vaginal tubal ligation such as the failure rate and possible effect on menstruation. Second, when these results are compared with those achieved by another method of sterilization, one risks comparing surgical proficiency rather than methods. I suspect that the excellent outcome in the present evaluation resulted from this series of vaginal tubal ligations being performed by experienced gynecologic surgeons who paid scrupulous attention to hemostasis and technique.

Since the incidence of female sterilization is increasing and the total number exceeds 670,000 yearly, consideration of sterilization methods is in order. At present, laparoscopic tubal cauterization with or without tubal division is by far the most common method of interval sterilization with more than 200,000 such procedures being performed yearly.[2] The logical question, it seems to me, is whether laparoscopy has more or less merit than vaginal tubal ligation as a method for interval sterilization.

The major complication rate of laparoscopic tubal cauterization has been reported by Hulka[2] as 0.37%. Kleppinger,[3] reviewing 4,361 laparoscopic procedures over a 5 year period, reported serious complications requiring laparotomy in only 0.47%, and my estimated average hospital stay of his patients was 1.8 days. More important, the complication rate decreased with expe-

rience of the staff, and serious bleeding and burn complications were eliminated entirely with the advent of the bipolar coagulating instrument.

Laparoscopic tubal cauterization will be favored over vaginal tubal ligation by most gynecologists for the following reasons. The results reported today are good, but those from laparoscopy are even better. The major complication rate of laparoscopic tubal cauterization is one third to one fifth that from vaginal tubal ligation. With laparoscopy, operating time and hospital stay are less; the procedure can be done on an outpatient basis and even with local anesthesia. Finally, the single-puncture technique allows female sterilization with little surgical assistance, thus increasing efficiency.

To consider the present report in more detail, I have the following questions:

1. Were there any failures resulting in pregnancy other than the one ectopic pregnancy reported?
2. Were physicians used routinely as surgical assistants? When I performed vaginal tubal ligations, "good help" often seemed the key to accomplishing the procedure easily.
3. Were any procedures done on an outpatient basis?
4. Did the patient with a tuboovarian abscess require hysterectomy?
5. Can you offer any personal comparison between vaginal and laparoscopic tubal ligation?

DR. ROBERT T. HOOVER, Orlando, Florida. Surgical sterilization is becoming a commonly performed procedure. Dr. Whitaker has given us his experience with one of the accepted methods. The most commonly used methods include the minilaparotomy postpartum sterilization via the abdominal route, laparoscopic sterilization using coagulation, clips, or rings, and finally the vaginal approach.

In commenting on Dr. Whitaker's paper it seems that the following should be borne in mind. All methods must be compared and the technique indicated for the individual patient should be the one with the lowest morbidity. In discussing the vaginal approach and its attendant morbidity it must obviously be compared with the morbidity of minilaparotomy and laparoscopy. My experience with colpotomy from 1960 to 1971 is not great and a review of my charts revealed 178 colpotomies of all types. In 1972, following a short course in laparoscopy, I began to use the laparoscopic approach for sterilization and evaluation of the pelvis for abnormal changes. Since 1972, I have performed three colpotomies for sterilization, these being done at the patients' request. Of these 181 patients the average hospital stay was 2.6 days, ranging from 1 to 12 days. In this group of patients two major complications occurred, one being a bilateral tuboovarian abscess secondary to gram-negative organisms and the other a postsurgical hemorrhage brought on by premature intercourse. This required suturing following anesthesia. Dr. Whitaker reported on 585 patients who underwent colpotomy for sterilization purposes. This large group adds considerably to the literature and I think that his paper is timely. His technique is essentially the same as I have used with the exception of the added curettage. For those using colpotomy I would like to reinforce his special attention to the angle of the vaginal incision, as the vascularity in the area of the uterosacral ligament is extensive and most bleeding occurs at this point. I would like to ask Dr. Whitaker if the curettage in association with this procedure uncovered any abnormal changes that aided him in the care of his patients. He made no observation on this in his paper.

I noted that he performed the procedure on 11 nulliparous patients. As those of you who performed colpotomies are aware, this is not an easy task and I would like to congratulate him on his surgical ability. Of his 585 patients, 15.3% were pregnant at the time the colpotomy was done and had undergone a vacuum extraction for termination of the pregnancy. I would like to ask Dr. Whitaker if blood loss was increased in these patients and were any of them involved in the three episodes of excessive bleeding.

The hospital stay averaged 2 to 3 days and while this is quite short when compared with that for most abdominal operations I feel that it should be compared with that of its competing procedure, the laparoscopy, which is somewhat shorter, averaging approximately 1 day or even less.

In 193 of the surgical procedures a time of 30 minutes or greater was required to complete the procedure. This seems like an excessive amount of time, particularly when compared to that with laparoscopy, which in my hands varies from 12 to 20 minutes and none that I have done has required as much as 30 minutes. Of the surgical complications I feel that two deserve special attention: the tuboovarian abscess and the vaginal bleeding which required suturing. In all likelihood these are procedure related.

I find several disadvantages to the procedure as compared to the laparoscopic approach. First, the hospital stay is prolonged when compared with that of laparoscopy and in this day of increased awareness of medical cost this should be considered. Second, with respect to surgical time, the procedure takes 10 to 15 minutes longer than laparoscopy and this could increase morbidity.

In the process of discussing surgical sterilization with patients the vaginal approach should be offered as an alternative method to minilaparotomy and laparoscopy and if the patient so desires the alternative procedure should be done

Radical hysterectomy: A critical review of twenty-two years' experience

PAUL B. UNDERWOOD, JR., M.D.
WILLIAM C. WILSON, M.D.
ALBERT KREUTNER, M.D.
M. C. MILLER III, PH.D.
EDMUND MURPHY
Charleston, South Carolina

One hundred seventy-eight patients who had radical hysterectomy performed for management of invasive carcinoma of the cervix over a 22 year period at the Medical University of South Carolina were critically analyzed. The degree of differentiation of the malignancy appeared to be of more significance than tumor size in Stage I lesions. With proper patient selection and excellent operative technique, survival rates well over 90% with minimal complications can be obtained. The radical hysterectomy should never be used in association with irradiation. (AM. J. OBSTET. GYNECOL. 134:889, 1979.)

THE IDEA of the surgical removal of a cancerous cervix can be accredited to J. Marion Sims in the early 1870s[1]; however, the surgical technique of the radical hysterectomy was developed by Wertheim[2] about 1900. X-irradiation and radium were discovered in the late 1890s, with their therapeutic use against cervical cancer being recognized about 1900.[3] Thus a debate began that continues to the present time as to the advantages and disadvantages of each of these two modalities in the management of cervical cancer.

Many retrospective studies have been published with varying results. Most deal with survival rates and complications. The purpose of this study is to analyze critically the radical hysterectomies performed at the Medical University of South Carolina by the Department of Obstetrics and Gynecology in an attempt to improve patient selection for radical hysterectomy in the future.

Methods

Since the opening of the Medical University Hospital in 1956, 2,838 women have been treated for carcinoma of the cervix. One hundred seventy-eight or 6% underwent radical hysterectomy. The patients within this 22 year span will be divided into two groups of 11 years each since a major change in management of cervical carcinoma occurred in July, 1967.

Prior to July, 1967 (Group 1—86 patients). Criteria for patient selection varied. The procedure was performed by several different surgeons and, at times, by an unassisted house officer. Preoperative irradiation was occasionally utilized.

After July, 1967 (Group 2—92 patients). Patient selection was standardized—individually selected, ideal candidates for operation with small lesions. All procedures were performed by a trained gynecologic oncologist. No preoperative irradiation was administered.

All inpatient and outpatient charts were reviewed by a single research technician with the data obtained placed on an IBM 370 computer for analysis. Specimens were re-evaluated by a single pathologist for cell type, histologic grade, and depth of invasion. All data was studied and analyzed by a biostatistician.

Results

When the socioeconomic status was grouped as private or indigent (Table I), a slightly higher percentage of the patients were indigent (51% to 45%). This difference was a reflection of Group 1. Seventy percent of the patients were white (Fig. 1) and no racial differ-

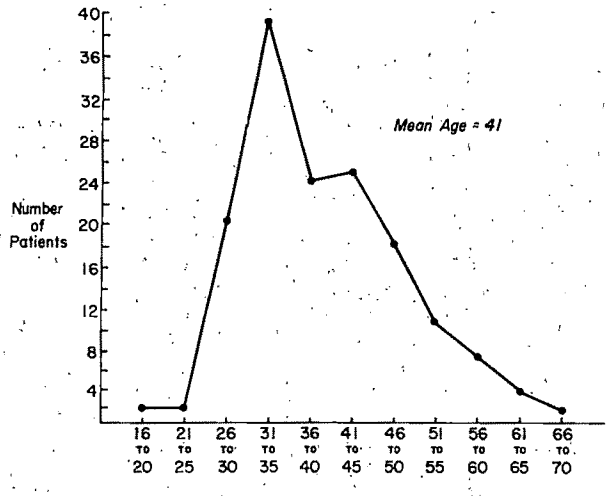

Fig. 2. Ages of patients, who had radical hysterectomy as grouped per 5 years (unknowns omitted).

ences existed between the two groups (P = 0.59). This markedly differed from the hospital population.

The clinical stage (International Federation of Gynecology and Obstetrics classification) is shown in Table II. The majority (62%) of the malignancies were Stage IB. No significant difference (P = 0.43) existed between the two groups. Seven patients had a cervical stump lesion.

The peak age for this procedure was between 31 and 35 years. The mean age was 41 years with ages varying from 16 to 70 years (Fig. 2). No differences existed between the two groups (P = 0.27). The 16-year-old patient had sarcoma botryoides.

The majority of patients weighed between 120 and 140 pounds (Fig. 3). Fifteen percent of Group 1 and 10% of Group 2 weighed over 150 pounds with 3% weighing over 200 pounds in both groups. The mean weight for the entire series was 155 pounds with

weights varying from 89 to 245 pounds. Group 1 had heavier women (P = 0.05).

Only 4% of the patients were nulliparous (Fig. 4) and almost half of the women had four or more children. Again no significant difference existed between the two groups (P = 0.28).

Sixty-three (35%) of the women were asymptomatic, and disease was suspected by an abnormal Papanicolaou smear (Table III). Postcoital spotting, the so-called presenting symptom of carcinoma of the cervix, was present in only 15%. Pain, the late symptom of cervical cancer, was the presenting symptom in 9%. The length of symptoms was significantly less in Group 2 (P = 0.03).

Factors that complicated the malignancy and/or surgical procedure are listed in Table IV. The patients with pelvic inflammatory disease and pyometra both did well without complications from the surgery; however, the patient with pyometra died of disease. The pregnant patients and those with cervical stump malignancy will be discussed later.

The status of all patients treated is illustrated in Table V. The corrected survival rate was calculated by omitting patients lost to follow-up and free of disease and patients who died of other causes. It should be pointed out that almost all patients who were lost to follow-up and free of disease or died of other causes did so after being observed 5 or more years. In the past 11 years, only one patient has been lost to follow-up

prior to 5 years. She had microinvasive carcinoma and was lost to follow-up at 25 months. Therefore, the corrected survival rate should closely approximate true survival. A 5 year uncorrected survival rate of 86% and a corrected rate of 93% were calculated for the entire series. Only one cancer death occurred in the past 11 years; diagnosis, treatment, and death took place in 1977. Likewise the one patient with recurrence was treated less than 3 years ago, and the disease recurred in the vaginal apex. The patient received irradiation and is presently free of disease. Even though both of these patients were not eligible for calculation in 3 year survival rates, they were included for completeness. Six of the 10 patients who died at 5 years had poorly differentiated or undifferentiated malignancy. Three of the deaths occurred in patients with early Stage II lesions.

These patients were analyzed in an attempt to identify factors that could possibly have influenced survival and/or complications. Tumor volume was clinically estimated by two means—cervical size and the degree of

cervical involvement by tumor. In a retrospective manner, the clinical size of the cervix was estimated by interpretation of the original description of the cervix and grouped into three categories (Table VI). Group 1 had significantly more patients with larger cervices ($P = 0.004$). Although the numbers were small for statistical analysis, it appears that the larger the cervical size from cancer, the lower the survival rate.

By the other means of attempting to evaluate tumor volume, the cervical neoplasms were grouped as to the degree of cervix involved with cancer. (Table VII). Again Group 1 had more larger tumors ($P = 0.01$). These data suggest, but not statistically significantly, that once the cervix was clinically involved with neoplasm the prognosis did not change.

The clinical appearance of the cervix was grouped (Table VIII). A granular cervix rendered poor results and may reflect diffuse involvement. Of significance was 100% survival rate of the patients with ulcerative

lesions as compared to the 33% survival rate of the patients with exophytic lesions.

Twenty-three (13%) of the patients had adenocarcinomas (Table IX). Nineteen were eligible for 5 year follow-up with a survival rate of 89%. Three patients died of disease at 12, 15, and 79 months, respectively. Two had Stage IB disease and one patient, at 7 weeks' gestation had Stage IIA disease. Only one patient had positive pelvic nodes. Of the four patients with adenosquamous carcinoma, one developed a vaginal recurrence at 3 months, and another was lost to follow-up at 1 month with positive nodes and was considered to have died of disease. This confirms the aggressiveness of adenosquamous carcinomas. The teenager with sarcoma botryoides of the cervix is living and well after 3 years.

The pathology slides that were considered adequate were measured for the exact depth of invasion. The early lesions (8 mm or less of invasion) are listed in Table X. No significant difference existed between the two groups ($P = 0.33$). No patient with 5 mm or less of invasion had positive nodes, developed a recurrence, or had a major complication. One patient in the 5.1 to 8 mm of invasion group is living with disease.

The degree of differentiation was determined in 123 patients (Table XI) and did not differ between the two groups ($P = 0.10$). None of the 17 patients with well-

differentiated malignancies died of disease. When the well-differentiated and moderately differentiated lesions were combined, the corrected survival rate was 94%. The number of recurrences drastically increased among the poorly differentiated and undifferentiated lesions. The combined corrected survival rate was 74%. When the degree of differentiation was compared to the clinical amount of cervix involved by tumor, a direct relationship existed (Fig. 5).

Ten patients were pregnant at the time of the diagnosis but none was less than 6 months post partum (Table XII). Of significance was that the mean blood loss was 2,190 ml (the mean for the series was 1,603 ml). The only death occurred in a patient with Stage IIA disease and she lived 79 months.

Seven patients had malignancy in the cervical stump (Table XIII). All were squamous malignancies and only one patient died of disease at 13 months.

Eight patients had positive pelvic nodes at radical hysterectomy (Table XIV). Of noteworthy significance were the following: (1) None had cervices over 6 cm; (2) only three lesions invaded over half way through the cervix; (3) six lesions were poorly differentiated or undifferentiated. Postoperative irradiation appeared to be beneficial since three of the four patients who received it were free of disease and three of the four who did not died.

In Group 1, 12 patients received preoperative irradiation (Table XV). Two thirds of these patients developed a fistula to the vagina and all patients who received both external irradiation and radium developed a fistula. These fistulas will be discussed in detail later. Six (50%) of these patients are living and free of disease. No preoperative irradiation was given in Group 2. Three patients had a modified radical hysterectomy for early central recurrence after primary irradiation. There were no postoperative complications; however, all died of disease. Two died in less than 1 year and one lived 37 months.

When the two groups were analyzed critically, significant differences existed in blood loss and days in hospital (Table XVI). Thirty-eight patients (41%) of Group 2 as compared to only 13 (17%) in Group 1 lost less than 1,000 ml of blood. On the opposite end of the scale, 12 patients in Group 1 and only one patient in Group 2 lost over 3,000 ml of blood.

Operative injuries to the urinary and gastrointestinal tracts are shown in Table XVII. All operative injuries were repaired primarily at surgery and healed without complications. Of interest was one patient in whom the ureter was transected at the common iliac artery at the beginning of the procedure. An end-to-end anastomosis was performed and healed primarily even

Weight		0.004					

*The numbers indicate the probability of a significant correlation. Only significant correlations are shown.

though the distal ureter was managed in the usual manner during the radical hysterectomy.

All postoperative fistulas occurred in Group 1 (Table XVIII). One of the three patients with vesicovaginal fistulas had preoperative radium. The other two were thin women with Stage IA and IB disease, respectively, who had no operative complication or other reason that could explain the fistula. Two fistulas closed spontaneously (including that in the patient who received preoperative radium) and the third patient refused surgery. She later developed a nonfunctioning right kidney and died 6 years later of other causes, free of disease, but with the fistula.

Ten patients developed ureterovaginal fistula. Five had received preoperative irradiation (three with radium only and two with x-irradiation and radium). There were no unusual characteristics in the five patients with no preoperative irradiation except three had prolonged procedures lasting over 5½ hours and three had a blood loss of over 2,500 ml. Fistulas in three of the nonirradiated patients, healed spontaneously; however, one patient later required a nephrectomy because of stone formation in the fistula site. Of the remaining two nonirradiated patients with fistulas, one required a nephrectomy and one an ileal conduit. All five are living and free of disease.

In the five patients who developed ureterovaginal fistulas and who received preoperative irradiation, one fistula closed spontaneously, two patients required nephrectomy, one an ileal conduit, and one received an unknown type of treatment. Two have died of the disease and three are living and free of disease. The patient with a colovaginal fistula died 3½ months postoperatively of infection.

Various factors were examined against one another for any significant correlation (Table XIX). Operative time was significantly related to blood loss, intraoperative complications, and days in the hospital. Weight was related only to blood loss.

The various factors studied were grouped within themselves and life tables for 5 year survival rates were calculated between Groups 1 and 2. Women who were under 35 years of age, weighed 110 to 134 pounds, had three or more children, and had operative procedures lasting less than 4 hours did significantly better in Group 2. None of the other factors showed any significant differences between the two groups.

Comment

The critical analysis of this series of radical hysterectomies reflects a departmental tendency to operate on the young, thin woman with a small Stage I neoplasm, especially in the past 11 years. The low incidence of only 4% positive pelvic nodes and the outstanding uncorrected survival rate of 86% and the corrected rate of 92% are undoubtedly directly related to this philosophy. The clinical estimate of the cervical size and degree of cervical involvement confirms this conservatism. The data confirm that the size of the cervical neoplasm is significant when related to survival; however, the degree of differentiation of the neoplasm appears to be of greater importance. There was a direct relationship between the degree of differentiation and the size of the cervical lesion.

Several important points can be obtained from these data: (1) Patients with well-differentiated and moderately differentiated tumors do far better than those with poorly differentiated and undifferentiated lesions. When the well-differentiated and moderately differentiated lesions are combined (79 patients) a corrected survival rate of 95% with only one patient with positive pelvic nodes indicates a too conservative approach in this series. (2) Two of the three patients with undifferentiated lesions died of disease despite their having small tumors. Also six of seven patients with positive nodes had poorly differentiated or undifferentiated carcinomas. (3) Three of seven patients with Stage IIA disease died of disease. (4) The patients with pure adenocarcinoma did well. (5) The adenosquamous carcinomas appear to act very aggressively. (6) Pregnancy did not affect the outcome.

Therefore, these data suggest that one could utilize

the radical hysterectomy as a means of management of a much larger Stage I carcinoma if it is well-differentiated or moderately differentiated. However, one should be very selective in performing radical hysterectomy in a patient with poorly differentiated or adenosquamous carcinoma and probably should never utilize it in the patient with undifferentiated carcinoma. These data also suggest that radical hysterectomy should not be performed in patients with Stage IIA or large, exophytic, Stage IB lesions and absolutely never in association with preoperative irradiation.

Surgical technique and experience in radical surgery cannot be overemphasized. This was reflected in blood loss, fistula formation, and days in the hospital over the past 11 years. Sharp rather than blunt dissection and ligation of the uterine artery and vein at their origin are two secrets to decreased blood loss. After ligation of the uterine artery and vein far laterally, they are lifted from over the ureter. This one procedure frees up over one half of the ureteral tunnels as well as the bloody part of the dissection. The identification of the ureter at its insertion in the bladder below the remaining tunnel renders the rest of the dissection easy and minimizes blood loss.

We believe that the most important points in preventing a ureteral-vaginal fistula are: (1) never directly handle the ureter and (2) preserve the blood supply to the ureter, especially at the lateral angle of its insertion into the bladder. The hypogastric and vesical arteries are left intact. Although the ureter is completely dissected from its bed in the broad ligament, the loose areolar tissue clinging to the ureter is carefully preserved. The ureter is sutured to the superior vesical artery to prevent it from dangling in the pelvis. As much peritoneum as technically possible is left attached to the ureter in the upper pelvis. Intravenous indigo carmine is injected after the removal of the specimen for identification of unsuspected lacerations.

Prophylactic antibiotic drugs and heparin, early mobilization, and extraperitoneal suction drainage minimize hospitalization. In the past 11 years, only one lymphocyst that required therapy has developed.

The radical hysterectomy has a definite role in the therapeutic armamentarium of the management of cervical carcinoma. Careful patient selection is the key to excellent outcome.

We wish to express our appreciation to Miss Wanda Fields and Mrs. Frances Mims for their assistance in the preparation of the manuscript.

Discussion

DR. JOHN D. THOMPSON, Atlanta, Georgia. All the aspects of this fine paper that deserve discussion cannot possibly be included in the 5 minutes allotted to me, so I have chosen only a few points for discussion.

First of all, it should be made clear that this paper does not compare the results of irradiation therapy and surgical therapy for invasive cervical cancer. The authors would be the first to admit that many of the patients selected for primary radical surgery also would have been cured if irradiation had been chosen for primary therapy. In fact, if one does not select patients for primary surgery or primary irradiation therapy in Stage IB cervical cancer but assigns treatment to alternate patients in a manner perhaps similar to that of the fine study that was done by Dr. Michael Newton, one finds that the results of irradiation and the results of surgery are fairly similar, both in terms of cure and in terms of complications. It is sometimes forgotten that irradiation for cervical cancer is also associated with significant complications and also with a few late recurrences not often seen in patients treated with primary surgery. Radical surgery does, of course, have adverse effects on urinary tract function, but it should be remembered that irradiation therapy also has adverse effects on urinary tract functions.

The important point that the authors' paper demonstrates is that certain advantages of radical surgery over irradiation can be offered to selected patients with early invasive cervical cancer if the operation is performed by an experienced gynecologic surgeon who is familiar with the natural history of the disease, familiar with the technique of radical hysterectomy, and working in an environment in which the patient can be properly prepared for operation and properly cared for after operation. Primary surgery, for example, offers the distinct advantage of being able to determine by careful examination of the radical hysterectomy specimen the exact dimensions of involvement, especially as regards the extent of the central disease and the involvement of the pelvic lymph nodes in metastatic disease, and also gives additional insight into the de-

gree of dedifferentiation of the tumor and its propensity for invading lymphatic and vascular channels. This information is useful for forming opinions about prognosis and making decisions about the need of postoperative irradiation therapy. This information is not available when patients have a few random cervical biopsies taken and are then treated with irradiation therapy. All other things being equal, nothing prospers the correct management of the patient's problem more than knowing the full extent of disease.

But, in addition to a more accurate prognosis and a better plan of therapy, other advantages are evident for such selected patients. The largest number of the authors' patients were in the 31 to 35 year age group (39 patients) and 112 of 155 patients were age 45 years and younger. Adequate therapy for early invasive cervical cancer in such young women can be given with radical surgery without the necessity of removing the ovaries, thus preserving their useful function. The ovaries are rarely involved with metastatic disease from cervical cancer, even in late Stages III and IV. The ovaries will continue to function normally, and normal ovulatory cycles can occur, even after an extensive operation. Leaving the ovaries in place does not jeopardize the adequacy of the central dissection or the pelvic lymphadenectomy.

A recent Emory University study of sexual function following treatment for cervical cancer has shown us another clear advantage of primary surgery over primary irradiation therapy. Patients who received irradiation experienced statistically significant decreased sexual enjoyment, decreased ability to achieve orgasm, decreased libido, decreased frequency of intercourse, decreased opportunity for intercourse, and diminished sexual dreams. This is not surprising, since vaginal vault necrosis, pelvic fibrosis, irradiation cystitis and proctitis, and vaginal stenosis and dryness are frequent and loss of ovarian function is inevitable after irradiation therapy. The surgically treated group did not have any significant change in sexual function after treatment. This study was done by Drs. Machelle Seibel and Malcolm Freeman.

As one might expect, there are still variations in the technique of radical hysterectomy from one gynecologic surgeon to another. I believe the anterior trunk of the hypogastric artery and its distal branches, including the branches to the bladder, can be removed without increasing the incidence of ureteral-vaginal fistulas and with the advantage of allowing a more adequate central dissection. I have been reluctant to employ the minidose heparin schedule in patients with such an extensive pelvic dissection. Constant suction of retroperitoneal spaces for several days postoperatively until they are dry is an extremely important measure in reducing postoperative lymphocele formation and ureteral-vaginal fistulas. I do not believe it is necessary to suture the lower ureter to the superior vesical artery. In my experience, very thin patients are at greater risk of developing postoperative urinary fistulas following radical surgery. Perhaps this is because the operation has a tendency to be more complete when the patient is very thin. I fully agree that the results of radical hysterectomy can be quite satisfactory even though the operation is done during pregnancy. I also fully agree that preoperative irradiation has no place in a patient in whom radical hysterectomy is planned.

I would like to ask the following questions of Dr. Underwood:

1. What percent of patients with Stages IA, IB, and IIA disease were treated with radiation and what were the results of treatment?
2. What criteria are now used for the selection of irradiation or surgery as the primary therapy in these stages?
3. In this group of patients with predominantly favorable lesions, is it necessary or useful to remove a sample of the para-aortic nodes for frozen-section examination before proceeding with the radical hysterectomy?
4. Is one ever justified in not doing pelvic lymphadenectomy in patients with very early invasive cervical cancer, so long as the section around the central disease can still be adequate?
5. Is a pelvic lymphadenectomy to the bifurcation of the aorta always necessary?
6. Should patients who have a large cervical lesion (and perhaps because of this also an inadequate margin of resection around the central tumor), especially if the histologic grade is undifferentiated, in addition to patients found to have positive nodes, also receive postoperative pelvic irradiation?
7. Do patients in your series who undergo radical surgery and postoperative irradiation have difficulty tolerating this combined therapy?
8. Do you believe a patient with a large, Stage IB, undifferentiated cervical cancer will have a better chance of cure with fewer complications if treated with primary irradiation alone, primary radical surgery alone, or primary radical surgery followed by postoperative irradiation to the pelvis?
9. Finally, what are your views about conservation of normal ovaries at the time of radical hysterectomy and pelvic lymphadenectomy for invasive cervical cancer in young women?

At the Seventy-eighth Annual Meeting of the American Association of Obstetricians and Gynecologists in Hot Springs, Virginia (September, 1957), Dr. Clyde Randall discussed a paper on "Conservation of ovarian tissue in the treatment of carcinoma of the cervix with radical surgery." The paper was presented by Dr. Milton McCall.[1] In closing his discussion, Dr. Randall said, "It will be a strange line for the surgeon to claim superiority, not on the basis that danger can be totally excised, but rather on the basis of what can be preserved. We now find cervical carcinoma early and treat it so well that a majority of patients now survive more

than five years. Is it not time to consider modifying the treatment so that those we cure may live with bodies more nearly normal than many present day survivors possess?"

REFERENCE

1. McCall, M. L., Keaty, E. C., and Thompson, J. D.: Conservation of ovarian tissue in the treatment of carcinoma of the cervix with radical surgery, AM. J. OBSTET. GYNECOL. 75:590, 1958.

DR. PHILLIP A. CARUSO, Fort Lauderdale, Florida. It has long been evident that radical hysterectomy can cure early invasive cancer of the cervix. Likewise, it is undeniable that irradiation therapy is nearly equally curative in such cases. There has been a dramatic improvement of both irradiation therapy and surgical technique within the past 20 years, resulting in a cure rate for Stage I carcinoma of the cervix in excess of 90%. This result has grown out of a mutual respect and healthy competitive spirit between therapeutic radiologists and gynecologic-oncologic surgeons. The problem of patient selection for each therapeutic modality remains a major issue for debate.

That both radical hysterectomy and irradiation therapy have survived as individually complete treatment for early invasive cancer of the cervix affirms that each has certain advantages over the other. While it is virtually impossible to determine if the 10% failures of each therapeutic modality would have benefited from the alternate form of therapy, it is only logical to look retrospectively at each group of such patients in the hopes of developing improved guidelines for optimum patient selection.

Dr. Underwood and his colleagues have reviewed 178 patients undergoing radical hysterectomy at the Medical University Hospital in Charleston, South Carolina, since its opening in 1956. They listed a multitude of adverse factors, including length of symptomatology, pyometra, loss of differentiation, advancing stage, size of the cervix, tumor volume, exophytic lesions, adenosquamous carcinoma, and increasing depth of penetration, not to mention the weight of the patient, prior irradiation, and inadequate surgical experience. On the contrary, pregnancy, adenocarcinoma of the cervix, and prior supracervical hysterectomy did not appear to adversely affect prognosis.

For these observations we must be grateful. I am not yet ready, however, to accept limited use of radical hysterectomy based upon a unilateral review of its shortcomings. When prospective studies indicate a definite benefit of irradiation therapy over radical hysterectomy in the management of poorly differentiated or adenosquamous carcinoma of the cervix, Stages IA and IB, I will reconsider this position.

Finally, I cannot help but entirely agree with the authors' views on surgical technique and their use of prophylactic antibiotics, minidose heparin, early mobilization, and extraperitoneal drainage. I sincerely compliment Dr. Underwood and his collaborators as their excellent results, especially within the past 11 years, bespeak the work of an experienced and talented surgical team.

I would like to ask Dr. Underwood the following questions. First, does he see any place for the use of combination irradiation and surgery as primary therapy in cancer of the cervix? Second, what tubing and suction apparatus has he found most to his liking?

Study of secretory component in patients with metastatic breast cancer

ELLEN A. THALMAN PULEO, M.D.
DARYL E. HAAGENSEN, JR., M.D., PH.D.
JEFFREY R. DAWSON, PH.D.
STANLEY A. GALL, M.D.
Durham, North Carolina

A radicimmunoassay was developed for secretory component, a glandular epithelial cell product secreted as an accessory protein with dimeric immunoglobulins A and M. Forty-four normal women between the ages of 40 and 70 had plasma concentrations of secretory component of 7.195 μg/ml ± 3.590 (±2 SD). Of the 37 patients with metastatic breast cancer of epithelial origin, 34 (91.9%) had plasma concentrations greater than 8.990 μg/ml; 29 (78.1%) had plasma concentrations greater than 10.785 μg/ml; 10 (27%) had concentrations greater than 15.000 μg/ml; and 3 (8.1%) had concentrations greater than 22.710 μg/ml. Serial plasma concentrations (averaging 3.48 per patient) of 35 (94.6%) of these patients reflected the clinical course of the disease. All patients had some combination of surgery, radiation therapy, and chemotherapy. No direct correlation was noted between the type of therapy and concentration of secretory component. However, plasma secretory component served as a marker in the systemic circulation of a change in the status of the metastatic breast cancer. The impact of this research may lie in its incorporation into clinical management. (AM. J. OBSTET. GYNECOL. 134, 899, 1979.)

DESPITE INTENSIVE INTEREST, the goals of early diagnosis and subsequent monitoring of the progress of patients with breast carcinoma have not been achieved. The possibility of tumor markers for this dynamic disease has been suggested.[1, 2] Free secretory piece (FSP), an epithelial secretory protein, provides another potential opportunity to monitor the status of mammary carcinoma.

Recent laboratory investigation has shown an increase in FSP in several epithelial malignancies such as in the colon, lung, breast, bladder, and ovary.[3–5] After an increased plasma concentration of secretory component in patients with metastatic breast cancer of epithelial origin was hypothesized, the need arose for the development of a reproducible radioimmunoassay of high specificity and sensitivity for secretory component. The goal of this research was to develop a reproducible, specific, and sensitive radioimmunoassay for secretory component in the peripheral blood and relate the concentration to the clinical status of the patient.

From the Departments of Obstetrics and Gynecology, Surgery, and Immunology, Duke University Medical Center.

Presented by invitation at the Forty-first Annual Meeting of the South Atlantic Association of Obstetricians and Gynecologists, Hot Springs, Virginia, January 28-31, 1979.

Reprint requests: Dr. Stanley A. Gall, Box 3313, Duke University Medical Center, Durham, North Carolina 27710.

Material and methods

Purification of FSP. FSP was purified from human colostrum by the procedure of Kobayashi,[6] incorporating ammonium sulfate fractionation, ion exchange chromatography, and gel filtration. Protein fractions were followed spectrophotometrically at 280 nm and the method of Lowry and associates,[7] revealed the protein concentration of FSP to be 1.4 mg/ml. Contaminating lactoferrin was removed[8] and sodium dodecyl sulfate polyacrylamide gel electrophoresis revealed a singular band for the purified FSP.[9]

Production of antisera to FSP. Rabbits were injected subcutaneously with 1 mg FSP in complete Freunds' adjuvant weekly for 6 weeks. On the tenth week another dose was given. Eight days later, serum was drawn and absorbed with 120 mg lyophilized normal human plasma per milliliter serum. Immunodiffusion detected the anti-FSP activity and aliquots were stored

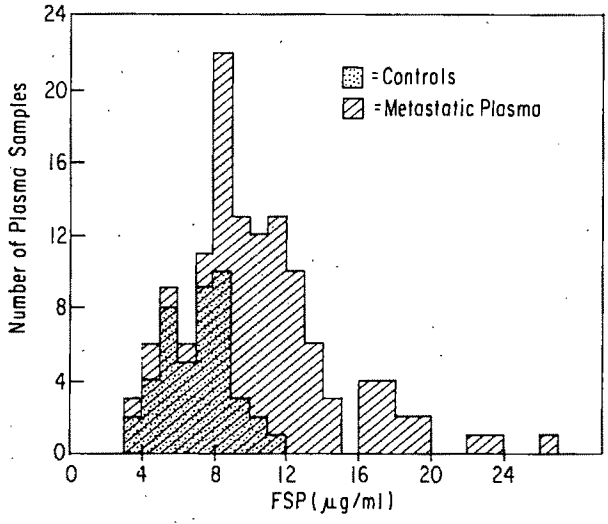

Fig. 1. FSP concentration and distribution in control patients and patients with metastatic disease.

at −20° C. When tested, this antiserum proved to be of the same potency as that obtained commercially.*

Labeling of FSP. The chloramine-T procedure was employed to label 98 mg (70 ml) of FSP with ^{125}I.[10] The labeled antigen was purified through a Sephadex G-50 column; the nonspecific protein fraction and the free ^{125}I fractions were discarded.

Determination of assay concentration of antiserum. Ammonium acetate, 0.1M, and albumin, 1 mg/ml, with sodium azide was employed to serially dilute the antibody in polypropylene tubes. Goat serum, 0.25 μl, was added to each dilution and incubated at 4° C overnight. Then 100 μl labeled antigen was added to each tube, incubated at 37° C for 4 hours, and total gamma emission/minute elicited. Precipitates were washed with Kynar† goat anti-rabbit–coated polymer beads. Kynar, 0.5 ml, was added to each tube, incubated at room temperature for half an hour, and mixed on a Vortex mixer every 10 minutes, and gamma emission/minute was again elicited. The percent bound to total counts was plotted, determining the assay concentration of antisera at 1/500.

Standard curve of precipitation. A two-stage inhibition curve for serial concentrations of cold FSP (0 to 50 ng) was prepared with each assay. Ammonium acetate, 0.1M, and albumin, 1 mg/ml, with sodium azide corrected the volumes to 500 μl. Antisera, 100 μl, was added to each tube and quenched with 25 μl goat serum. After incubation at 4° C overnight, 100 μl labeled antigen was added to each tube and gamma emission was noted. Optimal incubation proved to be 37° C for 4 hours. Precipitates were washed via the previously described Kynar procedure.

Samples. Serial plasma samples were obtained from 37 randomly selected patients with metastatic breast cancer from the Duke University Medical Center Department of Surgery. Plasma samples from 44 age-matched control subjects were obtained from the Columbia-Presbyterian Medical Center Department of Surgery. Samples were stored at −20° C and assayed in a double-blind manner. Clinical information was obtained directly from hospital records. All cancer patients had some combination of surgery, radiation therapy, and chemotherapy.

Assay procedure. Plasma samples, thawed at room temperature for 1 hour to avoid cryoprecipitate interference, were diluted 1/3,200. The sequential inhibition assay consisted of the addition of 100 μl of a 1/500 dilution of antisera with incubation at room temperature for 18 hours. Subsequently 100 μl labeled antigen was added with incubation at 37° C for 4 hours to reach equilibrium. The Kynar wash procedure was then employed.

The antigen proved to be stable and the reproducibility of the procedure was ±2%. Experimentation revealed that reduction and alkylation of the plasma samples as a pretreatment destroyed more antigenic sites than it freed. Alkylation alone had no effect on the data, suggesting that there was no consequential bonding of the label to nonspecific proteins or free immunoglobulins.

Results

Correlation of the plasma secretory component concentrations with the relative clinical information revealed the control range to be 7.195 μg/ml ± 3.590 (±2 SD) (Fig. 1). All samples tested with FSP concentrations greater than 11.185 μg/ml were from patients with a history of metastatic breast cancer. No correlation was noted between age, race, or type of therapy.

The patients with progressive metastatic breast cancer are a different population than the control subjects (Fig. 2), while FSP concentration is similar in control patients and in asymptomatic metastatic breast cancer patients (Fig. 3).

In some of the cancer patients, FSP concentrations were within the normal range despite active disease. Serial samples, however, reflected clinical improvement, stability, or progression.

Serial plasma FSP concentrations did not reflect the clinical status of two patients in this study.

Three illustrative cases are presented: the first with cancer progression, the second with positive response to chemotherapy, and the third with secretory compo-

nent concentrations monitoring the clinical course despite the absolute concentration being within the normal range.

Case reports

Patient A. This patient was treated with a radical mastectomy for medullary breast carcinoma and four of 22 lymph nodes were positive. Examination 10 months after operation was normal and FSP concentration was 10.880 μg/ml. The clinical condition remained stable and FSP concentration varied between 10.070 and 10.880 μg/ml. Seven months later, while she was hospitalized for evaluation of an axillary mass which proved to be a breast cancer metastasis, the FSP concentration was 19.200 μg/ml. Three weeks later she was discharged for terminal care by the family with a diagnosis of obstructive jaundice secondary to abdominal metastases. The FSP concentration at that time was 26.600 μg/ml.

Patient B. This patient, initially seen 2 years after radical mastectomy for papillary intraductal carcinoma with a positive liver scan, had a FSP concentration of 23.75 μg/ml. During the subsequent 3 weeks she had a beneficial response to chemotherapy and FSP concentration decreased to 17.930 μg/ml. A liver scan performed 2 weeks later revealed a decrease in metastatic lesions and FSP was 16.00 μg/ml.

Patient C. This patient underwent a radical mastectomy for mammary adenocarcinoma and six of 15 lymph nodes were positive. Initially she responded exceptionally well to chemotherapy and had a FSP concentration of 4.480 μg/ml. Within 3 months, however, metastatic pulmonary nodules appeared and FSP concentration had risen to 8.320 μg/ml. Chemotherapy was changed because of further progression. During the following 3 weeks her clinical status improved and FSP concentration decreased to 8.00 μg/ml. During the next 6 weeks she was asymptomatic with FSP concentrations of 5.600 and 5.300 μg/ml. However, the clinical condition deteriorated 5 months later and FSP concentration rose to 14.400 μg/ml. She subsequently developed abnormal liver chemistry tests and FSP concentration rose to 17.280 μg/ml.

Comment

Secretory component (molecular weight 70,000)[11] is believed to be a glandular epithelial cell product secreted as an accessory protein with dimeric immunoglobulins A (IGA) and (IGM) and containing a j chain. The immunoglobulins and j chain are synthesized by plasma cells.[11, 12]

Bound j chain is required for specific noncovalent bonding of secretory component to immunoglobulin.[13] The functions of secretory component are related to a homing mechanism for IgM polymers greater than 19S and for IgA, mediation of IgM and IgA travel through

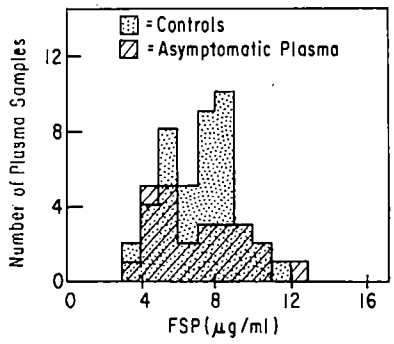

Fig. 2. FSP distribution in control patients and treated, asymptomatic cancer patients.

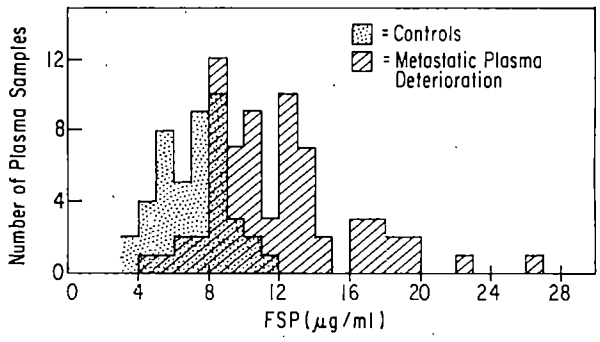

Fig. 3. FSP Distribution in control patients and cancer patients with progressive disease.

the epithelium to the lumen, and protection of the secreted immunoglobulin from proteolytic digestion.[14] Secretory IgA is the first line of defense against microbial invasion of mucous membranes.[11]

There are three antigenic sites on the secretory component molecule: A_1, A_2, and I. The I determinant is the most reactive but is inaccessible when secretory component is part of the IgA dimer. This determinant is the most readily inactivated by reduction and alkylation.[15]

The work of Garcia and associates[16] was a stimulus to our research in analysis of cystic effusions of ovarian epithelial neoplasms. Harris and colleagues[3] showed by direct immunofluorescence intense FSP antisera staining in stromal tumor cells. Normal breast cells revealed staining only in normal ductal epithelium. These investigators also demonstrated intense fluorescent staining in 50% of the patients with axillary node metastases. A lack of fluorescence was noted for patients with sarcomas of the breast.

One can therefore postulate that the increased secretory protein in tumor samples from patients with epithelial cancers reflects either increased production by malignant cells or absorption onto the malignant cells after synthesis in remaining normal ductal tissue. In either case, FSP is locally more abundant in mammary

malignancies of epithelial origin than in the normal breast.

The radioimmunoassay studies strongly suggest FSP was being measured because of identical curves obtained from purified FSP and comparable plasma samples.

Beyond detecting 34 (91.9%) of 37 cancer patients as having, at some time during the disease, plasma FSP concentrations greater than the normal range, this assay monitored the course of 35 (94.6%) of the 37 patients. No false positive results were noted.

The clinically significant potential of this assay may lie in screening and monitoring of therapeutic response and prognosis. In all likelihood, no one assay will provide all the relevant information, as human chorionic gonadotropin does for choriocarcinoma, but a group of complementary assays may certainly follow overlapping subsets of the population in question.[2]

Discussion

DR. JOHN P. GUSDON, JR., Winston-Salem, North Carolina. The most significant advances that have been made in medicine are those which result in the eradication or significant decrease in the incidence of a disease. All of us have seen this happen in a number of diseases in which the etiologic agent has been identified. In a number of infectious diseases, immunization against that specific organism, or in the case of polio, those three organisms, has resulted in an almost total absence of the disease in the immunized populations. When the vector of a disease against which immunization is not feasible, such as yellow fever, has been identified and eradicated, the disease is "cured." In industry we have an example that is both pertinent to the topic of malignancy and current. The presence of high levels of asbestos in the atmosphere during the production of ships during World War II led to a significantly elevated incidence of bronchogenic carcinoma and mesothelioma in those shipyard workers. Stringent efforts, as a result of governmental regulations, to decrease the level of that agent in the atmosphere in shipyards have been effective in decreasing the incidence of those diseases. There are examples of preventive medicine at its best. This is the ultimate toward which we must strive.

However, for most diseases we are not yet there. Most of our time as physicians is spent in diagnosing and treating existing disease processes. Our limitations in the early diagnosis of a malignancy are known to all of us. Our frequently inadequate treatments are recognized and fully appreciated. Most physicians have felt the despair of seeing a malignancy progress. We must find a balance between the effects of our treatments, which are often very hard on our patients, and the disease process. For example, the addition of another chemotherapeutic agent such as adriamycin to the treatment regimen of a patient with Stage I carcinoma of the breast is certainly not warranted. It will probably do more harm than good. This, then, is the problem. What really is the true stage of the disease and is it progressing? These are the things we need to

know. This is the point at which the authors have developed an attack against carcinoma of the breast. This work is based on the discovery by Harris and colleagues (reference 3 of original paper) that the secretory piece of IgA existed in superabundance, as determined by histopathology, in various types of breast carcinomas. The authors questioned whether or not this would be reflected by an increase in the circulating secretory piece and whether or not the levels might reflect the clinical status of the patient.

They have, therefore, developed a radioimmunoassay for this substance and applied it to breast carcinoma patients. The relationship between the course of the disease and the level of circulating secretory piece is clear. The study was well founded and well done. I believe that we now have one more tool to use in our appraisal of the status of the disease in patients with carcinoma of the breast. I congratulate the authors of this paper.

Information for authors

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. Therefore, all manuscripts must be accompanied by the following written statement, signed by one author: "The undersigned author transfers all copyright ownership of the manuscript (title of article) to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

Maternal transport: Behind the drama

MICKI L. SOUMA, M.D.
Columbus, Georgia

Despite a lack of proof that overall perinatal outcome is improved, physicians and patients participate in a growing regional maternal transport program in a community hospital setting. Over the course of 3½ years, 129 patients were transferred from 23 institutions. Maternal transport and the changes which result in the interactions of the physicians are compared to traditional referral systems. Obstacles and guidelines for minimizing them are discussed. (AM. J. OBSTET. GYNECOL. 134:904, 1979.)

MATERNAL TRANSPORT is not new. Mothers have been brought for years from small hospitals to obstetric centers because of serious maternal problems necessitating personnel, equipment, and expertise beyond the capabilities of small institutions. The newer component of maternal transport is fetal transport, which involves moving mothers (who are usually relatively healthy) to a center in order to accomplish delivery in proximity to a nursery able to care for a potentially sick newborn infant.

The development of maternal transport for the latter purpose has followed a retraceable course: The value of neonatal intensive care units in reducing perinatal deaths was documented, and this advantage was extended to neonates born outside the institution of the specialized nursery through neonatal transport.[1-3] A logical assumption was made that the newborn infant would fare better if transported to the perinatal center in the atmosphere of the warmth, oxygen, and nutritive supply of the uterus rather than after delivery. National guidelines were developed for future coordination of such activities within an area.[4] Early reports have been promising. For example, local methods of maternal transport programs in Arizona and Colorado have been published and overall encouraging outcomes have been described.[5-7]

Transport activity traditionally brought drama to the small community, awed by the helicopter and the reports of the modern care miles away. It brought pride to the center and its personnel by recognition of their unique services.

However, the now increased activity of transferring a patient (soon to be two patients) from one institution to another has brought with it subtle changes in the interaction of physicians. These changes affect care and are worthy of attention since they are representative of changes occurring with regionalization of medical care in general. These changes make the overall success and growth of maternal transport the more impressive because of obstacles seemingly overcome.

The purpose of this paper is to present a unique community hospital–based maternal transport program as background for describing the observed changes in interaction of participants during the course of development of such a program. The observations are based on discussions with physicians, personnel, and patients.

Material and methods

The perinatal center at the Medical Center, Columbus, Georgia, has one of the five recognized newborn intensive care units of the state. The unit's early influence on the institution's perinatal mortality rate has been previously reported.[8] Newborn transport promptly followed the nursery's development. Prior to 1975, maternal transports were for traditional maternal indications and were arranged by calls directly to community physicians of choice or through the house staff (Family Practice Training Program). As fetal transport requests began in 1975, a program was developed to formalize the transport activities.

Maternal transports are received from a referral region of southwest Georgia and eastern Alabama. Receiving physicians are six obstetrician-gynecologists: two full-time hospital-based faculty in a Family Practice Training Program, two in private solo practice, and two in private group practice. Scheduling enables indi-

vidual members of a group to participate without obligating all members. Calls for a transport are received in the Labor and Delivery Unit and are referred to the physician on call by use of a posted monthly roster. House staff participate actively in patient care but all transports must be personally authorized by the transport obstetrician-gynecologist. All patients are considered private patients regardless of the source of payment. The receiving physician first determines whether the transport pediatrician will be able to accept the potentially sick newborn infant. (Four pediatricians, one of whom is a neonatologist, are on call by a similar roster.) He then determines whether there are sufficient maternal beds to ensure adequate personnel coverage of all patients for whom the unit is responsible. Upon acceptance of a patient, the referring physician is asked to supply all records (including fetal monitor tracings and x-ray films) and provide a medical professional to accompany the patient (one-way transport). The patient is not considered the legal responsibility of the receiving institution and physician until admission at the door. Ambulance is the usual method of transfer but other methods range from helicopter (Military Assistance to Safety in Traffic of Fort Benning, Georgia) to family car.

At the receiving institution, family support is provided by personnel including maternal and newborn social workers. Financial status is reviewed for eligibility in state funding programs which by specific guidelines support optimum care of the high-risk patient.

An attempt is made to report to the referring physicians upon stabilization of the patient, delivery, change in newborn status, and dismissal. Discharge summaries are forwarded.

When a transport cannot be accepted, the transport physician assists the referring physician with alternative plans for maternal and newborn transport to another institution as needed.

Results

From June 1, 1975, through November 30, 1978 (42 months), 129 patients were accepted in transfer from 23 institutions. Communities sending patients in transport are listed in Table I. In the last 17 months of that time, transports "turned down" were documented as 20 for 58 accepted, or a ratio of approximately 1:3. Accepted transports increased over the 3½ years so that the number in the last 7 months of the program equalled that of the entire first year.

The reasons for transfer are listed in Table II, the majority being for the fetal indications of premature labor and premature ruptured membranes. The reasons for inability to accept the transport of 20 patients documented during the recent months of the program are indicated in Table III.

The reasons for no newborn beds included a full census, a shortage of beds because of remodeling, and closing of the unit because of an outbreak of bacterial infection. Maternal beds were also limited at times because of high census or remodeling.

On occasion patients who would need to be trans-

ferred across the Georgia-Alabama state line were assisted in transfer to an Alabama center. Patients at less than 26 weeks' gestation were not accepted in the transport program for fetal indications only. An error in estimating gestation necessitated one subsequent neonatal transport. One patient with conjoined twins was referred to a University Center for management.

The outcome of the 129 pregnancies is presented in Table IV. Twenty-eight or 21.7% of the patients were dismissed for return to the referring institution or home. Of those 101 delivered, four fetal deaths occurred prior to transport. There were no posttransport fetal deaths. There were 17 neonatal deaths.

Most undelivered patients were dismissed as a result of successful control of premature labor. Others represented initial management for problems not yet warranting delivery. Of the 28 undelivered patients, eleven returned to the center for delivery and 15 were delivered elsewhere (Table V). The perinatal losses included one fetal and one neonatal death secondary to abruptio placentae. Both maternal patients had been hospitalized for several days during the earlier transport, for third-trimester bleeding. Of the 15 patients delivered elsewhere, two newborn infants required neonatal transport back to the center.

The overall perinatal mortality rate of the 127 delivered transported patients was 186.9 in comparison to 23.7 for the institution's total inborn population for the same time period. The perinatal mortality rate is defined as the sum of fetal and neonatal deaths occurring after 20 weeks' gestation or in infants weighing 500 grams or greater and newborn deaths occurring in the first 28 days of life per thousand live births.

Of the 102 live births occurring after the first transport, the predicted neonatal mortality risk using the classification published by Lubchenco and co-workers,[9] in 1972, is 24.7. The actual neonatal mortality rate was 16.7%.

The cesarean section rate of the transported patients was 33.0% for the 122 patients delivered at the Medical Center. The cesarean section rate for the institution's total deliveries during the same time period was 16.4%.

Comment

The activities of the transport program described here are similar to those previously reported in reasons for and methods of transfer.[6, 10] The percentage of undelivered patients (21.2) is remarkably similar to that reported by Brown[6] in describing the outcome of patients transported to Fitzsimons Army Medical Center (20.8). Interpretation of the overall perinatal mortality rate of this high-risk group of patients will be discussed following a commentary on the attitudes encountered in participants.

The referring physician. In the past the referring physician identified a problem beyond his institution's or his own capabilities. He then selected an institution and physician with those capabilities for transfer of his patient. His selection was based on geographic considerations, friendship, respect, prior handling of cases, his patient's own choice, and intangible aspects including fitting the personality of the patient to that of the physician. This usually necessitated a single phone call. The patient usually automatically transferred confidence to the new source of care by virtue of the need for the care and the selection process.

This has been changed. Attempts to refer by the old system may well be met with: "I would be happy to take your patient but we have a program now and Dr. X,

whom you do not know, in another group is on today" or "I would be happy to take your patient but the pediatrician will not accept the newborn infant because of commitments to eight other sick newborn infants" or "I would be happy to take your patient as I have done for the last 5 years but unless she is prepared to pay several thousand dollars we will be doing her a favor to assist in sending her to the center in your own state."

The one-to-one choosing of a physician by a patient or her personal physician is lost in the system. If the referring physician still had the prerogative to select, he might well choose a different institution for the baby than that preferred for the mother, the latter being influenced by private-practice competitiveness for his patient's future care (especially in short-distance urban transports) and by personal niceties available for the adult patient.

The referring physician is usually fully capable of delivering his or her patient. (Note that 74% of the referrals in our program were for indications of premature labor or premature ruptured membranes alone.) He may take pride in the ability to perform an even better delivery than could be done at the referral institution (certainly true if there is house staff participation in the care). Decisions regarding methods of care such as aggressive or conservative management of ruptured membranes are delegated to others with different approaches unless the impractical route is chosen of traveling to the site to make use of courtesy privileges. Even if all calls and records reach him, the physician has a disappointing loss of contact and personal experience with his patient.

When a decision is made to transfer despite all these obstacles, frustration is enhanced when the transport is turned down.

The receiving physician. In the old system, the receiving physician felt pride in being able to offer expertise and pride in his (or his institution's) being selected. Good-quality provision of care and detailed feedback strengthened ongoing referrals with the referring physician. In that atmosphere, the patient greeted him with confidence. Decisions to decline a case were a matter of personal conscience.

In the new system, the receiving physician is most frequently asked to accept a healthy patient in order subsequently to provide a sick patient to another physician. If the patient is not completely healthy, at times her obstetric problems (such as pre-eclampsia) have been managed for days by methods unlike his own, only to be referred at the point of decision for delivery with even the method of delivery selected. In a program in which it is the receiving pediatrician who authorizes the transport, the receiving obstetrician's sense of being only a technician, a necessary processor, is further heightened.

Table VI. Maternal transport sample telephone log

Accepted Maternal Transport
1. Notified of call by Labor and Delivery Unit. Checks on bed status of unit
2. Returns call to referring physician. Request for transfer placed
3. Calls Neonatal Intensive Care Unit to determine bed status
4. Calls pediatrician on call who authorizes use of last bed
5. Calls back referring physician, accepting patient and reviewing transfer of records and care
6. Notifies Emergency Room of anticipated ambulance arrival
7. Notifies Admitting Office
8. Notifies house staff and other participating personnel

Turned Down Maternal Transport
1. Notified of call by Labor and Delivery Unit
2. Calls Intensive Care Nursery to determine bed status
3. Calls pediatrician to request exception (exception not possible)
4. Returns call to referring physician, turning down transport and offering to assist transfer elsewhere
5. Calls second unit (repeat process, transfer accepted)
6. Notifies referring physician of acceptance, helicopter transport selected
7. Calls helicopter service (formal telephone application process)
8. Notifies referring hospital of estimated arrival time
9. Notifies receiving hospital of estimated arrival time

No referral can be handled by a single phone call. In fact, when it becomes necessary to turn down a transport, the receiving physician is often faced with as much time investment as required in accepting a patient (Table VI), work which often cannot be delegated to others, at least 24 hours a day. The turning down of a case in itself is difficult for physicians who in the old system correlated not taking a patient with laziness. The feeling of guilt is magnified when the outcome later reported for the turned-down case is perinatal death. On the other hand, patients who may have been declined in the past may be accepted for the sake of supporting an overall program (such as a patient in premature labor with a nonviable gestation).

"Transport back" brings a completely new experience in obstetrics as the "higher" center bears the responsibility for judgment in transfer. Errors in judgment occur, resulting in perinatal loss and exposing the human components of the system.

Finally, the receiving physician discovers a new responsibility for financial survival of the institution of the program. Local patients with uncomplicated pregnancies, who provide a major source of income, need their rightful priority. In a day when a source of payment for all bills must be identified, transports 100 miles across a state instead of 5 miles across a state line may be fairer to the patient.

The mother. Separated from her family, her own doctor, her locale, her expectations, she travels, often medicated, on a nightmare ride to be greeted by strangers and a bill she cannot pay, often with no baby to show for the anguish.

With all these obstacles, why do we continue, why is maternal transport an increasing activity?

The newborn infant. Does maternal transport offer an advantage to the newborn infant? Reliable data are lacking. Random comparison of maternal and newborn transports is affected by the automatic selection which occurs with newborn transport: exclusion of the very sick or very well after direct observation of the neonate. Merenstein and associates,[5] minimizing this influence by evaluating the entire population of two referring hospitals, showed a benefit of in utero transfer.

The Lubchenco neonatal risk scoring as used by Harris and colleagues[7] to compare maternal and newborn transports suggests an impressive advantage of maternal over newborn transport. His maternal transport neonatal loss was 60% of that predicted while neonatal transport loss was 1.26 times greater than predicted. Our program's maternal transport results compare favorably with those in the Arizona report, in that the neonatal mortality rate was 68% of that predicted. A comparison with newborn transport in our referral area during the same time period was not made.

This method, while reassuring that maternal transport does not negatively affect outcome, does not clarify the reason for the apparent advantage.

In our country's present system of care, maternal transport patients compared with newborn transport patients most often come from practices using more sophisticated methods. Even if maternal transports were evaluated within a single care system, they are preselected as those patients in whom delivery can be delayed long enough to allow travel. It may be the delay of delivery itself, not the transport, which provides the benefit.

The only meaningful study would be an impractical series prospectively alternating maternal transport versus newborn transport. Similar information may eventually be gleaned from comparison of accepted maternal transports with turned-down maternal transports which necessitate subsequent newborn transfer.

Despite the limitations in adequate evaluation of outcome, additional benefits of maternal transport cannot be denied. The mother remains with the baby, enabling development of maternal attachment.[11] Hunter and associates[12] showed victims of child abuse who survived neonatal intensive care had fewer visits by their parents in the nursery.[12] Furthermore, maternal transport is simply easier. Even if precautions must be taken for delivery en route, the investment in personnel time and cost cannot approach that of stabilization of a neonate during travel.[13–16]

These benefits seem a sufficient incentive for all participants to overcome the frustrations of a new system of care.

Suggested guidelines to improve interaction are as follows:

1. Community education about regionalized medical care so that transfer is not a shock to the patient and her family.

2. Educational program exchange between referring and receiving personnel to share management perspectives in order to merge the care of the patients into a single system.

3. Preagreed medical reasons for accepting or turning down a transport and preagreed nonmedical criteria for a closed unit and an alternate plan for patients seeking care.

4. Transfer of the patient's confidence from physician to physician and back again.

Discussion

DR. JOHN S. INMAN, JR., Albany, Georgia. Optimum health care must be made available to all patients and to accomplish this goal the concept of regionalization has been developed. It is imperative that infants delivered of high-risk mothers immediately receive appropriate intensive care. To accomplish this goal it would be beneficial if the high-risk mother could be identified early in the course of her pregnancy and later transferred to a regional center where she could receive specialized care: her newborn baby could then be admitted to the high-risk intensive care nursery.

Dr. Souma has described the program of the Columbus, Georgia, Medical Center, one of the five Level III hospitals in the state of Georgia. Theoretically, a regionalization program should work smoothly because of our modern transportation system. Fortunately with the use of military helicopters and community ambulances all patients can be transported quickly to a Level III center.

There are many problems that must be overcome to make a regionalization system work. First, the attending physician must be convinced that his patient and her baby could receive better care at the Level III hospital. He should be very familiar with the program, so he could "sell" the patient on the idea of a transfer to another city. The attending physician should not have selfish motives and must be willing to transfer his private patient to the Level III physician. Second, the patient and her family must be "sold" on the idea of being transferred to a medical center some hundred miles from home. Many adjustments have to be made at home if the mother is to be away for several weeks.

In order to transfer a patient beds must be available for both mother and newborn baby. If beds are available then the transfer gets underway. If no beds are available the local physician has problems. Either he must try another Level III center or he must keep the patient and deliver the baby. This is hard for the family to understand and really puts the referring physician on the spot after he has convinced the patient and her family that she should be transferred. This can be a problem! Dr. Souma stated that in the last 17 months 20 referrals were declined and 58 accepted, approximately one patient declined for every three accepted.

To make a regionalization system work the community physician should know or at least know of the Level III physicians. A private physician–to–private physician relationship must be developed. Frequent communications by letter and by telephone are a necessity.

It takes time and much money to overcome many of the obstacles of a regionalization program. A similar program has worked well in the military services for many years. A military patient could be transferred from the small station hospital to the large general hospital with all its modern facilities and specialists with the greatest of ease. A similar program could be made to work for civilians. At no time, however, must the family physician feel that the obstetrician is trying to take his patients.

I am sure Dr. Souma would like to be able to accept more patients. Are there any plans for enlarging your facilities for both mother and baby? It seems to me declining one of four requests is rather high. This is indeed discouraging to the referring physicians.

Some physicians in our area do not understand the regionalization program and are reluctant to transfer their patients to another city. It would be helpful to have an educational program not only for physicians but also for patients. High-risk patients must be identified early in pregnancy and the staff of the regional centers must make themselves available for advice and consultation, not just for referral. I think it would be of great value if a physician and nurse could visit each medical community or hospital in southwest Georgia and explain the role of the tertiary care center. This would increase the number of referrals and in time decrease the perinatal mortality rate in our area.

As Dr. Souma has stated maternal transport with the fetus in utero is much better than newborn transport in reducing perinatal deaths. This makes it well worth the effort to create a system that satisfies both the referring and receiving physicians.

Dr. Souma, it is comforting to know that you are 85 miles away by highway or just 45 minutes by helicopter.

DR. PRESTON LEA WILDS, Norfolk, Virginia. Dr. Souma has drawn a distinction between maternal transport for maternal indications and maternal transport for fetal indications. The emotional impact of this

distinction is important only to obstetricians. For the mother, the nightmare ride, the care by strangers, the separation from familiar surroundings, and the anxiety over the outcome are all the same. There are cases where transfer of the mother is advisable for both maternal and fetal indications, but in cases where early delivery of the fetus is the only special risk, the mother indeed may be the transport vehicle for the fetus.

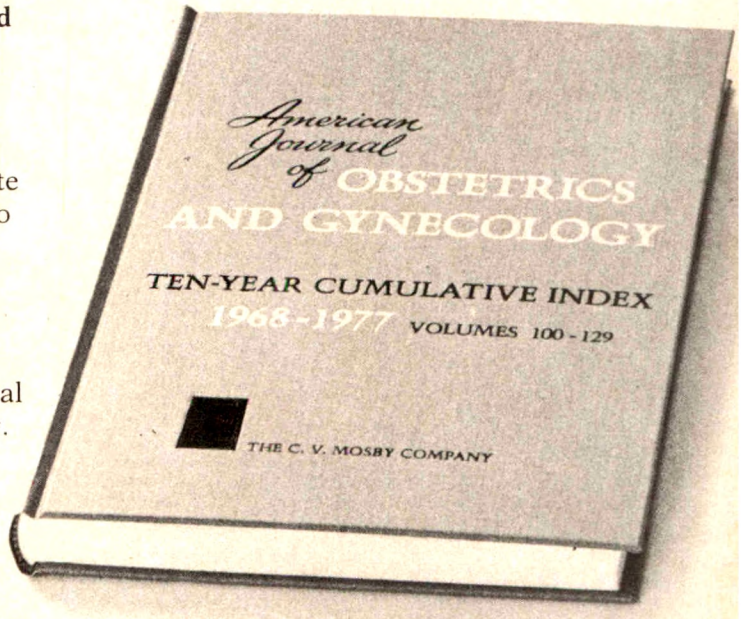
The relative safety of fetal transport, with the mother as the vehicle, and neonatal transport, in which the vehicle is an appropriately equipped and staffed mobile intensive care unit, cannot be separated from the availability of specialized care to prevent perinatal asphyxia. Prevention of this asphyxia prior to birth is an obstetric responsibility. The quality of this care is seldom sufficient reason to justify fetal transport. The obstetrician working in a community hospital with limited resources can be as skilled in the detection and prevention of asphyxia in management of labor and delivery of the premature infant as the obstetrician in the medical center working with the assistance of a team of residents.

The critical difference between fetal and neonatal transport, which may affect perinatal outcome in the small premature infant, is skillful treatment during the first few minutes after birth. Asphyxia at this time greatly increases the likelihood of respiratory distress syndrome and intracranial hemorrhage. These and other complications in surviving infants can lead to prolonged crippling disorders such as bronchopulmonary dysplasia and impaired neurological development.

The immediate care of the infant born early in the third trimester requires special skills including manual dexterity and instant expert judgment, as well as all the proper equipment immediately available. The skills are easily lost unless they are practiced frequently. Most obstetricians and pediatricians, usually working with healthy, term infants, have inadequate opportunities to develop these skills and to maintain them at the necessary state of readiness. A medical center, where large numbers of premature infants are delivered and where a neonatologist is available to attend each delivery, can provide facilities in staffing to reduce the risks of neonatal asphyxia. It can also offer continuity of care to the premature infant and can often involve the mother as a participant in that care from the very beginning. These advantages are denied to the infant who is transferred to the medical center while the mother remains in a hospital elsewhere.

At the medical center in Norfolk, the nurseries connected with the labor and delivery unit have recently increased their intensive care capacity two and a half times. There has been no observable decrease in the pressure for beds, but there has been a shift in policy toward maternal transports. Requests for maternal transport are given priority over requests for neonatal transport and are usually accepted even when the nurseries are full or perhaps overloaded. Under these circumstances, acceptance of a maternal transport often requires a simultaneous reverse neonatal transport, in which a premature infant who is doing well is moved to an intermediate nursery elsewhere to make space available in the intensive care unit. The team of neonatologists has agreed to make these arrangements on an emergency basis in order to prevent denial of a maternal transport. As a consequence, in the past 3 months we have had to deny only one of 60 requested maternal transports because of lack of space.

A neonatologist attends each maternal transport delivery and is available on request for all other high-risk deliveries, including those where an attending pediatrician or chief pediatric resident is also present. These efforts on the part of the neonatologist to minimize perinatal asphyxia in all infants born at the medical center perhaps will lead to improved acceptance and understanding within the community of the benefits of maternal transport for fetal indications and, in time, may lead to further improvements in the outcome of pregnancy.



Dr. Souma has observed a continuing increase in the number of maternal transports, from relatively small beginnings, over a period of 42 months. I wonder, was there a point as the frequency of transports increased at which her perinatal team was getting sufficient practice in special skills to provide a stable level of optimum care for each small premature infant?

New! Available for the first time

The ten-year **cumulative author and subject index** to volumes 100-129 (1968-1977) of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY is now available for your journal collection. It is a complete and comprehensive reference guide to over 28,000 pages of authoritative articles published in the Journal during the past ten years.

The world-renowned "Gray Journal" is the oldest specialty journal devoted to obstetrics and gynecology.

Now these influential papers, appearing between 1968-1977, have been cross-referenced to include over 23,100 subject entries. Each entry lists the complete article title, author(s), volume, page, and year of publication.

The author index lists more than 13,850 contributors from this period, along with respective article title, author-to-author referral, volume, page, and publication date.

The 479-page index is handsomely presented in a rust and gold cloth-cover volume. It is a must for every library concerned with obstetrics and gynecology. Send for your copy of this valuable reference today!

479 pages, 8¼" × 11", price $28.75

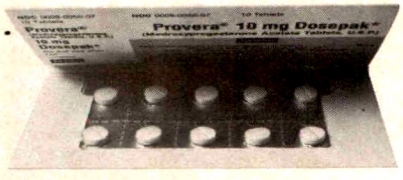
Upjohn

She may need progesterone too.

Breakthrough bleeding is a common complication of estrogen replacement.

Provera® Tablets 10 mg/day for 10 days.



When the unopposed action of exogenous (or endogenous) estrogen causes abnormal uterine bleeding in the perimenopausal woman, Provera, 10 mg a day for 10 days, transforms the estrogen-primed endometrium into a secretory endometrium. Optimum shedding of the endometrium follows cessation of therapy with Provera.

First, rule out organic pathology.

Abnormal uterine bleeding at any age calls for a thorough gynecologic examination. Only after organic causes have been ruled out can the bleeding be attributed to the action of exogenous or endogenous estrogen.

Additional clinical considerations.

Progestational agents should not be used during the first four months of pregnancy, as a diagnostic test for pregnancy, nor in women with liver dysfunction or disease, known or suspected malignancy of breast or genital organs, or a history of thrombophlebitis or pulmonary embolism.

The Dosepak* dispenser helps patients comply with your instructions...provides ten, 10 mg tablets for the ten days of therapy recommended

Provera® 10 mg Dosepak* Medroxyprogesterone Acetate Tablets

Please turn the page for additional prescribing information.

© 1979 The Upjohn Company

To control abnormal uterine bleeding in the absence of organic pathology

Provera® Tablets
2.5 & 10 mg
Medroxyprogesterone Acetate Tablets, USP, Upjohn

WARNING

THE USE OF PROGESTATIONAL AGENTS DURING THE FIRST FOUR MONTHS OF PREGNANCY IS NOT RECOMMENDED.

Progestational agents have been used beginning with the first trimester of pregnancy in an attempt to prevent habitual abortion or treat threatened abortion. There is no adequate evidence that such use is effective and there is evidence of potential harm to the fetus when such drugs are given during the first four months of pregnancy. Furthermore, in the vast majority of women, the cause of abortion is a defective ovum, which progestational agents could not be expected to influence. In addition, the use of progestational agents, with their uterine-relaxant properties, in patients with fertilized defective ova may cause a delay in spontaneous abortion. Therefore, the use of such drugs during the first four months of pregnancy is not recommended.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies including congenital heart defects and limb reduction defects. One study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 in 1000.

If the patient is exposed to Provera (medroxyprogesterone acetate) during the first four months of pregnancy or if she becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus.

DESCRIPTION AND ACTIONS: Medroxyprogesterone acetate is a derivative of progesterone. Administered orally or parenterally to women with adequate endogenous estrogen it transforms proliferative endometrium into secretory endometrium.

INDICATIONS: Secondary amenorrhea; abnormal uterine bleeding due to hormonal imbalance in the absence of organic pathology such as fibroids or uterine cancer.

CONTRAINDICATIONS: Thrombophlebitis, thromboembolic disorders, cerebral apoplexy or patients with a past history of these conditions. Liver dysfunction or disease. Known or suspected malignancy of breast or genital organs. Undiagnosed vaginal bleeding. Missed abortion. Known sensitivity to medroxyprogesterone acetate. As a diagnostic test to pregnancy.

WARNINGS: 1. Immediately discontinue administration should any of the following thrombotic disorders occur or be suspected: thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis. **2.** Beagle dogs treated with medroxyprogesterone acetate developed mammary nodules, some of which were malignant. Although nodules occasionally appeared in control animals, they were intermittent in nature; whereas the nodules in the drug-treated animals were larger, more numerous, persistent, and there were some breast malignancies with metastases. Their significance with respect to humans has not been established. **3.** Discontinue medication pending examination if there is sudden partial or complete loss of vision, onset of proptosis, diplopia, or migraine. If papilledema or retinal vascular lesions occur, withdraw medication. **4.** Detectable amounts of progestin have been identified in the milk of mothers receiving the drug. The effect of this on the nursing infant has not been determined. **5.** Usage in pregnancy is not recommended (See Warning Box). **6.** Three major studies in Great Britain and one in this country have shown a statistically significant association between thrombophlebitis, pulmonary embolism, cerebral thrombosis and embolism, and the use of oral contraceptives. It has been estimated that users are several times as likely to undergo thromboembolic disease without evident cause as nonusers. The American study indicated that the risk did not persist after discontinuation and it was not enhanced by long continued administration.

PRECAUTIONS: A pretreatment physical exam should include special reference to breast and pelvic organs and a Papanicolaou smear. This drug may cause fluid retention, therefore, observe carefully patients with conditions influenced by fluid retention such as epilepsy, migraine, asthma, and cardiac or renal dysfunction. In irregular bleeding per vaginum, bear in mind nonfunctional causes and perform adequate diagnostic measures. Advise pathologist of therapy when submitting relevant specimens. Carefully observe patients with history of psychic depression and discontinue drug if serious depression recurs. Any possible influence of prolonged therapy on pituitary, ovarian, adrenal, hepatic, or uterine function awaits further study. Decreased glucose tolerance has been observed in a small percentage of patients on estrogen-progestin combinations, therefore, carefully observe diabetic patients receiving progestin therapy. Age constitutes no absolute limiting factor, although onset of climacteric may be masked. Because of the occasional occurrence of thrombotic disorders (thrombophlebitis, pulmonary embolism, retinal thrombosis, and cerebrovascular disorders) in patients taking estrogen-progestin combinations and since the mechanism is obscure, the physician should be alert to the earliest manifestation of these disorders. (See Patient Information for complete prescribing information.)

ADVERSE REACTIONS: Pregnancy: (See Warning Box); **Breast:** rare reports of breast tenderness or galactorrhea; **Skin:** sensitivity reactions including pruritus, urticaria, edema and generalized rash; acne, alopecia and hirsutism in a few patients; **Thromboembolic phenomena** including thrombophlebitis and pulmonary embolism.

The following adverse reactions have been observed in women taking progestins including medroxyprogesterone acetate: breakthrough bleeding; spotting; change in menstrual flow; amenorrhea; edema; change in weight; changes in cervical erosion and secretions; cholestatic jaundice; rash (allergic) with and without pruritus; and mental depression.

A statistically significant association has been demonstrated between use of estrogen-progestin combination drugs and the serious adverse reactions of thrombophlebitis, pulmonary embolism and cerebral thrombosis and embolism. Therefore, patients on progestin therapy should be carefully observed.

Although available evidence is suggestive, a relationship has been neither confirmed nor refuted for the association of the serious adverse reaction of neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been observed in patients receiving estrogen-progestin combination drugs: rise in blood pressure in susceptible individuals; premenstrual-like syndrome; changes in libido; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; fatigue; backache; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; and itching. Therefore, observe patients on progestin therapy carefully.

The following laboratory results may be altered by the use of estrogen-progestin combination drugs: increased sulfobromophthalein retention and other hepatic function tests; coagulation tests (increase in prothrombin factors VII, VIII, IX and X); metyrapone test; pregnanediol determination; thyroid function tests (increase in PBI and butanol extractable protein bound-iodine, and decrease in T^3 uptake values).

HOW SUPPLIED: 2.5 mg in bottles of 25. **10 mg** in bottles of 25 and 100. MED B-11-S

Caution: Federal law prohibits dispensing without prescription.

A report of the safety and accuracy of midtrimester amniocentesis at the Medical College of Georgia: Eight and one half years' experience

PAUL D. MANGANIELLO, M.D.
J. ROGERS BYRD, PH.D.
PHUNG T. THO, M.D.
PAUL G. McDONOUGH, M.D.
Augusta, Georgia

HUMAN AMNIOTIC FLUID cells were successfully cultured and karyotyped in 1966.[1] The technique was used in the prenatal detection of chromosomal abnormalities starting in 1967.[2-4] The application of biochemical techniques to human amniotic fluid in 1968 extended the spectrum of detectable disorders to some inborn errors of metabolism.[4] In the following years, successful prenatal diagnosis was reported for a variety of isolated metabolic disorders.[5] Amniotic fluid alpha-fetoprotein (AFP) determinations for neural tube disorders (NTDs) in 1972 further expanded the indications for midtrimester amniocentesis.[6]

The success and increasing use of amniocentesis for prenatal diagnosis during this time span created the need to evaluate its safety and accuracy. In 1978, the findings of the collaborative study of the National Institute of Child Health and Human Development (NICHD) Amniotic Fluid Registry, created for this purpose, based upon 1,040 women who underwent diagnostic midtrimester amniocentesis, were published. The incidence of pregnancy loss was 3.5% in the amniocentesis group versus 3.2% in the control group. No clear evidence of direct fetal injury was reported from the nine participating centers. Maternal complications related to the procedure, such as transient bleeding and fluid loss, were reported to be 2%. Five incorrect cytogenetic diagnoses were discovered after delivery and one inborn error was incorrectly diagnosed. The overall accuracy rate of amniocentesis reported by these nine centers was 99.4%.[7]

Whether separate reports from different centers will confirm this collaborative study as to the safety and accuracy of prenatal diagnosis remains to be seen. This report is an 8½ year (June, 1969, to January, 1978) resumé of prenatal diagnosis at the Medical College of Georgia.

Material and methods

Patients were referred to the Medical College of Georgia for counseling and amniocentesis. The visit was scheduled between the fourteenth and eighteenth week of pregnancy, based upon the menstrual age provided by the referring physician. Preliminary ultrasonography has been routine since 1973. Maternal serum for AFP and Rh typing was obtained prior to the amniocentesis. The procedure has been performed utilizing a 20 gauge spinal needle by the attending physician or by a resident with the attending physician present. Supervision has been afforded by the same personnel since the inception of the study. The number of needle insertions per tap was not recorded in every instance. A minimum of 30 ml of amniotic fluid was removed and transported immediately to the adjoining laboratory for culturing. Fetal heart tones were documented and the patient was discharged. Rhogam was given routinely to unsensitized Rh-negative mothers. Subsequent patient and fetal follow-up was through correspondence directed to the referring physician.

Amniotic fluid cells were cultured in the Medical College of Georgia Cytogenetic Laboratory by standard techniques and stained routinely with Giemsa-trypsin

From the Department of Obstetrics and Gynecology, Reproductive Endocrine Division, and the Department of Endocrinology and Pediatrics, Medical College of Georgia.

Presented by invitation at the Forty-first Annual Meeting of the South Atlantic Association of Obstetricians and Gynecologists, Hot Springs, Virginia, January 28-31, 1979.

Reprint requests: Dr. Paul G. McDonough, Medical College of Georgia, Department of Obstetrics and Gynecology, Augusta, Georgia 30901.

8	Term stillbirth	Postmaturity
9	Term stillbirth	Cord accident
10	Term stillbirth	Maternal hypertension
11	Neonatal	Rh sensitization*

*Tap related.

†Amnionitis present at time of amniocentesis.

‡Infant was found to have trisomy 21.

Table II. Indications for amniocentesis abnormalities detected

Indication	*Total pregnancies*	*Affected fetuses*
Chromosomal aberrations:		
Maternal age	149	3
Previous trisomy 21	33	1
Balanced translocation parent	8	3*
Remote history of trisomy 21	7	0
Total	197	7
Neural tube defect	30	0†
Sex-linked disorders	9	2 (male fetuses at risk)
Inborn errors of metabolism	3	2
Miscellaneous	13	0

*Four additional phenotypically normal fetuses had balanced translocations and are not included in this table.

†One closed neural tube abnormality was not detected prenatally.

banding. Supplementary banding techniques were used only as indicated. Following centrifugation, the amniotic fluid supernatant was sent by mail to the Eunice K. Shriver Center (1974 to 1977*) for determination of amniotic fluid AFP. Recently, maternal serum and amniotic fluid AFP determinations have been performed by Thomas Jefferson University.†

Results

The patient sample consisted of 252 patients who had diagnostic amniocentesis for genetic indications. Six pregnancies were lost to follow-up.

*Aubrey Milunsky, Ph.D., Eunice K. Shriver Center, Waltham, Massachusetts.

†Susan Cowchock, M.D., Thomas Jefferson University, Division of Medical Genetics, Philadelphia, Pennsylvania.

Procedural problems. The problems encountered with the procedure itself were (1) failure to obtain fluid and (2) failure, or delay, of cell cultivation.

Of the 252 patients referred for diagnostic amniocentesis, 233 (92%) required only one visit for a diagnosis to be made. Of the remaining 19 patients, no fluid could be obtained from one and 18 represented initial cultivation failures. Twelve of the initial 19 patients with diagnostic failures underwent a second amniocentesis. The remaining seven patients declined a second procedure. The second procedure was successful in 11 of the 12 remaining patients. One patient had an unsuccessful second amniocentesis. The latter individual plus the seven who declined a second procedure represent 8/252 (3%) of the study group who had no benefit from the procedure.

The mean time interval from fluid sampling to diagnosis was 17 days, ranging from 7 to 42 days. The time interval from fluid sampling to medically indicated termination of pregnancy was 4 to 5 weeks.

Maternal complications. Transient maternal complications, such as vaginal bleeding or amniotic fluid leakage, were not reported over the duration of the study.

Fetal loss. All spontaneous abortions, premature fetal deaths in utero, stillbirths at term, and neonatal deaths are considered together under the term "pregnancy or fetal loss."[7] The absence of fetal heart tones or motion on ultrasound prior to planned amniocentesis excluded a patient from the fetal loss category.

There were 11 fetal losses in the patient series. One of these was an immediate death secondary to fetal cardiac puncture. The remaining 10 fetal losses ranged from 7 days after amniocentesis up to and including the early neonatal period (Table I).

Five women experienced premature fetal death occurring 7 to 36 days after the amniocentesis. One of these fetuses, at the time of the initial diagnostic amniocentesis, had audible heart tones despite turbid, infected anmiotic fluid. A second premature postamniocentesis death at 28 days occurred in a fetus with trisomy 21. The other three had no apparent etiology except the amniocentesis.

There were four stillbirths at term. Two of these infants died during labor, of postmaturity and a cord accident, respectively. The third and fourth stillbirths at term were diagnosed when the mothers presented in labor. One of these was of unknown cause, while the other was related to maternal hypertension and diabetes. The tenth delayed fetal loss was caused by Rh sensitization. This patient had a positive indirect Coombs titer of 1:8 dilutions prior to amniocentesis. The amniotic fluid was free of blood, but maternal serum titers rose precipitately and intrauterine transfusion was re-

quired. The fetus died one week after birth as a result of Rh disease.

The overall number of fetal deaths encountered in this series was 11/252 (4.4%). Of these 11 fetal losses, only 6/252 (2.4%) were felt to bear some relationship to the tap (Cases 1, 3, 4, 5, 6, and 11, Table I).

Fetal morbidity. There was one case of mild hydrops fetalis, due to Rh isoimmunization, possibly related to the amniocentesis. The infant was born at term, treated with exchange transfusion, and did well in the neonatal period.

Indications and abnormal findings. Table II lists the primary indications for amniotic fluid studies and the abnormal findings in each group. The primary indication is defined as that indication for which the patient is at greater risk. For example, a 37-year-old female carrier of hemophilia is listed under "sex-linked disorders."

Chromosomal aberrations. There were 197 patients referred primarily for having a child at risk of a chromosomal aberration (78%). These patients can be subdivided into the following categories: maternal age-related nondisjunction, a previous trisomy 21 infant, a balanced translocation, and a remote family history of trisomy 21.

MATERNAL AGE. One hundred forty-nine patients were referred primarily at risk of maternal age-related nondisjunction. The majority of patients were seen between the ages of 35 and 44 (95%). In this group of patients, three abnormal amniotic fluid karyotypes were detected. Two mothers, both 37 years of age, had fetuses with trisomy 21; the third patient, age 41, was found to have a male infant with a 47,XXY karyotype (Klinefelter's syndrome). Both trisomy 21 pregnancies were interrupted and cytogenetic documentation was obtained from one by fetal skin karyotyping. The Klinefelter's syndrome pregnancy was not interrupted. Cytogenetic studies on the normal male newborn infant were confirmed as 47,XXY.

PREVIOUS TRISOMY 21 INFANT. Thirty-three couples, although cytogenetically normal, were referred with a history of having had one previous trisomy 21 infant. Amniotic fluid study revealed a repeat trisomy 21 in one of these couples. Pregnancy interruption with cytogenetic documentation was performed.

BALANCED TRANSLOCATION CARRIER. Amniotic fluid studies were performed on eight pregnancies in seven couples who were carriers of a balanced translocation in the peripheral blood. One amniotic fluid study was cytogenetically normal and four others revealed a balanced karyotype. Three studies were cytogenetically unbalanced. The first five pregnancies resulted in phenotypically normal children and the latter three had pregnancy interruptions. Two of the three unbalanced amniotic fluid studies represented consecutive pregnancies in the same patient. Cytogenetic confirmation of the antenatal diagnosis was obtained by peripheral blood studies in only one of these eight pregnancies.

REMOTE HISTORY OF TRISOMY 21. Seven couples presented because a remote relative had a child with clinical Down's syndrome. These couples usually presented in the second trimester and in most instances no accurate cytogenetic diagnosis was available on the affected relative. Amniotic fluid studies in these seven instances were normal.

NTDs. A total of 30 patients were referred because of NTDs. Twenty-seven patients had had one previously affected child, while three patients had two previously affected infants. One couple with one child affected with meningomyelocele also had a child affected with esophageal atresia. In this group there were no abnormal amniotic fluid karyotypes or elevated AFP levels. One false negative AFP value occurred in a patient who subsequently gave birth to a male infant with hydrocephaly, a closed neural tube disorder.

Sex-linked disorders. Nine patients were referred for sex-linked genetic disorders. Two patients at risk for hemophilia and Duchenne's dystrophy were diagnosed as carrying male fetuses. Both pregnancies were interrupted, but biochemical documentation of an affected male fetus was unsatisfactory in both instances.

Inborn errors of metabolism. Three patients were referred with a history of a relative affected with specific metabolic disorders. One patient had a history of two nephews affected with methylmalonic aciduria (MMA). Analysis of the amniotic fluid for MMA revealed an unaffected infant. Two other couples referred for metachromatic leukodystrophy and congenital adrenal hyperplasia were both found to have affected fetuses. The couple with the fetus affected with metachromatic leukodystrophy elected to undergo a therapeutic abortion. Histochemical documentation of metachromatic leukodystrophy was made in the aborted fetus. A male infant with confirmed congenital adrenal hyperplasia treated in the newborn period was born to the second couple.[8] There were no abnormal karyotypes or abnormal AFP values encountered in this group of patients.

Miscellaneous indications. Thirteen patients were classified as "miscellaneous." This group included couples with remote histories of abnormal undiagnosed family members. All parameters investigated (karyotype, AFP, and ultrasound) failed to disclose any abnormalities. No abnormalities were detected in the neonates.

Confirmation of diagnosis

Documentation of the amniotic fluid diagnosed was attempted whenever possible. All of the abnormal find-

ings were confirmed as correct by subsequent cytogenetic studies, fetal pathology, or enzymatic analysis.

One incorrect biochemical diagnosis was encountered. This occurred in a patient referred because of a previous infant with hydrocephaly. The AFP determinations were normal. The patient was delivered of a second child with hydrocephaly. Due to this "closed type" of NTD, the AFP values failed to reveal the abnormality.

During the study period, there were two amniotic fluid cytogenetic results which were not confirmed in the newborn infant. One amniotic fluid study revealed a dicentric number 20 chromosome in 33% of the cultured cells. The clinical significance of this cytogenetic abnormality was not known. The couple was advised that an accurate diagnosis of the child's phenotype could not be made. They elected to continue the pregnancy and a phenotypically normal infant was delivered. Peripheral blood cultures from the newborn infant failed to reveal this abnormality. The second case was an amniotic fluid mosaic 46,XX/46,XY. Among 30 cells counted, a single 46,XY cell was present in the amniotic fluid study. This XY cell line could not be detected in peripheral blood karyotyping of the normal term female infant.

Comment

The results of this smaller study, strictly supervised, do have some similarities to and differences from the collaborative NICHD study.

In the NICHD study, no diagnostic information was obtained in 27 patients (2.6%) because of tap or culture failure. The Medical College of Georgia (MCG) study subjected eight patients (3%) to amniocentesis without any tangible results. The absolute failure rate is very similar in both study groups and must be considered as one of the hazards of the procedure.

In the MCG group, only 19 patients, or 7.5% of the patient population, required a second procedure. This is considerably less than the 136 patients (13.1%) requiring a repeat tap in the NICHD study. Overall, in the smaller study group (MCG), there is a lesser incidence of diagnostic failures with the first amniocentesis. Second taps in the MCG study, when necessary, have been limited almost exclusively to initial culture failure. The principal reason for a second amniocentesis in the NICHD study was inability to obtain fluid at the initial tap.

In the collaborative study, 19 fetuses with chromosomal abnormalities (other than balanced translocations), 15 with metabolic disorders, and 11 male fetuses at risk of an X-linked disorder were detected in the total of 1,040 women, giving a 4.3% positive detection rate. In our series, 11 abnormalities (4.4%) were detected: three fetuses with trisomy 21, one fetus with Klinefelter's syndrome, three fetuses with unbalanced translocations, two male fetuses at risk of a sex-linked disorder, one fetus affected with metachromatic leukodystrophy, and one fetus affected with congenital adrenal hyperplasia. One closed neural tube abnormality was not detected prenatally and is not included in this figure.[11] Four balanced translocations similar to those in the collaborative study protocol are not included in the detection figure.

Misdiagnosis occurred in six instances in the collaborative study. Five of these were gross cytogenetic discrepancies between amniotic fluid and fetus. One was a positive amniotic fluid diagnosis of galactosemia in a normal infant. Only two cytogenetic misdiagnoses occurred in our series, both of them involving equivocal amniotic fluid findings that could not be identified in the two normal newborn infants. The closed neural tube defect and normal amniotic fluid AFP probably represented the limitations of the technique rather than misdiagnoses. The overall accuracy of the collaborative study was 99.4% compared to 98.8% in the MCG study.

In the collaborative study fetal death occurred in 3.5% of the total amniocentesis group. In this series there were 11 instances of fetal death (4.4%). Two of these cases, a fetal cardiac puncture and a postamniocentesis Rh sensitization with neonatal death, are clearly related to the tap. Four additional fetal deaths occurring in the postamniocentesis period had no discernible etiology. If the latter are assumed to be tap related, then six of the 11 pregnancy losses are causally related to the procedure. This gives a 2.4% overall tap-related mortality figure.

This series has a distressing number of term stillborn infants. The four stillbirths constitute 1.6% of the total amniocentesis group. In the collaborative series, the percentages of stillborn infants were 0.79% and 0.2% in the control and study groups, respectively. The increased number of term stillborn infants is puzzling. Although a causal relationship seems remote, one wonders whether the almost nonexistence of tap failures has been purchased at the cost of increased fetal deaths.

As each genetic center dating back to the late 1960s adds to the data pool, more information will be available to ensure the safety of prenatal diagnosis.

Discussion

DR. FAY REDWINE, by invitation, Richmond, Virginia. This is the era of informed consent, and I think that the paper presented points out one of the most difficult questions about intrauterine genetic studies, that is, the question of risk. Risk of a midtrimester amniocentesis has been variously reported in the literature as not significantly different from that of a control group (reported by the NICHD National Registry for Amniocentesis Study Group) to a 1% to 3% incidence of direct fetal puncture (reported by Carp and Haddon in 1977) to a 13½% incidence of spontaneous rupture of the membranes within 5 days of the procedure (reported by Taramo and Sipinen in 1978). The problem with the literature is that most reports do not limit themselves strictly to amniocentesis for genetic studies but rather lump data from second- and third-trimester amniocentesis. One of the largest studies in the literature is by Galjaard (Cytogenetic cell genetics, 1976). He reported a series of 6,121 cases of prenatal diagnosis strictly for genetic disease, compiled from 46 centers in western Europe. The risk in that series of fetal loss following the amniocentesis was 1.4% with a range in different centers from 0.3% to 2.6%. As pointed out by the author, this falls within the range of spontaneous abortion during this period in pregnancy which was reported by the NICHD study as 3.2%.

This study, as are all studies in the literature except for the NICHD studies, is uncontrolled and due to this fact is somewhat difficult to analyze. The fetal mortality rate at the Medical College of Georgia was 4.4% which is higher than the control rate of the NICHD study but perhaps not higher than the fetal loss rate at that stage of gestation in Georgia. The corrected fetal mortality rate was 2.3%. I think that the conclusion of the NICHD study that the risk of amniocentesis for prenatal genetic studies is no greater than that of a control group may be statistically true, but one need only be presented with one case of an intracardiac fetal puncture and immediate death to know that amniocentesis must carry a risk of its own. In our series at the Medical College of Virginia, we have had one patient with chorioamnionitis developing 24 hours after amniocentesis, one with ruptured membranes the day of the procedure, and no other losses within two weeks of the procedure, giving a fetal mortality rate directly due to the amniocentesis of 0.5%.

Perhaps it seems quibbling to worry whether the complication rate is 0.5% or 4.4%, but in this study of 252 patients, seven patients were studied because of a remote family history of trisomy 21 and 13 patients were studied for miscellaneous indications. This is an incidence of 7.3% of amniocentesis done for a nonrecurrent genetic condition. Although in some cases anxiety alone may be adequate indication for intrauterine genetic studies, I do believe that determining an accurate complication rate is critical to adequately informing any patient but especially the ones with "miscellaneous nonindications."

The question of innate risk due to age is also an interesting one. In their total series of procedures done because of maternal age of 149 patients, two of the affected fetuses were in the maternal age group between 35 and 39 and one was in a patient over 40; however, the size of these subpopulations was not reported. From the series at the Medical College of Virginia, there has been an interesting trend. We have had four cases of nondysjunction in a group under 39 and one case in a 40-year-old patient. This is an incidence of risk for the 35 to 39 age group of 2.4% versus a risk in women 40 and older of 1% with both groups being composed of over 100 patients. We then find that the risk between 35 and 39 is actually greater than that over 40 in our series to date. It would be interesting if the authors from the Medical College of Georgia have looked at those statistics in that respect.

Perhaps one of the most exciting things about a series of this nature is what it does not include. The

future for the field of the intrauterine detection of genetically abnormal fetuses is very bright indeed. With the advent of gray-scale ultrasonography which enables us to measure fetal parts and examine fetal structure, real-time ultrasonography, which allows us to diagnose motion defects, such as cardiac abnormalities and urinary output, and fetoscopy, which has created for the first time the capability of obtaining fetal blood for diagnosis of hemoglobinopathies and muscular dystrophy, the scope of this field of interest is tremendous. I believe that groups such as the one at the Medical College of Georgia, combining the expertise of medical geneticists, obstetricians, and ultrasonographers, will enable us to use all of the modern advances in technology to allow our patients to reproduce safely.

Hypothalamic-pituitary function and radiographic evaluation of women with hyperprolactinemia and an "empty" sella turcica

A. F. HANEY, M.D.
RICHARD S. KRAMER, M.D.
R. HERBERT WIEBE, M.D.
CHARLES B. HAMMOND, M.D.
Durham, North Carolina

A primary "empty" sella may be associated with significant hypothalamic-pituitary dysfunction. This report characterizes the endocrinologic and radiographic findings in six patients with hyperprolactinemia (range 34.3 to 1,170 ng/ml) ultimately found to have an enlarged empty sella. Lateral skull x-ray films and thin-section tomograms were suggestive of pituitary tumors in all patients. Four patients underwent transphenoidal sellar exploration after pneumoencephalography (PEG) failed to demonstrate air within the sella. The inability of PEG to demonstrate an empty sella in two patients was explainable on the basis of an intact diaphragma sellae with previous transient intrasellar pathology responsible for the sellar enlargement. Dynamic hypothalamic-pituitary testing yielded no consistent pattern of response. These studies suggest that an empty sella: (1) may be associated with hyperprolactinemia, regardless of etiology, (2) is not diagnosable by dynamic hormonal testing, and (3) may be indistinguishable from a pituitary tumor by current radiographic techniques. (AM. J. OBSTET. GYNECOL. 134:917, 1979.)

THE PRIMARY "EMPTY" SELLA syndrome is frequently diagnosed when air enters an enlarged empty sella turcica during pneumoencephalography (PEG) in a patient without previous sellar surgery or irradiation.[1] This syndrome may be associated with hypothalamic-pituitary dysfunction,[1–5] and the patients are characteristically obese, parous, middle-aged women with hypertension and headaches as frequent concomitant findings.[1]

The coexistence of a primary "empty" sella and galactorrhea with or without hyperprolactinemia has previously been reported[6–15] and, with two exceptions,[11, 15] prolactin (PRL) values have been reported as either normal or lower than those usually associated with functioning pituitary adenomas.[16] This report details our experience with six women complaining of amenorrhea or amenorrhea/galactorrhea who were ultimately diagnosed as having a primary "empty" sella and in whom hyperprolactinemia and the initial radiographic assessment strongly suggested pituitary tumor. In only two of the six patients described did PEG accurately diagnose an empty sella; the remaining cases were diagnosed at the time of transsphenoidal sellar exploration. The radiographic and hormonal assessment of these patients, as well as possible mechanisms of the hyperprolactinemia, is presented.

Material and methods

A clinical profile of each of the patients is shown in Table I; Table II presents the initial baseline endocrine evaluation, and Table III illustrates the opthalmologic and radiographic assessment. Dynamic hypothalamic-pituitary axis testing was carried out utilizing: (1) the gonadotropin responses to luteinizing hormone–releasing hormone (LRF) stimulation (Figs. 1 and 2); (2) the growth hormone (GH) response to either insulin-induced hypoglycemia or arginine infusion (Fig. 3); and (3) L-dopa suppression of PRL (Fig. 4).

Table III. Ophthalmologic and radiographic assessment

Case	*Visual fields*	*Lateral skull x-ray film*	*Thin-section tomograms*	*PEG*
1	Normal	Symmetrically enlarged sella	Empty sella, no soft tissue apparent	Air entered an enlarged sella
2	Normal	Abnormal sella consistent with an expanding intrasellar lesion	Thinning and ballooning of anterior sella with dorsum completely eroded	Air entered an enlarged sella
3	Normal	Symmetrically enlarged sella	Asymmetrically enlarged sella without erosion	No air in sella, no suprasellar extension of tumor
4	Complete blindness of right eye, normal left visual field	Mild enlargement of sella	Enlarged sella with some erosion of floor	Failed twice because of an incompetent cisterna magna and failure to fill ventricles
5	Normal	Suspicious for tumor	Suspicious for tumor	No air in sella, no suprasellar extension of tumor
6	Normal	Double floor of sella	Definite tumor with focal ballooning	No air in sella, no suprasellar extension of tumor

Medications when first evaluated
Conjugated equine estrogens, 0.625 mg orally every day; diazepam, 5 mg orally every day
None
Chlorthalidone, 100 mg every day; oxtriphylline, 100 mg orally 4 times a day; terbutaline sulfate, 5 mg orally 3 times a day
Diazepam, 1 mg orally 3 times a day
Ortho-Novum-2, (norethindrone, 2 mg, and mestranol, 0.10 mg), in a cyclic fashion; thiothixene, 2 mg orally 3 times a day; Rauzide, 1 tablet orally twice a day powdered rauwolfia serpentina, 50 mg and bendroflumethiazide, 4 mg)
Diazepam, 5 mg orally every day; Chlorthalidone, 50 mg orally every day

Serum values for total estrogen (E), luteinizing hormone (LH), follicle-stimulating hormone (FSH), prolactin (PRL), growth hormone (GH), and thyroid-stimulating hormone (TSH) were obtained by standard clinical radioimmunoassay. Serum values for thyroxine (T_4) and cortisol were obtained by competitive protein-binding analysis. Normal values for these hormones at this institution are included in Table II. Responses to dynamic pituitary tests considered normal were: (1) a rise of GH to a value of 6 ng/ml or greater in response to either an insulin-induced 50% reduction in blood sugar (0.1 U insulin/kg administered intravenously) or an intravenous infusion of a 10% arginine solution (0.5 gm/kg); (2) a decrease of PRL of 50% or greater in response to a single oral dose of L-dopa (10 mg/kg); and (3) a "normal" response to LRF. While there is no well-accepted normal pattern of gonadotropin response to a single 100 μg subcutaneous injection of synthetic LRF (AY-24031, courtesy of Ayerst Labs.), the range of values from 18 normally cycling women tested in the early follicular phase of the cycle was used for comparison. The Second International Reference Preparation of human menopausal gonadotropin was used for the gonadotropin assays.

Case reports

Case 1. The first patient, a 43-year-old, black woman, para 6-0-0-6, presented with "fullness" in both breasts for "several" years with bilateral galactorrhea, greater on the left, noted for 2 months prior to admission. Menses were regular until 6 months previously when she underwent removal of the uterus, tubes, and ovaries for enlarging uterine leiomyomas and was placed on a regimen of Premarin, 1.25 mg orally, 25 days per month. The diagnosis of an empty sella was made when air entered the sella during PEG (Fig. 5) and no further diagnostic or therapeutic measures were recommended. Galactorrhea has continued to the present time.

Case 2. The second patient, a 27-year-old, black woman, para 2-0-0-2, presented with a 10 year history of galactorrhea coincident with oral contraceptive use and a 1 year history of amenorrhea after discontinuance. She underwent laparoscopic tubal cauterization in March, 1977, and discontinued oral contraceptives with no further menses. The diagnosis of a primary "empty" sella was made when air entered the sella during PEG (Fig. 5). Galactorrhea and amenorrhea have persisted to the present time.

Case 3. The third patient, a 38-year-old, massively obese, black woman, para 5-0-0-5, had cyclic menses from her last delivery in 1971 until April, 1975, when she developed amenorrhea. She denied galactorrhea, but Sudan IV–positive fluid was easily expressible from both breasts on examination. The diagnosis of a pituitary microadenoma was advanced but at transsphenoidal exploration the patient was found to have an arachnoid diverticulum filling the sella. Biopsies revealed only normal pituitary tissue. No return of menstrual function has occurred and galactorrhea persists.

Case 4. The fourth patient, an obese, 36-year-old, white woman, para 0-0-0-0, was referred with an 8 year history of amenorrhea without galactorrhea. Menses had been irregular since menarche at age 12, after 2 years of amenorrhea she was noted to have an enlarged sella on a lateral skull x-ray film at age 30. She had congenital blindness of the right eye secondary to a coloboma and was found to have polycystic kidneys in 1972. Two attempts at PEG were unsuccessful because of incompetence of the cisterna magna and inability to fill the vertricular system or the suprasellar cistern. Because of partial anterior hypopituitarism and the likelihood of a pituitary adenoma, she underwent transsphenoidal exploration of the sella. A large arachnoid diverticulum was found to nearly fill the sella with the pituitary compressed posteriorly. The diaphragma sellae was incomplete, allowing visualization of a portion of the optic chiasm. Microbiopsy of the pituitary remnant revealed only fibrovascular tissue (compatible with an atrophic anterior pituitary). The hypopituitarism has persisted postoperatively and the patient requires vasopressin nasal spray to control mild diabetes insipidus.

Case 5. This patient, a 39-year-old, massively obese, black woman, para 2-0-0-2, presented with 7 years of amenorrhea/galactorrhea. Her last delivery had occurred 10 years prior to admission, and she had used oral contraceptives for 2 years post partum, with resumption of cyclic menses upon their discontinuance, 2 years prior to the onset of amenorrhea/galactorrhea. Because of the massive elevation of PRL a pituitary

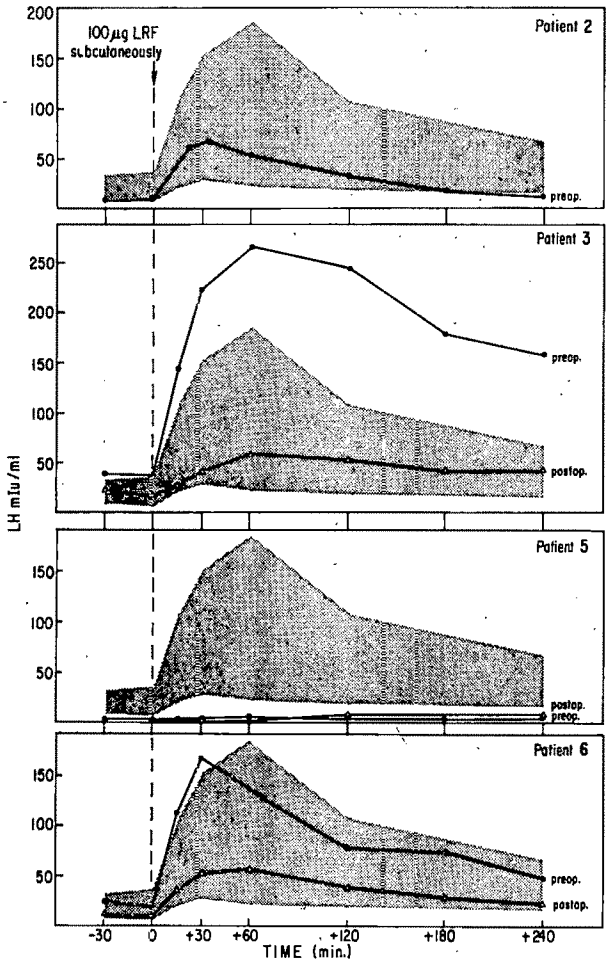

Fig. 1. LH response to a single subcutaneous injection of 100 μg of LRF. The shaded area represents the range of normal values in 18 cycling women tested in the early follicular phase of the menstrual cycle. No consistent pattern of LH response was observed, with Case 3 above, Case 5 below, and Cases 2 and 6 within the normal range.

tumor was thought to be present but at surgery the patient was found to have a large, empty sella with multiple arachnoid trabeculations and adhesions within the sella. The pituitary was noted to be atrophic and displaced posteriorly to the left; no tumor could be identified at surgery. Serum PRL level determined immediately *prior* to surgery, but not available the day of surgery, revealed a marked drop (1,170 to 64 ng/ml). It has remained at this level during the 2 years since surgery and the patient remains galactorrheic with a single episode of vaginal spotting several months postoperatively.

Case 6. The sixth patient, a 38-year-old, obese, white woman, para 0-0-0-0, had cyclic menses until 1969, when she began having irregular menses, bleeding approximately every 3 months, and after another year she developed amenorrhea. She denied galactorrhea but had easily expressible Sudan IV–positive galactorrhea on examination. Because of hyperprolactinemia

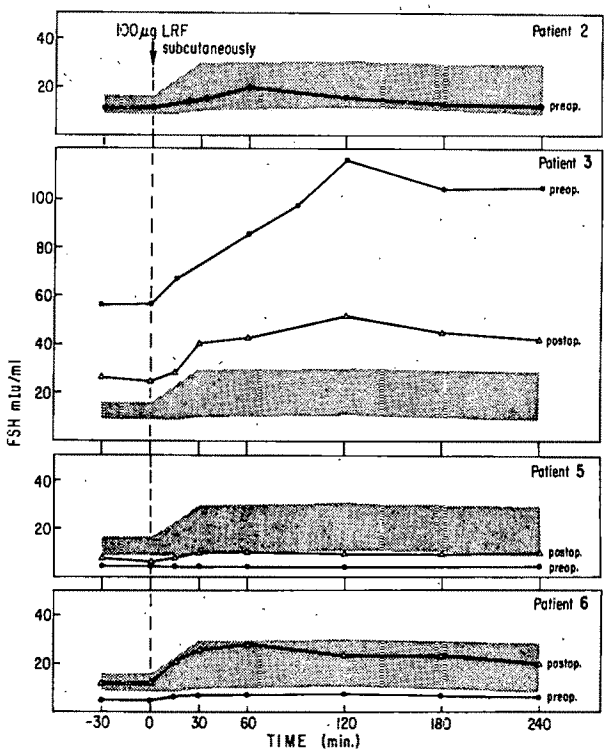

Fig. 2. FSH response to a single subcutaneous injection of 100 μg of LRF. The shaded area represents the range of normal in 18 cycling women tested in the early follicular phase of the menstrual cycle. There was no consistent FSH response, with Case 3 above, and Cases 2 and 5 below, and Case 6 within the normal range.

and obvious sellar erosion on polytomography, she underwent transsphenoidal exploration but at surgery the sellar abnormality, though lined with dura, contained only strands of nondescript fibrous tissue. Microbiopsy of the pituitary gland revealed no evidence of tumor. Serum PRL returned to the normal range postoperatively, the galactorrhea ceased, and cyclic menses have resumed.

Comment

Speculation as to the etiology of the primary "empty" sella focuses upon four theories. In the first, a congenitally absent or incompetent diaphragma sellae allows herniation of an arachnoid diverticulum with resultant transmission of cerebrospinal fluid (CSF) pressure, compressing the pituitary and enlarging the sella. In support of this theory, Busch[17] and Kaufman and Chamberlin[18] found absence of the diaphragma sellae frequently at routine postmortem examination. Second, transient physiologic or pathologic hyperplasia of the pituitary enlarges the sella, resulting in an empty sella when the gland returns to normal size.[19] Multiple pregnancies and treated primary hypothyroidism, respectively, represent such physiologic and pathologic entities. Third, because of the precarious blood supply

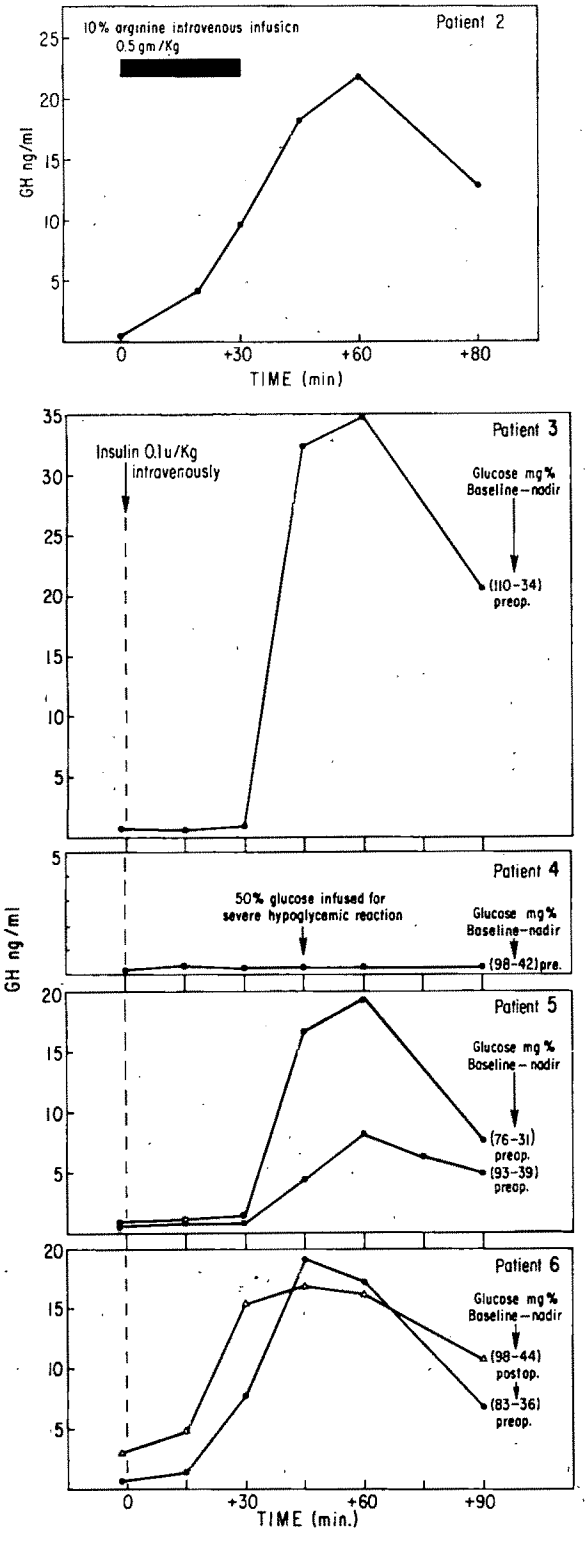

Fig. 3. Growth hormone dynamic testing. Normal GH response to arginine infusion (0.5 gm/kg over 30 minutes) was observed in Case 2. The GH response to insulin-induced hypoglycemia appears completely normal in Cases 3 and 6, absent in Case 4, and impaired in Case 5. Two preoperative tests were performed in Case 5, and the reduced response occurred immediately prior to surgery.

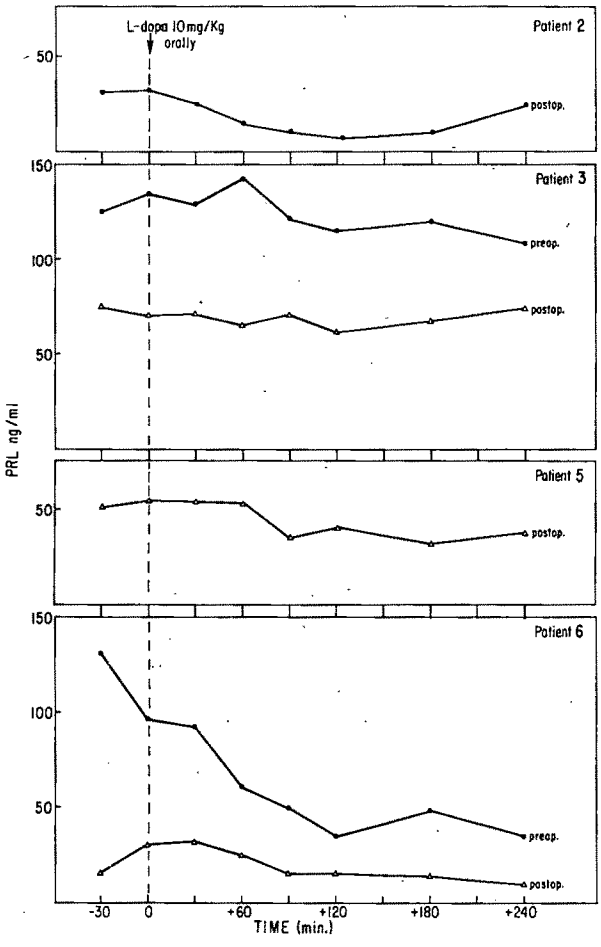

Fig. 4. Serum PRL responses to a single oral dose of of L-dopa (10 mg/kg body weight). Cases 2 and 6 had "normal" responses as defined by a greater than 50% suppression while Case 3 had no significant drop in PRL. A preoperative test was performed in Case 5 but the values remained at approximately 1,000 ng/ml without suppression.

to the pituitary, a tumor which causes sellar enlargement may occasionally undergo spontaneous necrosis, resulting in a partially empty sella.[5] Finally, an intrasellar cyst causing sellar enlargement may rupture, leaving the normal pituitary within an enlarged sella.[20]

The mechanism responsible for elevated serum PRL levels in patients with a herniated, CSF-filled arachnoid diverticulum in the sella remains speculative, but pressure on the pituitary stalk may interrupt prolactin-inhibiting factor transport in a fashion similar to that of stalk section. Since both the pituitary stalk and the diverticulum of arachnoid must pass through the constricting, albeit incompetent, diaphragma sellae, pressure on the pituitary stalk is easily envisioned. Increases in CSF pressure would theoretically be expected further to increase the pressure on the pituitary stalk, explaining the frequent association of factors which increase CSF pressure and an empty sella.[1, 21] The vari-

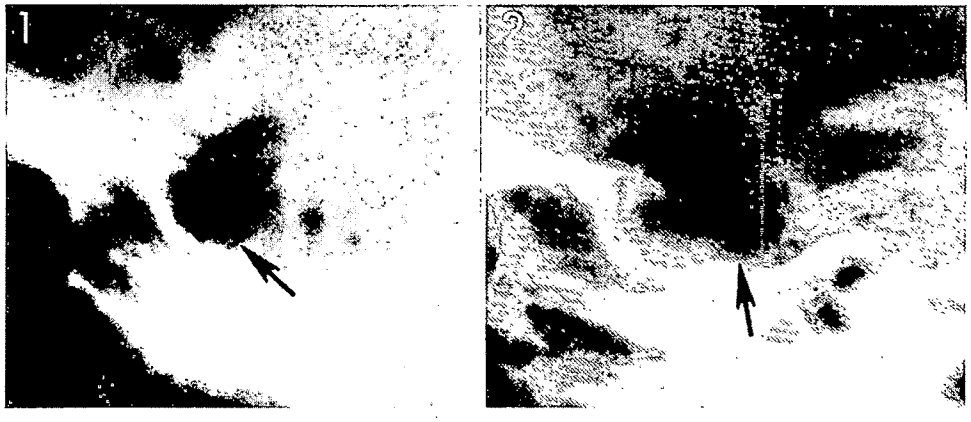

Fig. 5. PEG in Cases 1 and 2, demonstrating air entering the sella (arrows) and confirming the diagnosis of an empty sella secondary to an arachnoid herniation through the diaphragma sellae.

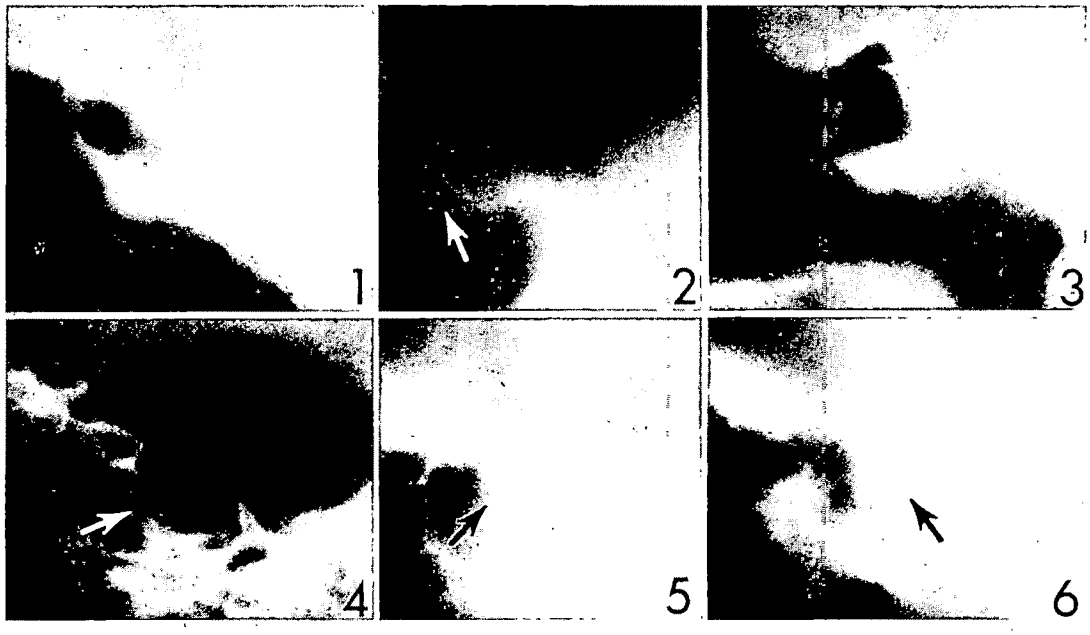

Fig. 6. Tomograms of the sella. Cases 1 and 3 demonstrate symmetric enlargement of the sella while Cases 2, 4, 5, and 6 have more asymmetric enlargement and localized areas of apparent bony erosion (arrows). Trispiral thin-section tomograms are presented for Cases 1, 2, 3, 5, and 6 while the tomogram of Case 4 was obtained by the standard 5 mm tomographic technique.

able loss of trophic hormone function associated with the empty sella syndrome suggests a similar mechanism for other releasing hormone loss. Cases 1 through 4 may represent this clinical situation. Herniation of the arachnoid into the sella was documented by PEG in Cases 1 and 2 and by surgery in Cases 3 and 4. Why PEG failed to demonstrate the arachnoid diverticulum in Cases 3 and 4 is unclear, but this must be considered technical failure.

A PRL-secreting pituitary adenoma which has enlarged the sella may undergo partial ischemic or pressure necrosis with the subsequent findings of hyperprolactinemia secondary to residual adenoma with a coexistent enlarged empty sella. A similar clinical situation has been reported in a patient with spontaneous remission of acromegaly.[5] This appears to be the situation which occured in Case 5, as the PRL level dropped from 1,000 to 64 ng/ml prior to surgery. Unfortunately, the immediately preoperative PRL level was not available until 2 weeks postoperatively and surgical exploration could have been avoided.

Pressure from within the sella, not originating in the pituitary itself, sufficient to permit continued galactotrophic function while compressing the pituitary stalk

against an intact diaphragma sellae, could result in an empty sella and hyperprolactinemia. In Case 6 an expansion of the sella projected inferiorly, simulating tumor erosion. The operative findings seem most compatible with the spontaneous rupture of an intrasellar cyst. Since this patient's sellar enlargement occurred secondary to increased intrasellar pressure with an intact diaphragma sellae, it is not surprising that PEG did not demonstrate air within the sella.

A recent report of the coincidental occurrence of very small pituitary adenomas in association with a partially empty sella[22] raises the possibility that occult microtumors might have escaped surgical detection in one or more of the patients reported here. We are inclined to reject such conjecture, since in five of six patients (Cases 1 to 5) pneumographic or direct surgical visualization revealed a pituitary remnant no more than 3 mm in thickness; furthermore, in each patient operated upon, a small tumor was diligently sought after (with incision and biopsy of the deformed pituitary) without success. Four of our six patients had been symptomatic for 6 to 10 years; to speculate that a true adenoma might achieve less than 3 mm diameter after such an interval requires a new definition of "neoplasia." On the contrary, we are inclined to believe that an uncertain percentage of the "microadenomas" which we, and others, have removed with increasing frequency in the past 5 years may actually represent focal areas of lactotrophic hyperplasia possessing negligible neoplastic potential.

A variety of medications have been associated with mild elevations of PRL.[16, 23] A review of all the medications taken by the patients reported revealed that only the Ortho-Novum-2, Rauzide, and thiothixene taken by the patient in Case 5 have clearly been associated with elevations in PRL. In view of the massive elevation in PRL (1,100 ng/ml) it is unlikely that these agents were responsible.

One or both gonadotropins were elevated in three of the six patients—LH only in Case 6 and both LH and FSH in Cases 1 and 3. In Case 1, the previous gonadectomy probably accounted for the elevation in gonadotropins, the replacement conjugated estrogen being insufficient for suppression. In Case 6, there is no obvious explanation for the single elevated LH value found preoperatively except possible laboratory error. Interestingly, in this patient cyclic menses resumed postoperatively and gonadotropins have remained in the normal range for ovulatory women. In Case 3 FSH and LH levels were persistently elevated both preoperatively and postoperatively. The most reasonable explanation would be a somewhat premature menopause at 38 years of age, but a small gonadotropin-secreting adenoma remains a less likely possibility.

No consistent pattern of trophic hormone loss is associated with an empty sella, but abnormalities in GH response, thyrotropin, and gonadotropins as well as panhypopituitarism have been described.[1–5] Dynamic hypothalamic-pituitary axis testing did not enhance diagnostic accuracy in the six cases presented. This suggests that variable pituitary dysfunction may occur regardless of the etiology of the increased intrasellar pressure.

Expanding intrasellar masses, regardless of origin, enlarge or "balloon" the bony sella turcica, causing upward displacement and osteoporosis of the clinoid processes. Interestingly, two of the four patients with documented CSF-filled arachnoid diverticula within the sella had symmetric enlargement (Cases 1 and 3) while both patients with intrasellar pathology (Cases 5 and 6) had localized erosions. PEG remains an integral part of the evaluation of patients with an enlarged sella as it may distinguish a tumor-filled sella from an empty sella, as well as assess suprasellar extension of tumor. However, the air study may fail to reveal an arachnoid diverticulum within the sella, as demonstrated in Cases 3 and 4. Additionally, transient intrasellar pathology causing sellar enlargement, represented by Cases 5 and 6, may be indistinguishable from pituitary tumor by PEG. Computerized axial tomography appears of limited value in assessing intrasellar disease in the absence of significant suprasellar extension.[16] Unfortunately, none of the currently available endocrinologic or radiographic tests can equivocally distinguish patients with a primary "empty" sella from those with pituitary tumors.

We acknowledge the participation of Dr. Harry T. McPherson in the care of one of the patients.

Discussion

Dr. Mason C. Andrews, Norfolk, Virginia. The recent availability of serum PRL determinations and the even more recent marketing of bromocriptine for treating PRL excess have vastly increased the interest of clinician and researcher in pituitary adenomas. These adenomas probably occur in 5% to 10% of all women and are almost always asymptomatic. The few which become intolerable "guests," by enlarging sufficiently to damage the surrounding gland and erode surrounding bone, usually take years to do so. They usually signal their presence by amenorrhea, ovulation failure, and frequently galactorrhea. In more than half of these, serum PRL excess provides a useful marker for identification and follow-up. These chromophobe cells seem to be stimulated to multiply and enlarge by increased estrogen such as occurs during pregnancy and, conceivably, medication with oral contraceptives.

The six cases reviewed here were selected from a much larger number managed at Duke University Medical Center which also had x-ray findings of enlargement of the sella turcica, suggesting the presence of an adenoma, and in which an adenoma was found. But these six were eventually found to be different, because the enlarged sella was not occupied by an adenoma at the time diagnosis was made.

It is most important to develop the capability to recognize the difference between a health-threatening adenoma and an empty sella, because operation may potentially produce morbidity and may also result in persistent CSF drainage through the fistula created surgically.

The typical empty sella syndrome involved a defect in the diaphragm above the sella, allowing arachnoid herniation and pressure erosion of the sellar bone along with pressure atrophy of the pituitary gland. Of the six cases, the first four appear to fit this category, and only half of these patients were spared surgery by the radiologic techniques and the endocrine analyses then available.

The vacant space in the sella in the other two appeared more likely to represent the consequence of diminution of a prior cyst or tumor. They too were not spared surgery, because alternative diagnostic techniques proved insufficient. The declining PRL values could have served as a marker in Case 5.

The use of present-generation computer tomography (CT) in several institutions, including our own, seems to offer an avenue for additional information that may reduce the need for the more strenuous PEG, while improving results. The CT scan can detect CSF fluid in the sella especially when the enlargement is moderate or great. The quantity of pituitary hormones in the CSF, obtained by lumbar puncture, may also help to distinguish between tumor and an empty sella.

The surgical treatment of microadenomas is now being approached more conservatively in general. Certain cases may even be treated with bromocriptine in lieu of surgery on an experimental basis. The potential for enlargement during pregnancy should be appreciated.

Perioperative cephalosporin prophylaxis in cesarean section: Effect on endometritis in the high-risk patient

A. KAREN KREUTNER, M.D.
VICTOR E. DEL BENE, M.D.
DIANE DELAMAR, M.T.
JOAN L. BODDEN, R.N., B.S.
CLAUDE B. LOADHOLT, PH.D.
Charleston, South Carolina

A total of 120 patients who were to be delivered by cesarean section and who were at high risk of postoperative infection received three doses of either cefamandole, cephalothin or placebo perioperatively. Maternal serum levels for both antibiotics were in the therapeutic range. Although both drugs reduced the incidence of febrile morbidity and endometritis, only cefamandole significantly reduced the fever index. Risk factors for postoperative infections were the presence of ruptured membranes, labor, and internal fetal monitoring. Cefamandole beneficially influenced all risk factors while cephalothin was able to reduce only the risk of ruptured membranes. When a new method for obtaining endometrial tissue was utilized, 50% of cultures were negative. There was no difference in the organisms isolated from patients with and without endometritis. (AM. J. OBSTET. GYNECOL. 134:925, 1979.)

THE RISK OF INFECTION following primary cesarean section is at least ten times that seen after a vaginal delivery; however, an elective repeat cesarean section is not associated with significant febrile morbidity. An operative delivery after labor, ruptured membranes, or internal fetal monitoring is associated with a greater risk of infection.[1] Unfortunately, there is no agreement as to what constitutes risk factors since general anesthesia, preoperative anemia, and obesity also have been implicated in the genesis of postoperative infection. It is also unclear which risk factors can be beneficially influenced by the use of antibiotics.

Several recent studies have shown that a short perioperative course of intravenous antibiotic is as effective as 3 to 5 day therapy in reducing endometritis, wound infection, and febrile morbidity.[2, 3]

Any agent selected for prophylaxis should be safe, well tolerated, and not a first-line drug for treatment of serious infection. Most members of the cephalosporin family meet these requirements. Cephalothin and cefazolin have been used with variable results in cesarean section.[3-6] Cefamandole, a new semisynthetic cephalosporin, retains activity of the family against common gram-positive organisms but has an expanded spectrum against gram-negative facultative bacilli and some anaerobes. Cefamandole has not been used previously for prophylaxis in cesarean section. Little information is available about antibiotic levels in maternal and cord blood and amniotic fluid when the antibiotic is used for prophylaxis.

Bacteriologic evaluation of the endometrium is technically difficult because of the ease of contamination by endogenous organisms residing in the cervix and vagina. Ledger and colleagues[7] advocated transabdominal endometrial aspiration, but this method would be contraindicated in a patient who has had a recent cesarean section.

The present study compared the effectiveness of cefamandole, cephalothin, and placebo as prophylaxis against infection in a high-risk population undergoing cesarean section. A number of parameters were correlated with endometritis to identify those which contribute to infection and which could be overcome by

0002-9378/79/160925+11$01.10/0 © 1979 The C. V. Mosby Co.

perioperative antibiotics. A new method for endometrial aspiration was used which would theoretically decrease contamination from vaginal and cervical flora. Maternal and cord blood and amniotic fluid antibiotic concentrations were correlated with outcome.

Material and methods

All obstetric patients at the Medical University Hospital between April 27, 1977, and November 16, 1978, became candidates for the study when the decision was made to perform a primary cesarean section. A few patients needing a repeat cesarean section became eligible if they presented with ruptured membranes, labor, extreme obesity, or chronic medical conditions associated with increased risk of infection, such as sickle cell disease or severe diabetes. Reasons for exclusion were signs of infection (oral temperature greater than 100.4° F or clinical amnionitis), known allergy to penicillin or cephalosporins, antibiotic therapy for any reason within the previous 2 weeks, or inability to obtain valid informed consent.

The protocol called for randomized triple-blind allocation of 120 patients into one of three groups. Each patient received either 1 gm of cephalothin,* cefamandole,† or a similar volume of placebo intravenously. The first dose was given on call to the operating room with subsequent doses at two and eight hours after surgery.

Complete blood count, urinalysis, and measurement of serum creatinine levels were performed on each patient before operation and repeated on the second and fourth postoperative days.

Amniotic fluid and maternal and cord blood were sampled at the time of delivery for assay of antimicrobial activity. The blood samples were refrigerated until the serum could be separated by centrifugation. A biologic plate-cup assay, in which the degree of inhibition of susceptible organisms by the patient's serum or amniotic fluid was compared to a simultaneously tested known concentration of cephalothin or cefamandole, was employed to estimate antimicrobial activity; this value was expressed as micrograms of cephalothin or cefamandole per milliliter.

Routine urine cultures were performed on specimens obtained on insertion and removal of the indwelling Foley catheter. Amniotic fluid was cultured at the time of cesarean section for anaerobic and aerobic organisms. Each patient had a uterine aspiration 3 to 5 days after operation to obtain material for culture. All specimens were transported within 30 minutes to the experimental anaerobe laboratory, evaluated by Gram stain, and placed on nonselective media for primary isolation of organisms.

The initial plating of the specimen took place in an anaerobic environment provided by a glove box. Primary isolation of anaerobes was obtained using prereduced, enriched blood agar incubated in a carbon dioxide jar. Anaerobic organisms were identified by means of Gram stain characteristics, gas chromatographic analysis of the end products, and biochemical reactions as determined by the Mini-tec* system. Facultative and aerobic bacteria were identified according to commonly accepted techniques.

A broth dilution assay was utilized to determine the susceptibility of anaerobic bacteria to cefamandole and cephalothin and of aerobic bacteria to cefamandole.[8] Standard agar-diffusion techniques were used to determine susceptibility of aerobic and facultative organisms to cephalothin.[9] Resistance to cefamandole was defined when growth was visible in concentrations of 12.5 μg of cefamandole per milliliter of broth. Resistance to cephalothin was defined as growth in 6.25 μg of cephalothin per milliliter of broth. Standard inhibitory zone sizes were used to determine resistance of aerobic and facultative organisms to cephalothin.

The endometrial aspiration was done by the nurse-co-ordinator with the patient in the lithotomy position. The vagina was swabbed with aqueous Zephiran. The specimens were collected using individually autoclaved, specially modified menstrual aspiration kits† (Fig. 1). After the short outer cannula was placed into the cervix, the inner cannula was inserted into the uterine cavity; endometrial tissue, usually 1 to 5 ml, was obtained under negative pressure with the 50 ml syringe.

Each patient in the study was carefully monitored for signs of infection. Morbidity was defined according to the criteria established by the Committee of Maternal Welfare as an oral temperature of 100.4° F on any 2 of the first 10 postpartum days excluding the first 24 hours. If a patient was considered morbid, appropriate cultures were obtained and the infection was classified under one or more of the following categories: (1) endometritis—fever, uterine tenderness, with or without a positive culture, or fever and a pathogen without other apparent cause; (2) urinary tract infection—fever, urinary tract symptoms, and a positive culture (the infection was subclassified as asymptomatic if a single urine culture obtained post partum contained 100,000 organisms per milliliter after a negative pre-

operative culture and no fever or urinary tract symptoms were present); (3) wound infection—fever, cellulitis, and/or exudate; (4) pulmonary-fever with abnormal x-ray film or physical signs of consolidation. Each infected patient was treated with appropriate antibiotics of the physician's choice, utilizing the results of available cultures and Gram stains.

The fever index[10] was calculated for each patient to quantify clinical response to the short course of antibiotic therapy. Data obtained were subjected to several different statistical analyses.

For the continuous variables one- and two-way analyses of variance were used to estimate and test for mean difference in the placebo and medication groups as well as morbidity and endometritis groups. Relationships between discrete variables were tested utilizing the chi-square test of independence for a contingency table.

A one-way analysis of covariance with dose time as the covariate was utilized in testing for significant mean differences among the placebo and medication groups for the dependent variables cord blood, maternal blood, and amniotic fluid.

Results

There were significant differences with respect to morbidity, endometritis, and fever index (Table I) among the three groups. Although both antibiotics were effective, cefamandole was superior. Endometritis was the major cause of morbidity in each group (Table II).

Although the groups differed in size, they exhibited similar obstetric and demographic variables (Table III). The patients in the stuey reflected the obstetric population served by the hospital—predominantly nonprivate, black, relatively young, and of low parity. All but two of the patients undergoing a repeat cesarean section had either ruptured membranes, active labor, or both.

The placebo group was eliminated after the study was 70% completed because the suspicion of an unacceptably high morbidity rate in that group was confirmed. The remaining patients were allocated in a double-blind fashion to reach a total of 120 evaluable cases. This alteration in protocol was done with permission of both the Institutional Human Research Committee and Eli Lilly & Co. Twenty-one additional patients were not evaluable because they did not adhere to the protocol. There were no adverse reactions to either antibiotic.

Mean cefamandole and cephalothin levels are given in Table IV. No antibiotic activity was present in patients who received placebo. Maternal blood levels were in the therapeutic range for both agents studied, but mean cefamandole levels were twice as high as cephalothin levels. When antibiotic concentrations were corrected for the time of administration, only the maternal blood levels showed a relationship to time; however, a twofold difference between the maternal blood levels of cephalothin and cefamandole remained (Table IV).

All patients who became infected were treated with appropriate antibiotics, usually ampicillin and an aminoglycoside. Half of the 42 patients with endometritis received clindamycin. One noninfected patient in the cephalothin group developed pulmonary emboli requiring heparin therapy. No patient needed an operation for serious postoperative infection. Three patients were readmitted but the only infection-related admission was for acute pyelonephritis 10 days after operation.

The 120 pregnancies included seven sets of twins.

Table I. Comparison of the effect on morbidity between placebo and antibiotic prophylactic groups

	Placebo (N = 29)	*Cephalothin (N = 48)*	*Cefamandole (N = 43)*	*P*
Febrile morbidity (No.)	19	18	–	≤0.05
	19	–	12	≤0.01
	–	18	12	NS
Endometritis (No.)	17	15	–	≤0.05
	17	–	10	≤0.01
	–	15	10	NS
Fever index (mean degree hours)	90.4	68.2	–	NS
	90.4	–	49.5	≤0.01
	–	68.2	49.5	NS

Within each risk factor group, the first P value reflects the difference between placebo and cephalothin; the second P value, the difference between placebo and cefamandole; and the third P value represents the difference between the two antibiotic groups. NS: Not significant.

Table II. Febrile morbidity by cause

Infection	*Placebo (N = 19)*	*Cephalothin (N = 18)*	*Cefamandole (N = 12)*

*The same organism as that in amniotic fluid was cultured from endometrium or blood in three.

†The same organism was also cultured from endometrium.

‡One culture of the same organism from endometrium.

Two unsuspected intrauterine fetal deaths, each occurring in one of twins, were a result of underlying hypertensive disease. Two neonatal deaths occurred in low–birth-weight infants (less than 1,021 grams) delivered for maternal indications unrelated to infection. No infant in the study developed problems from intrauterine exposure to antibiotics or masked infections.

Twenty-one patients with previous cesarean sections were included in the study. None of the four who received placebo or the seven given cefamandole developed endometritis while five of the 10 who received cephalothin did so. In the placebo group, a repeat cesarean section was protective against endometritis ($p < 0.01$) even if ruptured membranes or labor was present. No common factor could predict risk for endometritis following a repeat cesarean section in the cephalothin group; four of the patients with endometritis experienced labor, two had ruptured membranes, and one had a twin pregnancy.

Bacteriology. Eleven of 97 amniotic fluid cultures were positive (Table V), all but three for anaerobes only. Endometritis developed after a positive amniotic fluid culture in four of six patients, one of two patients, and no patients in the placebo, cephalothin, and cefamandole groups, respectively. The same organism that was recovered from amniotic fluid was also isolated from blood or endometrium in three patients who re-

ceived placebo; these were *A. fermentans, Bacteroides* species, and *B. melaninogenicus.* One paired positive culture occurred in both the cephalothin and cefamandole nonmorbid groups; the organisms were *B. melaninogenicus* and *S. intermedius* in each group, respectively.

Fifty-four of the 107 (50.4%) endometrial cultures were negative (Table VI). There was no correlation between a negative endometrial culture and the presence or absence of endometritis. Fewer positive cultures were obtained from patients with endometritis who received cefamandole; all organisms isolated in these patients were anaerobes. In general, those patients with endometritis on each medication showed fewer species of organisms.

Cefamandole	12/28	43	14/28	50
Cephalothin	14/41	34	4/41	10

*No. resistant/total no.

The types of organisms associated with specific infectious morbidity were compared to the organisms cultured from uninfected patients (Table VII). Undisputable pathogenic organisms were *Bacteroides, Fusobacterium,* anaerobic cocci, *Staphylococcus,* and *Streptococcus,* which were cultured from the blood of five patients with endometritis. The organisms cultured from the endometrial cavity were the same in infected and noninfected patients; however, the frequency of isolation of each organism except for *Bacteroides* was greater from the noninfected patient's uterine cavity. *E. coli* was a common urinary tract contaminant but was responsible for only one urinary tract infection while enterococcus was the causative agent in three urinary tract infections.

The susceptibility of the microorganisms to the cephalosporins used as prophylactic agents is shown in Table VIII. Cefamandole, when compared to cephalothin, has an expanded spectrum for both aerobes and anaerobes. The improved antimicrobial activity of cefamandole is especially noticeable when aerobic bacteria are considered (Table VIII).

Analysis of the effect of prophylactic antibiotics on

Table X. Comparison of risk factors present in patients with endometritis

Risk factor	*Placebo*	*Cephalothin*	*Cefamandole*	*P value*
Labor (%)	63.4	38.2	–	NS
	63.4	–	17.8	≤0.0009
	–	38.2	17.8	NS (0.07)
ROM (%)	70.0	28.5	–	≤0.004
	70.0	–	14.8	≤0.0001
	–	28.5	14.8	NS
IFM (%)	66.7	33.3	–	NS
	66.7	–	23.5	≤0.02
	–	33.3	23.5	NS
Obesity (%)	60.0	66.7	–	NS
	60.0	–	26.6	NS
	–	66.7	26.6	≤0.03
Anemia (second postoperative day) (%)	66.6	53.8	–	NS
	66.6	–	41.6	NS
	–	53.8	41.6	NS
General anesthesia (%)	58.0	35.0	–	NS
	58.0	–	27.0	NS
	–	35.0	27.0	NS

Within each risk factor group, the first P value reflects the difference between placebo and cephalothin; the second P value, the difference between placebo and cefamandole; and the third P value represents the difference between the two antibiotic groups.

Table XI. Comparison of risk factors present in patients with febrile morbidity

Risk factor	*Placebo*	*Cephalothin*	*Cefamandole*	*P value*
Labor (%)	68.1	44.1	–	≤0.07
	68.1	–	25.0	≤0.002
	–	44.1	25.0	NS
ROM (%)	70.0	35.7	–	≤0.01
	70.0	–	18.5	≤0.0004
	–	35.7	18.5	NS
IFM (%)	66.6	41.6	–	NS
	66.6	–	29.4	≤0.04
	–	41.6	29.4	NS
Obesity (%)	60.0	66.6	–	NS
	60.0	–	26.6	NS
	–	66.6	26.6	≤0.03
Anemia (second postoperative day) (%)	66.6	50.0	–	NS
	66.6	–	46.1	NS
	–	50.0	46.1	NS

Within each risk factor group, the first P value reflects the difference between placebo and cephalothin; the second P value, the difference between placebo and cefamandole; and the third P value represents the difference between the two antibiotic groups.

the resistance to each drug shows that in patients receiving cefamandole organisms are more frequently resistant to both antibiotics while the organisms recovered from patients receiving cephalothin are more likely to be resistant to that agent but not to cefamandole (Table IX).

Risk factors. Analysis of over 50 variables was carried out to ascertain the relationship of these to differences in morbidity and endometritis in placebo and medication groups. Those variables in which there was a clustering of ill patients found were labor, prolonged rupture of membranes, internal fetal monitoring, multiple gestations, and abnormal presentations. Only the first three were statistically significant risk factors (Tables X and XI). The number of vaginal examinations, anemia, and obesity were similarly analyzed but were not risk factors for our patients.

General anesthesia was not a significant risk factor; most patients in the study received a general anesthetic with only one case of atelectasis in the postoperative period. Twenty-one patients had regional anesthesia for the cesarean section (18 epidural and three spinal). One patient in each antibiotic group and two of the three who received placebo developed endometritis as did two of six patients who had general anesthesia to supplement an epidural anesthetic.

Green and Sarubbi[11] categorized patients as low risk if they had only one risk factor present and high risk if they had two or more present. With general anesthesia included among the other variables (obesity, anemia,

prolonged ruptured membranes, labor, and internal fetal monitoring) only 18 of 120 patients were classified as low risk, and there was no correlation with the presence or absence of endometritis or febrile morbidity. After general anesthesia was removed as a risk factor in this analysis for the reasons described above, only 28.5% of the placebo group with one risk factor developed endometritis as opposed to 70% of those with two or more ($p \leq 0.05$).

When the variables of anemia and obesity in addition to general anesthesia were removed, only 28% of the placebo group with one risk factor developed endometritis as opposed to 72% of those with two or more ($p \leq 0.01$).

When cephalothin was compared to placebo, only the risk effect of a longer duration of ruptured membranes could be overcome by administration of that antibiotic ($p \leq 0.004$). When cefamandole was compared to placebo, the antibiotic was highly effective in reducing the risk from prolonged ruptured membranes ($p \leq 0.0001$) and longer duration of labor ($p \leq 0.0009$), and also was effective against the effect of internal monitoring ($p \leq 0.02$). When the two antibiotics were compared, fewer patients were infected in the cefamandole group but the differences were not statistically significant.

Comment

Both cefamandole and cephalothin are effective in reducing febrile morbidity and endometritis following cesarean section in a high-risk population; cefamandole is also effective ($p \leq 0.01$) in reducing fever index (Table I). Endometritis with or without bacteremia, urinary tract infection, and wound infection remain the major causes of postoperative febrile morbidity. The present findings differ from our previous study[6] in which cefazolin was bacteriologically but not clinically effective in reducing post–cesarean section febrile morbidity. The difference in results might be accounted for, in part, by the fact that repeat cesarean section patients were excluded from the present study unless they had ruptured membranes, labor, or significant underlying medical conditions. No patient undergoing repeat cesarean section who received either placebo or cefamandole developed endometritis, even in the presence of labor or prolonged ruptured membranes. The protective effect of a repeat cesarean section does not hold true in the group of patients who received cephalothin; the finding that five of 10 patients in that group developed endometritis cannot be explained.

The present study compared favorably with other reports using a single agent in a short perioperative fashion. Cefamandole levels were twice as high as cephalothin levels in all areas examined. The serum levels (maternal) were in the expected range based on dosage and elapsed time between administration and sampling. One must assume the therapeutic levels of 15 to 20 μg/ml of cephalothin and cefamandole were obtained at the end of intravenous infusion of the drugs at about the time of cesarean section.[12] No patient in the present series developed an allergic reaction to the medication received or had masked serious postoperative infection. Thus, neither prolonged antibiotic prophylaxis nor the use of multiple agents appears justified.

None of the infants was infected. The neonatologists were aware of the study and did not feel hampered in evaluating potential neonatal problems following the exposure to one dose of a cephalosporin before delivery.

Fifty-four of 107 endometrial cultures obtained using a new double-lumen catheter via a transvaginal approach were bacteriologically sterile. These results are similar to those achieved by Ledger and colleagues[7] with transabdominal uterine cultures in patients with endomyometritis after vaginal delivery. In their series 36.8% of transabdominal cultures were positive as compared to 96% of transvaginal cultures in the same patients. A transabdominal culture would be contraindicated in patients 2 to 4 days after a cesarean section. An additional fact which supports reduced cervical and vaginal contamination of specimens obtained through the new collecting system is that fewer species of organisms per patient were recovered, even in the placebo group. Only 109 strains were isolated from the 107 cultures which is a reduction in number from those we obtained postoperatively in our previous study[6] and those reported by others.[13] The most prevalent organisms isolated, *Bacteroides* species, anaerobic cocci, and *Enterobacteriaciae*, are the same as those previously reported by Ledger and colleagues and Gibbs and associates.[13] Although the results with the new collecting system look promising, further evaluation and direct comparative study are necessary.

As previously noted by Gibbs and associates,[13] there was no difference in the organisms isolated from patients with or without endometritis. This may reflect the fact that endometritis is predominantly a clinical diagnosis based on fever and uterine tenderness with abnormal lochia. Further work is necessary in the area of host-bacteria interaction to find out why pathogenic organisms in the endometrium of some patients do not lead to infection. Possibly, the organisms in some of the infected patients are deep within the myometrium and not amenable to sampling through currently available

techniques. Perhaps the absolute number of organisms present would correlate with infection.[14]

The lack of association between positive amniotic fluid cultures and later endometritis had previously been noted by Wong and co-workers.[3] In his study, the antibiotic was not administered until after the cord was clamped, so it is reasonable to expect that no antibiotic was present in the amniotic fluid. This might have accounted for the higher number (39 of 45) of positive cultures in patients without postoperative infectious morbidity. Our data suggest the organisms cultured from amniotic fluid could be useful in predicting the causative agent of endometritis and bacteremia. In the present study only anaerobes were isolated from patients who had received cefamandole; these organisms were present in only a few cases, and none of the patients developed postoperative endometritis. This possibly reflects both the antibacterial spectrum and the greater concentration of that antibiotic within the amniotic fluid.

The different pattern of antibiotic resistance in organisms isolated from patients who received cefamandole (Table IX) may be accounted for in several ways. Cefamandole may favor selection of strains whose mechanism of resistance is due to factors other than beta-lactamase production.[15] These strains might be permeability mutants and therefore resistant to cephalothin also. On the other hand, beta-lactamase production plays a role in the resistance of organisms selected by cephalothin administration, and these would not be resistant to cefamandole, which is not easily hydrolyzed.

The presence of risk factors which influence cesarean section morbidity must be considered in the proper utilization of prophylactic antibiotics. Green and Sarubbi[11] postulated that obesity, anemia, general anesthesia, and prior labor were the significant variables influencing postoperative fever and infection. In a prospective study Green and co-workers[2] found that the use of short-course perioperative prophylactic ampicillin reduced morbidity from 63% to 15% in the high-risk group (two or more risk factors present) while 25% of untreated low-risk patients had febrile morbidity.

Gibbs and colleagues[16] challenged these risk factors and stated that labor, ruptured membranes, and the number of vaginal examinations were most significant. Internal fetal monitoring was not a risk factor for infection beyond that already imposed by the presence of labor and ruptured membranes. They reported that general anesthesia and obesity were not risk factors.

The 129 patients in whom the risk factors were originally established by Green and Sarubbi were distributed as follows: private, 42%; white, 52%; and regional anesthesia, 36%. Our patient population resembles that of Gibbs and co-workers—primarily indigent, nonwhite, and likely to receive general anesthesia. Common risk factors seen in both groups include ruptured membranes and the presence of labor; we also cannot be sure if internal fetal monitoring is in itself a risk factor. There was no significant difference between the number of vaginal examinations in patients who became infected as opposed to those who did not. Anemia, obesity, and general anesthesia were not risk factors in our patient population. A repeat cesarean section appears to be protective against the development of postoperative endometritis even if ruptured membranes, labor, or both are present, and the procedure is no longer elective.

Risk factors must be assessed for the population served. In our patients, administration of cephalothin was effective only in overcoming the risk of ruptured membranes. The administration of cefamandole when compared to placebo significantly reduced the risks of labor, ruptured membranes, and internal fetal monitoring. The administration of either antibiotic significantly reduced the incidence of postoperative febrile morbidity and endometritis, but only cefamandole significantly reduced the fever index.

Conclusions

1. Both cephalothin and cefamandole significantly reduced the incidence of postoperative febrile morbidity and endometritis; cefamandole significantly reduced the fever index ($p \leq 0.01$).
2. Risk factors for postoperative endometritis and febrile morbidity were the presence of ruptured membranes, labor, and internal fetal monitoring.
3. Obesity, general anesthesia, and anemia were not risk factors in our patients.
4. Cefamandole was able to reduce all of the risk factors while cephalothin was able to overcome only the effect of ruptured membranes.
5. There were no differences in the organisms isolated in patients with and without endometritis.
6. When a new endometrial sampling technique was used, 50% of cultures were negative.

Discussion

DR. SAMUEL M. GOODRICH, Milledgeville, Georgia (Official Guest). Antibiotic prophylaxis implies the preventive use of antibiotics where contamination might occur but is not yet present. Once contamination occurs, then antibiotic administration should be considered therapeutic. Burke[1] summarized five principles to be considered in using prophylactic antibiotic therapy:

1. The effectiveness of defense against bacteria depends largely on natural host resistance.

2. The abnormal physiology induced by anesthesia and operation reduces host resistance.

3. Infection can be prevented or reduced by supplementing host antibacterial resistance but the supplement must be delivered before bacterial contamination of the tissue occurs.

4. Supplements to host resistance serve no purpose in prevention if they are given for periods longer than 4 hours after the end of active bacterial contamination of tissue or bloodstream.

5. Preventive antibiotic supplement should be used only if the risk of infection is clearly greater than the risks of side reaction to the preventive antibiotic.

Chodak and Plant[2] reviewed the English literature over a 16 year period from 1960 to 1976, on the subject of prophylaxis with systemic antibiotics in surgery. Of 131 articles, only 24 met the criteria of an appropriately designed study that generated evaluable data. Major faults in experimental design included: (1) inadequate controls, (2) failure to randomize patients, and (3) failure to begin prophylaxis preoperatively. Even when the studies were well designed, some could not be evaluated because of inappropriate antibiotics, imprecise definition of wound infection, study of nonhumans, and selective removal of more than 15% of patients. Chodak and Plant concluded that those forms of surgery where prophylaxis is clearly of value include hysterectomy, cesarean section, Charnley total hip operations, and microsurgical craniotomies.

There seems to be general agreement that properly administered prophylactic antibiotics reduces febrile morbidity in patients undergoing cesarean section.[3, 5, 7, 8] The incidence of urinary tract infections, wound infections, and serious postoperative pelvic infections is not decreased.[7] The patient undergoing a repeat cesarean section, not in labor, and with intact membranes is considered to have a low risk of developing febrile morbidity. However, there appear to be different high-risk factors when papers from various institutions are studied.[3, 5, 7, 8]

In 1977, Green and Sarubbi[4] published a study identifying four risk factors, which in their institution are associated with post–cesarean section febrile morbidity. These factors were discussed in the paper just presented. If at least two of the factors were present, they could identify 87% of patients who would develop febrile morbidity.

Then, in a study treating those high-risk patients meeting at least two of these criteria, they demonstrated a significant reduction in febrile morbidity. However, in a recent study by Kreutner and coworkers,[6] no reduction in febrile morbidity by using perioperative antibiotic prophylaxis could be demonstrated. However, 43 of the 97 patients were undergoing repeat cesarean sections and would be expected to be in a low-risk group. Also, they did not find the Green and Sarubbi[4] criteria for high risk to correlate with febrile morbidity in their patients. Gibbs and coworkers[3] did not find general anesthesia or obesity to be high-risk factors in their patients.

It seems from these observations that it is not realistic for one institution to use another hospital's criteria for

high risk. Each institution should determine its own high-risk factors, since there will be differences in microbiologic population, patient population, and surgeons.

The present study by Kreutner and associates differs from the earlier study by demonstrating the effectiveness of prophylactic antibiotics. However, I am concerned about this being a blind study if it could be recognized that the placebo group had unacceptable febrile morbidity before the study was completed. Also, the removal of 21 patients from the study, due to failure to meet protocol, is equivalent to exclusion of 15% of the potential study population.

In studying the effects of labor, ruptured membranes, and number of pelvic examinations, how accurate are these estimates? Are all pelvic examinations during labor charted? If membranes rupture out of the hospital, can this time be accurately determined?

In this study, Kreutner stated that a few patients requiring repeat cesarean section became eligible for study if they presented with ruptured membranes, labor, extreme obesity, or medical conditions associated with increased risk of infection. These 21 patients amount to 17.5% of the study group. There are no data presented indicating that the duration of exposure to such variables as ruptured membranes, labor, or internal fetal monitoring can be correlated to the occurrence of febrile morbidity. If membranes are ruptured over 24 hours, should we consider prophylactic antibiotics or therapeutic antibiotics? I suspect that the duration of ruptured membranes and labor would be much shorter in the group of patients undergoing repeat cesarean section.

I am reluctant to accept the statement that a placebo was protective against endometritis in repeat cesarean section. This is based on four patients in the placebo group, none of whom developed endometritis. I suggest if the data in the repeat cesarean section groups indicate anything it would be that antibiotic prophylaxis is of little benefit in this group of patients. Again it would be interesting to examine data presenting the duration of exposure to ruptured membranes and labor.

I was pleased to note that this study also investigated the clinical course of the infants delivered by cesarean section. It would be interesting to know of the course of the infants whose mothers developed febrile morbidity.

Finally, we must never forget that antibiotic prophylaxis is a supplement but not a replacement for following good surgical principles and technique.

DR. W. SIEGFRIED SMITH, JR., Greensboro, North Carolina (Official Guest). The present-day practice of obstetrics has seen the emergence of invasive techniques of monitoring the fetus which provide us with a more accurate assessment of the fetus during labor. Accompanying this has been a trend for an increase in the cesarean section rate. Because of the increase in the cesarean section rate and invasive monitoring, there has been an increase in morbidity and specifically endometritis. As a result, numerous studies have been undertaken to decrease the incidence of postpartum febrile morbidity by employing prophylactic antibiotics in cesarean section.[1-3]

Sweet and Ledger[4] reported the incidence of antepartum amnionitis and postpartum endometritis in a prospective study of 6,436 deliveries as 3.8%. This patient population consisted of indigent patients and private patients. The incidence of endometritis following cesarean section was increased to 13% in the private group and 27% in the indigent group. Wong and colleagues[3] recently reported the incidence of uterine infection following cesarean section in patients with invasive fetal monitoring as 40.4% compared to 20.4% in a group of patients undergoing cesarean section without invasive fetal monitoring.

Clearly there are questions which need to be answered concerning postpartum infection in cesarean sections and fetal monitoring. Some of the questions which we might ask are: Which patients do or do not need antibiotics? How does one select the patient who may be helped by antibiotics? Which antibiotics does one use? For how long should they be used? What is the bacterial flora of the endometrium?

Green and Sarubbi[5] listed four risk factors which they considered important in identifying the patient at risk of postpartum infection. They concluded that febrile complication occurred four times more frequently in patients with two or more of these risk factors than in those patients with less than two risk factors. Their factors included general anesthesia, obesity, hematocrit of 30% or less, and labor prior to delivery. This study indicated that general anesthesia and obesity are not risk factors, which supports the data from Gibbs and co-workers[6] who found that general anesthesia and obesity did not seem to be major determinants of infection.

Gibbs and co-workers[6] feel that the factors to be con-

sidered are rupture of membranes, labor, internal fetal monitoring, and vaginal examinations. Statistically they calculated that internal fetal monitoring was the least important. Vaginal examination and rupture of membranes were felt to be twice as important as internal fetal monitoring and the duration of labor was calculated to be four times as important.

Gassner and Ledger[7] stated that infection rates in elective repeat cesarean section were 5% as compared to 40.4% and 20.4% for patients in labor who were or were not monitored. Both Gibbs and co-workers[6] and Gassner and Ledger[7] feel that internal fetal monitoring in itself is not the cause of increased infection, but it indicates those patients who have longer labors, longer intervals of ruptured membranes, and more vaginal examinations. This paper indicates that there was no significant difference between the number of vaginal examinations in patients who became infected and those who did not. The length of labor needs to be clarified further to assess accurately its role as a risk factor.

The incidence of endometritis in this series was 58.8% in the placebo group compared to 31.2% with cephalothin and 23.2% in the Mandol group. The incidence of endometritis in the placebo group when general anesthesia was eliminated as a risk factor was 28.5% in those with one risk factor and 70% in those with two or more risk factors. This compares with most series and further emphasizes the fact that there are multiple factors to be considered in selecting patients who are at high risk of infections.

That antibiotics are effective in reducing postpartum morbidity and postpartum endometritis seems to be clear from a review of different antibiotic regimens.[1-3, 8-12] Which regimen to use is more difficult. The infection rate in this series of 58.5% in the placebo group and 31.2% and 23.2% with antibiotics compares to the series of Gibbs and colleagues[2, 10] who reported an overall morbidity rate of 63% in the placebo group compared to 25% in the treated group. Multiple regimens of antibiotics including penicillin-kanamycin and clindamycin-kanamycin have been used. The evidence here indicates that a short course of an intravenous, perioperative cephalosporin is quite effective in decreasing the incidence of endometritis.

I support the authors in the use of cephalosporin as a prophylactic antibiotic when used perioperatively for a short term in order to reserve penicillin, kanamycin, and clindamycin for those patients who do develop endometritis. The treatment of Gibbs and colleagues[13] of postpartum endometritis would be suitable for those patients who develop postpartum endometritis even though they received a cephalosporin as a prophylactic antibiotic.

Since anaerobic cultures are not easily obtained at most hospitals the bacteriologic data are important to the practicing obstetrician. Reports vary somewhat but the predominant organisms which consistently appear are *Bacteroides,* anaerobic cocci, *Streptococcus,* and *Escherichia coli.*[2, 3, 9, 11]

In summary this paper supports the hypothesis that a short-term course of a cephalosporin does increase the incidence of endometritis in cesarean section. General anesthesia, obesity, anemia, and vaginal examinations do not appear to be high-risk factors. Labor, fetal monitoring, and rupture of the membranes need further examination as to their relative risk in infection. A general idea of the bacteriology one can expect to encounter in most cases of endometritis has been provided. Most important, it has been emphasized that prophylactic antibiotics are not a panacea and the incidence of postpartum infection in cesarean section patients treated with prophylactic antibiotics is still in the range of 20% to 30%.

CHARLES W. MONCURE, M.D.
WILLIAM J. FRABLE, M.D.
JOHN R. TAYLOR, M.D.
Richmond, Virginia

Investigations were performed in eight young women to determine if the findings of secondary amenorrhea and high follicle-stimulating hormone levels were due to primary ovarian follicular atresia or to other causes. Karyotypes were determined from both peripheral leukocytes and ovarian tissue; one woman had XXX/XX/XO mosaicism. Another woman had normal ovarian histology and probably had the "gonadotropin-resistant ovary syndrome." No autoimmune antibodies were detected, but one woman with myasthenia gravis also had ovarian histology that demonstrated primary ova and a developing follicle. Only five of eight women had primary ovarian follicular atresia, and two of the other three women had conditions theoretically compatible with subsequent pregnancy. (AM. J. OBSTET. GYNECOL. 134:936, 1979.)

PREMATURE MENOPAUSE is defined as ovarian failure with cessation of menses occurring prior to the age of 40 years. In both premature and normal menopause, the usual cause for these changes is ovarian follicular atresia with greatly reduced ovarian estrogen production. As a result of the lack of negative estrogen feedback from the ovarian follicles to the hypothalamic-pituitary area, there is increased follicle-stimulating hormone (FSH) production, resulting in high blood and urine FSH levels that are useful in the diagnosis of menopause (either normal or premature) and in distinguishing it from other causes of amenorrhea.

In this investigation, we sought to determine if a group of young women with premature menopause all had ovarian follicular atresia or if other conditions existed which were associated with high FSH levels and secondary amenorrhea.

From the Departments of Obstetrics and Gynecology, Pathology, and Neurology, Medical College of Virginia/Virginia Commonwealth University.

Presented at the Forty-first Annual Meeting of the South Atlantic Association of Obstetricians and Gynecologists, Hot Springs, Virginia, January 28-31, 1979.

Reprint requests: Dr. John A. Board, Department of Obstetrics and Gynecology, Medical College of Virginia Station, Box 34, Richmond, Virginia 23298.

Material and methods

The eight women studied were between 22 and 34 years of age, and all had elevated serum gonadotropin levels plus amenorrhea. All women had experienced spontaneous menses in the past, had given informed consent for the experimental parts of the study, and had a history of between 2 and 12 years of amenorrhea. There had been only one pregnancy in the group, and this had resulted in spontaneous abortion. All participants had normal sella turcicas by x-ray films and normal blood levels of serum free thyroxine.

Serum FSH and luteinizing hormone (LH) were determined by radioimmunoassay[1, 2] in which FSH values over 70 mIU/ml were considered postmenopausal. Total urinary gonadotropin excretion was determined by bioassay[3] in which a postmenopausal level consisted of over 50 mouse uterine units (muu)/24 hours. Estrogen status was assessed by the maturation index of vaginal cells and by 24 hour urine estrogen excretion determined by Brown's[4] method.

Karyotypes were determined after a modification of the method of Moorehead and colleagues[5] for both peripheral blood and tissue removed from the ovaries at the time of biopsy. Histologic examination of the ovaries was done in all cases. The tissue was obtained by laparoscopic biopsy in seven instances and by

4	Rare follicle and no ova or cysts seen. Stroma compact with fibrotic capsule	46,XX	46,XX	Neg.	Neg.
5	No ova, cysts, or follicles. Stroma compact	46,XX	46,XX	Neg.	Neg.
6	Rare follicular and germical cyst and no ova seen. Stroma compact	46,XX	46,XX	Neg.	Neg.
7	No ova, cysts or follicles. Stroma compact	46,XX	46,XX	Neg.	Neg.
8	Rare ova, no cysts or follicles. Stroma compact	46,XX	46,XX	Neg.	Neg.

laparotomy in one case. The tissue was stained with hematoxylin and eosin and evaluated by light microscopy by a single examiner.

Serum from each patient was examined for the presence of autoimmune antibodies by a modification of the method of Coon and associates[6] of indirect immunofluorescence utilizing rat liver for antinuclear antibody and human corpus luteum for anti–theca interna antibody.

Results

Clinical data and the results of various examinations are shown in Tables I, II, and III. Three cases which are different from the remaining five are reviewed below.

Case reports

Case 1. A 24-year-old woman, gravida 0, noted the beginning of breast development at about age 12, and

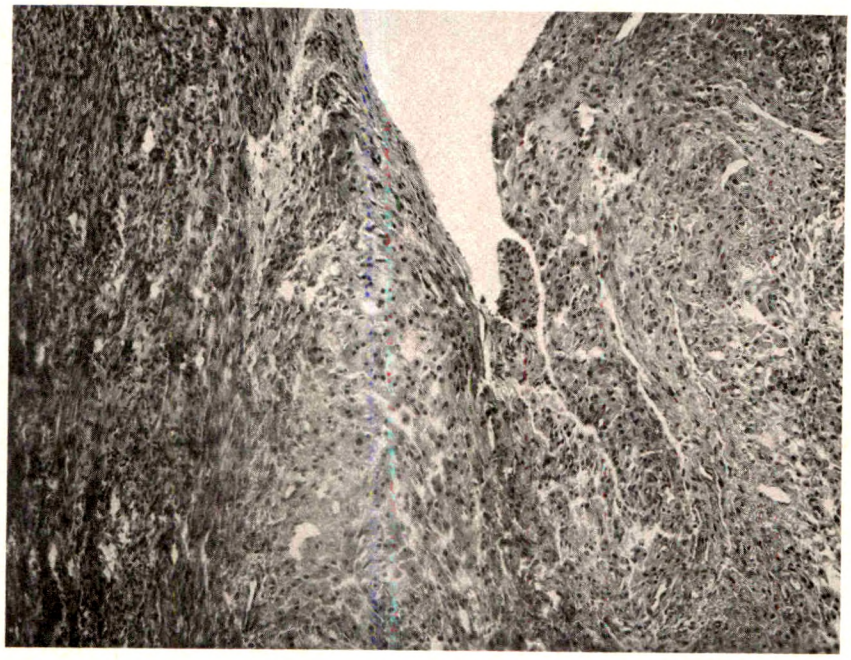

Fig. 1. Ovarian tissue from Case 2 obtained by laparoscopic biopsy. Note normal ovarian tissue with an involuting corpus luteum. (Hematoxlin and eosin. Original magnification ×100.)

axillary hair development at around age 18. At 18, she experienced her only spontaneous menses, although subsequent episodes of vaginal bleeding were induced with estrogen and progestin. When the patient was 20 years old, a bioassay for total urinary gonadotropins was between 6 and 16 U/24 hours (a normal value). A buccal smear showed 32% of cells having a single Barr body and 5% having double Barr bodies.

At age 24, blood FSH and LH were at menopausal levels, and vaginal maturation index showed 20% to 40% superficial cells. Laparoscopy was performed and streak gonads were seen. Biopsies were taken from each of these for both histologic examination and karyotyping. A karyotype from peripheral blood was also done. Culture of the ovaries was obtained with 17 cells being analyzed, 15 of which were 47,XXX, one of which was 46,XX, and one of which was 45,XO. Chromosome analysis of 20 peripheral leukocytes showed 11 to be 45,XO and nine to be 47,XXX. The patient was considered to be female with mosaicism and has subsequently been treated with replacement estrogen-progestin medication. She experiences regular episodes of withdrawal bleeding while taking this medication.

Case 2. A 26-year-old woman, gravida 0, experienced breast development at age 12, had two spontaneous menses at age 15, and had only intermittent vaginal spotting since then. On examination, there was a small amount of facial hair on the upper lip, normal breast development, and normal pelvic structures. There was abundant cervical mucus. Urinary 17-ketosteroid levels were 11.5 mg/24 hours, maturation index was 0/10/90, serum FSH level was 124 mIU/ml, and serum LH level was 74 mIU/ml. One month later, there was withdrawal bleeding following oral medroxyprogesterone, 10 mg daily for 5 days. At this time, the serum FSH level was 92 mIU/ml and two urinary total pituitary gonadotropin assays had values of between 16 and 50 muu/24 hours. Two months after the progestin-induced withdrawal bleeding, there was spontaneous bleeding for 5 days.

The patient was hospitalized 2 months after the spontaneous bleeding, and at this time there was no cervical mucus. Maturation index was 30/70/0, serum FSH level was 207 mIU/ml, and serum LH level was 72 mIU/ml. Total urine gonadotropins were over 100 muu/24 hours on two different occasions. Total urinary estrogen was 12 mcg/24 hours. Chorionic gonadotropin was undetectable by beta-subunit radioimmunoassay, done through the courtesy of Dr. C. B. Hammond of Duke University, Durham, North Carolina. Laparoscopic visualization and biopsy of the ovaries were done. The right ovary appeared to be a wide streak whereas the left ovary appeared to be a small ovary with a follicle on its surface, and histologic examination of both showed ovarian tissue containing a corpus luteum (Fig. 1).

After the patient received ethinyl estradiol, 0.1 mg daily for 3 weeks, the serum FSH level fell to 20 and LH level to 22 mIU/ml.

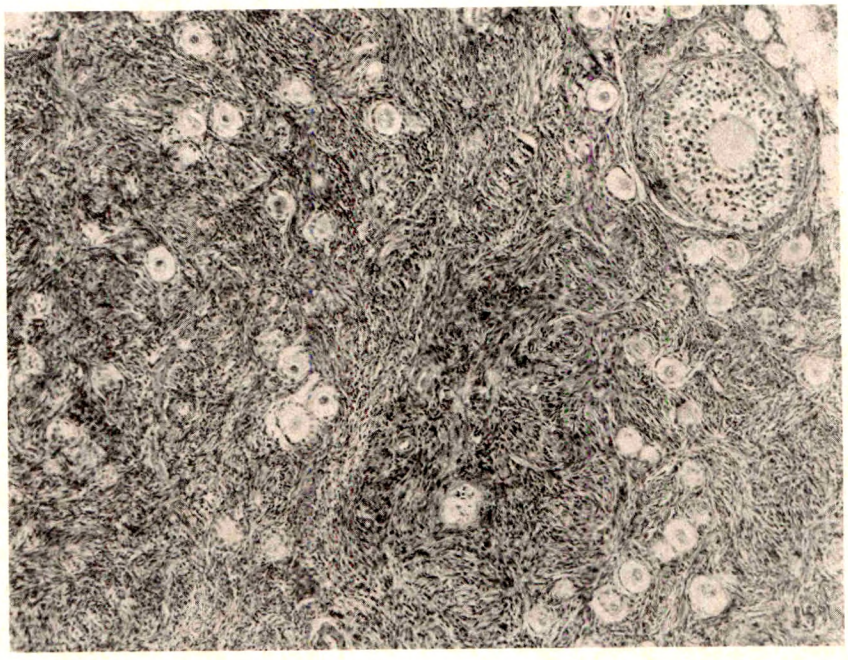

Fig. 2. Ovarian tissue from Case 3 obtained by laparoscopic biopsy. Note normal ovarian tissue with many primary ova and an early developing follicle. (Hematoxylin and eosin. Original magnification ×100.)

Since her initial hospitalization, the patient has had recurrence of abundant clear mucus on several occasions, and at these times the serum FSH level has been 98 and 97 mIU/ml and the serum LH value has been 66 and 93 mIU/ml. Once when there was abundant mucus, human chorionic gonadotropin, 10,000IU, was administered intramuscularly, without producing evidence of ovulation.

Three years after the initial investigation, the patient experienced another episode of spontaneous vaginal bleeding.

Case 3. A 22-year-old woman, gravida 0, experienced menarche at age 13 and had regular menses until oral contraceptive tablets were begun at age 20. She discontinued this medication after 13 months and had no subsequent spontaneous vaginal bleeding. The last episode of withdrawal bleeding had occurred 15 months prior to the patient's first visit.

Approximately 6 months prior to the first visit, the patient developed weakness when climbing stairs and actually fell while going downstairs and also while climbing into a car. She also reported weakness when brushing her teeth and combing and washing her hair at night and increased fatigue in the evenings. She had bilateral ptosis and diplopia. Neuromuscular electrical studies disclosed a decrement in the evoked compound action potential with supramaximal repetitious stimulation of the median nerve; this decrement was corrected following intravenous edrophonium chloride, confirming the presence of neuromuscular blockade consistent with myasthenia gravis.

The thyroid was normal to palpation, and there were no stigmas of Addison's disease. Pelvic examination disclosed moderately atrophic vaginal mucosa, a normal cervix and uterus, and no adnexal masses. Laparoscopic examination demonstrated two small atrophic ovaries, and ovarian biopsy was performed. Histology is shown in Fig. 2. The patient was subsequently treated with estrogens for 3 of each 4 weeks with medroxyprogesterone added during the last 5 treatment days. Withdrawal bleeding occurred. She was also given pyridostigmine bromide for the treatment of myasthenia gravis.

Comment

Associated with normal menopause, there is a gradual loss of primordial ova and follicles, and the ovarian stromal cell nuclei shrink, with fibrous tissue becoming more abundant. In the age group 45 to 49 years, some small follicular cysts and some mild cortical stromal hyperplasia are usually present. The ovary may seem to be formed almost entirely of stroma. After age 50, there is rarely any evidence of follicular activity, and the ovarian cortex is distinguished with difficulty from fibrous tissue elsewhere in the body.[7]

On histologic examination, the ovaries of all but two of the eight patients studied here showed changes typi-

cal of those found in women who had undergone menopause after age 40. There were few or no primordial ova and follicles, along with a compact stroma. Two exceptions in this series are Cases 2 and 3. In both cases, the histology was normal, with a corpus luteum or a developing follicle and ova being identified.

Case 1 is an example of chromosome mosaicism associated with premature menopause. In 1959, Jacobs and associates[8] reported the first case of the 47,XXX syndrome. This particular patient, in addition to mental retardation, had premature menopause at age 19, confirmed by elevated urinary gonadotropins and ovarian biopsy. Other phenotypically female subjects with 47,XXX karyotypes were subsequently studied; the coexistence of premature menopause has proved to be rare, and many patients actually have normal fertility.[9] Gordon and Paulsen[10] reported a single case of premature menopause in XO/XX/XXX/XXXXX mosaicism. Their patient had the onset of menopause at age 17, and the above mosaic was identified in peripheral blood. Attempts to culture ovarian cells were unsuccessful, but they did identify nuclei with zero, one, and two sex chromatin masses in the ovary, suggesting that at least an XX/XXX mosaic existed here. In our Case 1, XO/XX/XXX mosaicism existed with a predominance of XXX in the ovary. Our patient had ovaries which grossly resembled the streak gonads of ovarian agenesis, but she had experienced one spontaneous menses, and a developing follicle was visualized on histologic examination of the ovary. When gonadal abnormality is present in these women with excess X chromosomes, it occurs after ovarian differentiation with some degree of ovarian function possible, and the patient later experiences secondary amenorrhea or premature menopause.[9]

Case 2 is probably an example of the "gonadotropin-resistant ovary syndrome," which was initially described in association with primary amenorrhea.[11] Criteria for diagnosis include endogenous hypergonadotropinemia, presence of normal ovarian follicles, and resistance of ovaries to excessive stimulation with exogenous human gonadotropins. Starup and associates[12] described two patients with secondary amenorrhea, well-developed secondary sex characteristics, and normal 46/XX karyotypes with elevated urinary excretion of FSH and LH, along with normal development of ovarian primordial follicles. A single case was reported by Konickx and Brosens.[13] Efforts to stimulate these ovaries with menopausal gonadotropin plus chorionic gonadotropin were unsuccessful. Our Case 2 is similar to these, but we did not attempt excessive ovarian stimulation with exogenous human gonadotropins except to give human chorionic gonadotropin on one occasion.

The "gonadotropin-resistant ovary syndrome" may be due to an inhibitor that prevents hormone action or to nonresponsiveness of the target cells.[11, 13] Patients with this condition are potentially treatable since follicles are present, and Shangold and associates[14] described one patient who was resistant to stimulation by gonadotropins but who subsequently conceived while receiving estrogenic medication.

Case 3 was associated with myasthenia gravis, and it has been suggested that an autoimmune mechanism is involved in the pathogenesis of this disease.[15] Irvine and associates[16] found antibodies reactive with the theca interna of ovary and with the adrenal cortex in five women with idiopathic adrenal insufficiency and either complete failure of menstruation or premature menopause. This caused them to speculate that ovarian failure may be part of a polyendocrinopathy of which Addison's disease is a part and which is characterized by the formation of autoantibodies. Since autoantibodies have been implicated in premature menopause associated with adrenal insufficiency as well as with myasthenia gravis, we searched for autoantibodies in Case 3 as well as in all other cases. As none was found against theca interna or other normal ovarian tissue, this case may also be an instance of the "gonadotropin-resistant ovary syndrome." Whether or not autoantibodies play a part in the etiology of this condition remains unknown.

In a small group of eight young women with secondary amenorrhea and high FSH levels, only five had findings of typical premature menopause due to ovarian failure with follicular atresia and irreversible sterility. Three women had other conditions, at least two of which are compatible with subsequent pregnancy if appropriate treatment methods can be developed. The possibility of the existence of conditions other than primary ovarian follicular atresia should be investigated, therefore, in young women who have secondary amenorrhea and elevated FSH levels in blood or urine.

Discussion

Dr. Francis G. Griffin, Virginia Beach, Virginia. (Official Guest) Dr. Board and colleagues have presented eight cases of premature ovarian failure. The first five cases are grouped together as primary follicular atresia, a process during which the vast majority of ova die before reaching full maturation. The ovaries contain about 6 million primordial follicles during the twentieth week of gestation, about 1 to 2 million at birth, and about 400,000 follicles at puberty. There is apparently some inherent mechanism of atresia that starts with formation of the ovary in the fetus and continues until the menopause. It is suggested that premature ovarian failure could result from: (1) unsuspected disease process with destruction of the ovaries, (2) increased utilization of follicles due to increased pituitary overactivity, and (3) congenital small ovaries with decreased primordial follicules. It is fair to assume that all ovaries of women do not contain the same number of primordial follicles; therefore, women having ovaries with decreased follicles with normal atretic rates will experience premature menopause prior to the age of 40.

There has been no evidence presented to suggest the mechanism of follicular atresia, which is the most common ovarian change seen in premature menopause. Until we understand the mechanism of the follicular atresia, the etiology of premature menopause in this group will remain an enigma.

The first case presented in detail is that of a young woman with premature ovarian failure associated with chromosomal mosaicism. In 1959, Jacobs and associates[1] presented a case of a female subject with chromosome triploid XXX, termed "super female," and Gordon and Paulsen[2] presented a case of sex chromosomal mosaicism with four stem cell lines XO/XX/XXX/XXXXX. They explained this by simple terms of nondisjunction in two episodes in the postzygotic period. Both of these patients manifested premature menopause.

When injury to the gonad occurs prior to differentiation the patient will appear phenotypically female but will lack pubertal development. These patients will have a sex chromosomal pattern of X/O. The patient of the case presented had developed secondary sexual characteristics but menstruated only at age 18. When injury to the gonad occurs after differentiation into the ovary, these patients appear to be phenotypically female with secondary sexual characteristics and may have normal fertility. The sex chromosomal pattern is one of triploid X−. Depending on the extent of the ovarian injury, the total number of follices are reduced and with the normal atretic rate ovarian failure is manifested at an earlier age. These patients have high gonadotropin levels symptoms of menopause and the ovaries exhibit an afollicular pattern with hypocellular ovarian stroma, rare corpus albicans, and no mature follicles.

It is essential that chromosome analysis be performed in these patients with "spontaneous premature menopause" in order to identify the role of sex chromosomal abnormalities in the pathogenesis of this entity.

Case 2 represents a 26-year-old woman, gravida 0, with the "gonadotropin-resistant ovary syndrome," which was initially described in 1969 by Jones and associates[3] and includes primary amenorrhea, hypergonadotropinemia, and normal follicular apparatus. In 1972, Van Campenhout and associates[4] defined the "resistant ovarian syndrome," as it is known, by the following characteristics: (1) endogenous hypergonadotropinemia, (2) presence of normal ovarian follicles, and (3) hyporeceptivity of the ovaries to excessive stimulation with exogenous human gonadotropins. This young woman had normal secondary sexual characteristics, infrequent episodes of vaginal bleeding,

high gonadotropin levels, and a normal follicular apparatus. She was stimulated with only human chorionic gonadotropins, 10,000 IU, without evidence of ovulation or menstruation.

As our knowledge of the hypothalamic-pituitary-ovarian axis expands, it is apparent the function cannot be explained in simple terms of a positive and negative feedback. It cannot be assumed in the presence of gonadotropins in the menopausal range with an intact follicular apparatus that hypergonadotropinemia is prima facie evidence of ovarian failure. There have been 11 cases of insensitive ovary syndrome previously reported, revealing only primordial follicles with some developing to the antrum stage. As reported by Goldenberg and associates,[5] the first state of follicular development (to the stage of primordial follicle) does not appear to be dependent on gonadotropin stimulation. Development beyond the primordial follicle, however, seems to be dependent on the availability of FSH and LH. Just how the ovary becomes "sensitized" so that it can respond to gonadotropins is unknown. It appears endogenous and exogenous stimulation with gonadotropins is greater when estrogen levels are, high as demonstrated by work of Bradbury[6] and Kullander.[7] Three patients have been described in the literature with gonadotropin resistant ovaries who later conceived while receiving exogenous estrogens.

It is of interest that patients reported by Shapiro and Rubin.[8] Polansky and DePapp,[9] and Shangold and associates,[10] conceived while taking exogenous estrogens after the ovaries had shown marked resistance to exogenous gonadotropin therapy. It appears estrogens might have something to do with gonadotropin receptor sites in the ovary.

It has been suggested by Jones[11, 12] that the "insensitive ovary syndrome" might represent FSH-receptor protein defect. This was supported by familial tendency. But this concept is hard to explain since Starup and colleagues[13] reported a case of "insensitive ovary syndrome" developing after a reported pregnancy. However, if this is an acquired defect, normal ovarian function is possible, including pregnancy before onset of this dysfunction.

The third case was of a 22-year-old woman with normal secondary sexual characteristics with regular menstrual periods until age 20, followed by amenorrhea after oral contraceptives were discontinued, with an additional diagnosis of myasthenia gravis, ovarian biopsies revealed a normal follicular apparatus.

There is serologic and histologic evidence that some cases of premature ovarian failure may have an autoimmune basis. Such cases have been associated with idiopathic adrenal insufficiency,[14] and these have been explained immunologically by the sharing of antigens between the adrenal cortex and the ovary, since myasthenia gravis might be considered in the group of diseases that have an autoimmune mechanism as an etiology. This patient, however, did not reveal any autoimmune antibodies.

A number of cases have been presented in the literature with secondary amenorrhea and high gonadotropins, in which the patients have received steroid treatment before the onset of amenorrhea. It is interesting that these patients had no further menstrual periods after discontinuing oral contraceptives. The activity of noxious agents cannot be excluded.

In conclusion, the basic etiology of premature menopause remains unknown. Dr. Board's group has presented several categories of patients who fall into clinical patterns with premature menopause but have offered no new concepts as to the basic etiology of premature ovarian failure. I advocate a thorough investigation of these patients at an early date, particularly laparotomy for ovarian biopsy when fertility is a consideration.

DR. JAMES D. KITCHIN III, Charlottesville, Virginia. The differential diagnosis of hypergonadotropic hypogonadism includes primary ovarian follicular atresia (menopause), gonadal dysgenesis, gonadotropin-resistant ovary syndrome, and various destructive conditions (castration, autoimmune disease, infiltrative disorders, irradiation, infection). With the exception of menopause and the resistant ovary syndrome, diagnosis is usually suggested by history and associated physical findings.

The report of Dr. Board and colleagues re-emphasizes the necessity of caution in assuming irreversible ovarian follicular atresia in young amenorrheic women with elevated gonadotropins. In cases that appear to be hopeless with regard to future ovarian function and fertility, the important questions are what diagnostic methods are available (and rational) to establish irreversibility with certainty and what, if any, treatment is available.

Goldenberg and associates[1] studied 234 women with primary or secondary amenorrhea and correlated gonadal biopsy findings with measurements of urinary gonadotropins and plasma LH and FSH levels. They concluded that a single plasma FSH value was sufficient to diagnose the presence or absence of ovarian follicles in every case. However, they conceded that women with the resistant ovary syndrome[2] may prove exceptions to this conclusion. This condition, also known as the Savage syndrome,[2] has now been reported in women with primary amenorrhea[2-6] as well as with secondary amenorrhea[7-12] and may be related to an abnormality or deficiency of FSH receptor protein,[14] although earlier successful pregnancies in at least two patients suggest that such a defect may be acquired.

Although the gonadotropin-resistant ovary syndrome is rare, it is the probable diagnosis in two of Dr. Board's patients and it is the most important differential diagnosis because ovarian follicles are present and fertility potential exists. One of the original patients of Jones and deMoraes-Ruehsen[2] ovulated after high dosages of exogenous gonadotropins. Other authors[4-6, 7, 12] have used dosages of menopausal gonadotropins as high as 271 ampules over a period of weeks[12] without ovulation and with little or no increase in estrogen production. Few patients have been exposed to this form of therapy and additional data would be desirable if for no other reason than to rule out the theoretical possibility of biologically abnormal endogenous gonadotropin.

At least four successful pregnancies[7, 9-11] have been reported in women with a diagnosis of resistant ovary syndrome and it is intriguing that in each case pregnancy occurred either during estrogen replacement therapy or shortly after it had been discontinued. Suggested mechanisms include: (1) a rebound effect on endogenous gonadotropin levels following suppression and (2) an estrogen enhancement of follicular response to FSH or an increased content of receptor for both FSH and LH.[9]

It is doubtful that extensive diagnostic testing of hypergonadotropic, hypogonadal women is indicated if fertility is not a consideration. However, if a pregnancy is desired or if a definitive diagnosis is required the question is not whether to perform biopsy of the gonads but whether laparoscopic biopsy is adequate. Sutton[13] has presented convincing data to support the contention that laparoscopic ovarian biopsy is not necessarily representative of the histologic structure of the whole ovary and that the procedure is not free of hazard. In the patients reported by Shangold and associates[7] and Polansky and DePapp[10] no follicles were seen on the laparoscopic ovarian biopsy specimen although both later conceived.

The association of hirsutism and the resistant ovary syndrome as noted in Case 2, has been reported previously.[8, 12] Kim[8] suggested that the slight elevation of plasma androgens in his patient could be related to a relative resistance of the follicular compartments to gonadotropic stimulation but a normal or hyperactive stromal response.

I congratulate the authors for this succinct contribution to the expanding literature on primary ovarian failure. In view of current uncertainties regarding specific diagnosis of disorders within this category and because of prognostic implications and connotations of the term "premature menopause" I would like to suggest that "primary ovarian failure" is more suitable. I would also like to ask Dr. Board the following questions.

1. Was the family history helpful in any of these patients? Jones[14] has reported a familial tendency in the resistant ovary syndrome.
2. Are the patients reported currently on a regimen of estrogen-progestin replacement treatment?
3. How many of the eight women have ever tried to conceive? Apparently five of them had menses for 4 to 14 years. Since only one had ever been pregnant (with a subsequent abortion), does this imply that women subject to premature ovarian failure are relatively infertile as a group?

Information for authors

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. Therefore, all manuscripts must be accompanied by the following written statement, signed by one author: "The undersigned author transfers all copyright ownership of the manuscript (title of article) to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

SO EFFECTIVE YOU'D EXPECT TO WRITE A PRESCRIPTION

SO SAFE YOU DON'T HAVE TO

Preparation H and its principal ingredient—Skin Respiratory Factor (SRF) have been studied *in vitro*.* A group of world renowned wound-healing specialists confirmed that SRF stimulated wound oxygen consumption, epithelialization and collagen synthesis.

The unique Preparation H formula temporarily relieves pain and itching in many cases and actually helps shrink swollen hemorrhoidal tissue due to inflammation. All without anesthetics or steroids.

PREPARATION H®
Clinically tested.
Available in ointment and suppositories.

PREPARATION H ACTIVE INGREDIENTS:
Live Yeast Cell Derivative, supplying 2,000 units Skin Respiratory Factor Per Ounce of Base; Shark Liver Oil 3.0%, supplying Vitamin A.

PERSONALIZED LIBRARY CASES

Keep your personal copies of AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY in these specially designed library file cases. Designed to keep your journal copies near at hand in your office, library, or home.

Your case is heavy bookbinder's board in a rich red Kivar cover. Files are scuff-resistant and washable.

Lettering is stamped in gold leaf and the cases make a fit companion for the most costly binding.

Files are reasonably priced—only $4.95 each, postpaid (3 for $14., 6 for $24.). Add $1.00 postage per case for orders outside U. S. Satisfaction unconditionally guaranteed or your money back! Use the coupon for prompt shipment.

...is a step ahead.

...ious as well as minor side ...ects have been reported with the ... of oral contraceptives. These ...lude thromboembolic disease. ... physician should remain alert ...he earliest manifestations of any ...mptoms of serious disease and ...continue oral contraceptive ...rapy when appropriate. The ...ysician should be fully aware of ... complete Prescribing ...ormation for this product.

"Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism. . ."than those that contain 50 mcg of estrogen. . . and in terms of contraception, 50 mcg products have the same range of effectiveness as those with higher doses of estrogen.

Ortho-Novum 1/50 TRADEMARK 21- and 28-day regimens.

...h yellow tablet contains 1 mg norethindrone and 0.05 mg mestranol.
...h green tablet in the 28-day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables, and references. The physician should be thoroughly familiar with the complete prescribing information and patient information before prescribing the product.

INDICATION: CONTRACEPTION. The pregnancy rate in women using conventional combination oral contraceptives (containing 35 mcg or more of ethinyl estradiol or 50 mcg or more of mestranol) is generally reported as less than one pregnancy per 100 woman-years of use. Slightly higher rates (somewhat more than one pregnancy per 100 woman-years of use) are reported for some combination products containing 35 mcg or less of ethinyl estradiol, and rates on the order of three pregnancies per 100 woman-years are reported for the progestogen-only oral contraceptives. Table 1 gives ranges of pregnancy rates reported in the literature for other means of contraception. The efficacy of these means of contraception (except the IUD) depends upon the degree of adherence to the method.

Table 1: Pregnancies Per 100 Women-Years. IUD, less than 1-6; Diaphragm with spermicidal product (creams or jellies), 2-20; Condom, 3-36; Aerosol foams, 2-29; Jellies and creams, 4-36; Periodic abstinence (rhythm) all types, less than 1-47; 1. Calendar method, 14-47; 2. Temperature method, 1-20; 3. Temperature method—intercourse only in postovulatory phase, less than 1-7; 4. Mucus method, 1-25; No contraception, 60-80. **DOSE-RELATED RISK OF THROMBOEMBOLISM FROM ORAL CONTRACEPTIVES:** Two studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral contraceptives be started on preparations containing .05 mg or less of estrogen. **CONTRAINDICATIONS:** Oral contraceptives should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed, abnormal genital bleeding. 7. Known or suspected pregnancy (see WARNINGS, No. 5).

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.
The use of oral contraceptives is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Four principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. Overall excess mortality due to pulmonary embolism or stroke is on the order of 1.0 to 3.5 deaths annually per 100,000 users and increases with age. **CEREBROVASCULAR DISORDERS:** In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than in nonusers and the risk of thrombotic stroke was 4.0 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION: An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia), the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. The annual excess case rate (increased risk) of myocardial infarction (fatal and nonfatal) in oral contraceptive users was estimated to be approximately 7 cases per 100,000 women users in the 30-39 age group and 67 cases per 100,000 women users in the 40-44 age group. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10-to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent. **Risk of Dose:** In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only oral contraceptives have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk. The risk of thromboembolic and thrombotic disorders, in both users and nonusers of oral contraceptives, increases with age. Oral contraceptives are, however, an independent risk factor for these events. **ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES:** A large prospective study carried out in the United Kingdom estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of oral contraceptives according to age, smoking habits, and duration of use. The overall excess death rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking, and duration of use, nor to compare the effects of continuous versus intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for five or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for five or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. This study reports that the increased risk of circulatory diseases may persist after the pill is discontinued. Another study published at the same time confirms a previously reported increase of mortality in pill users from cardiovascular disease. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of oral contraceptives) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The findings of this analysis are shown in Figure 1 below. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke. (The rates given for pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 cigarettes a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50 percent.) The mortality associated with oral contraceptive use in nonsmokers over 40 is higher than with any other method of contraception in that age group. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia and especially by cigarette smoking. The risk of myocardial infarction in oral contraceptive users is substantially increased in women age 40 and over, especially those with other risk factors. Based on the data currently available, the following chart gives a gross estimate of the risk of death from circulatory disorders associated with the use of oral contraceptives:

SMOKING HABITS AND OTHER PREDISPOSING CONDITIONS—RISK ASSOCIATED WITH USE OF ORAL CONTRACEPTIVES

Age	Below 30	30-39	40+	
Heavy smokers	C	B	A	A—Use associated with very high risk.
Light smokers	D	C	B	B—Use associated with high risk.
Nonsmokers (no predisposing conditions)	D	C,D	C	C—Use associated with moderate risk.
Nonsmokers (other predisposing conditions)	C	C,B	B,A	D—Use associated with low risk.

The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four- to six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2. OCULAR LESIONS. There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue oral contraceptive medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions and institute appropriate diagnostic and therapeutic measures. 3. CARCINOMA. Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in oral contraceptives, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on oral contraceptives. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time oral contraceptives were first given, polycystic ovaries), nearly all occurred in women who had used a sequential oral contraceptive. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only oral contraceptives. Several studies have found no increases in breast cancer in women taking oral contraceptives or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with oral contraceptives, found an excess risk in the subgroups of oral contraceptive users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of oral contraceptives has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleed-

Figure 1: Estimated annual number of deaths associated with control of fertility and no control per 100,000 nonsmoking women, by regimen of control and age of woman.

	15-19	20-24	25-29	30-34	35-39	40-44
No method	5.5	5.2	7.1	14.0	19.3	21.9
Abortion only	2.3	2.5	2.5	5.2	9.8	6.6
Pill only-nonsmokers	1.3	1.4	1.4	2.2	4.5	3.1
Pill only-smokers	1.5	1.6	1.6	10.8	13.4	58.9

Traditional contraception and abortion	0.3	0.4	0.4	0.8	1.4	0.8

4. HEPATIC TUMORS. Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study showed that oral contraceptive formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of oral contraceptives. Two studies relate risk with duration of use of the contraceptive, the risk being much greater after four or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time. 5. USE IN OR IMMEDIATELY PRECEDING PREGNANCY, BIRTH DEFECTS IN OFFSPRING, AND MALIGNANCY IN FEMALE OFFSPRING. The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be on the order of 1 to 4 in 1000 exposures. Although there is no evidence at the present time that oral contraceptives further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including oral contraceptives, in pregnancy. One case control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if the progestogen-only oral contraceptives are used), and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy. 6. GALLBLADDER DISEASE. Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives and estrogens. In one study, an increased risk appeared after two years of use and doubled after four or five years of use. In one of the other studies, an increased risk was apparent between six and twelve months of use. 7. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. An increase in triglycerides and total phospholipids has been observed in patients receiving oral contraceptives. The clinical significance of this finding remains to be defined. 8. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in patients receiving oral contraceptives. In some women hypertension may occur within a few months of beginning oral contraceptive use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two and a half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in oral contraceptive users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. Hypertension that develops as a result of taking oral contraceptives usually returns to normal after discontinuing the drug. 9. HEADACHE. The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of oral contraceptives and evaluation of the cause. 10. BLEEDING IRREGULARITIES. Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Postuse anovulation, possibly prolonged, may also occur in women without previous irregularities. 11. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. 12. BREAST FEEDING. Oral contraceptives given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of oral contraceptives should be deferred until the infant has been weaned. **PRECAUTIONS: General:** 1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another physical examination being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by oral contraceptive therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping oral contraceptives, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. **INFORMATION FOR THE PATIENT: (See Patient Package Insert). DRUG INTERACTIONS:** Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and ampicillin. **CARCINOGENESIS, PREGNANCY, NURSING MOTHERS: See CONTRAINDICATIONS and WARNINGS. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS): Thrombophlebitis. Pulmonary embolism. Coronary thrombosis. Cerebral thrombosis. Cerebral hemorrhage. Hypertension. Gallbladder disease. Liver tumors. Congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis. Neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea, usually the most common adverse reaction. Vomiting, occurs in approximately 10% or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Dysmenorrhea. Amenorrhea during and after treatment. Temporary infertility after discontinuance of treatment. Edema. Chloasma or melasma which may persist. Breast changes: tenderness, enlargement, and secretion. Change in weight (increase or decrease). Change in cervical erosion and cervical secretion. Possible diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Increase in size of uterine leiomyomata. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome. Cataracts. Changes in libido. Chorea. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. (ORTHO-NOVUM 1/50□21 and ORTHO-NOVUM 1/50□28 contain tartrazine. Allergic reactions have been reported with the ingestion of this dye in some patients.) **ACUTE OVERDOSE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Subject index*

A

Abdominal endometriosis, extensive, case of (Cantor, Fenoglio, and Richart), 846 (Comm. in brief)
hysterectomy for gynecologic disease, value of intravenous urography prior to (Sack), 208
Abdominopelvic irradiation, improved survival following, in patients with completed pelvic operation: Ovarian carcinoma (Dembo et al.), 793
Abortions, midtrimester, induced by intra-amniotic prostaglandin $F_{2\alpha}$ with urea and intravenous oxytocin, laminaria use in (Strauss et al.), 260
Acceleration/constant ratio: Nonstress test, II. Antepartum fetal testing (Barrada, Edwards, and Hakanson), 538
of fetal heart rate (Wood, Walker, and Yardley), 523
in labor: Excellent prognostic indicator (Powell, Melville, and MacKenna), 36
Accuracy and safety of midtrimester amniocentesis, report of, at Medical College of Georgia; Eight and one half years' experience (Manganiello et al.), 911
Acid, amniotic fluid uric, study of: Pregnancy in women with xanthinuria (Curiel and Bandinelli), 721 (Comm. in brief)
Activity, fetal, effect of maternal glucose load on (Aladjem et al.), 276
Adenomas, prolactin-secreting pituitary, in women. II. Menstrual function, pituitary reserves, and prolactin production following microsurgical removal (Keye et al.), 360
Adoption, does affect subsequent fertility (Lamb and Leurgans), 138
Adrenalectomy, progesterone, oxytocin, estradiol, and hypophysectomy, influence of, on metabolic fate of ^{3}H-epinephrine in central and peripheral regions during late pregnancy (Parvez, Raza-Bukhari, and Ismahan), 13
Age, gestational, relationship to, I. Fetal breathing movements in uncomplicated pregnancies (Fox, Inglis, and Steinbrecher), 544
infants, small–for–gestational, platelet life span in pregnancies resulting in (Wallenburg and van Kessel), 739
Aggregation, increased platelet, and decreased high-density lipoprotein cholesterol in women on oral contraceptives (Bierenbaum et al.), 638
Alcohol-related problems, screening for, in outpatient obstetric-gynecologic clinic (Russell and Bigler), 4
Amenorrhea, postpill and non-postpill secondary, galactorrhea and pituitary tumors in (March et al.), 45
secondary, effect of dexamethasone on gonadotropin responsiveness to luteinizing hormone–releasing hormone and clomiphene in women with (Sowers and Fayez), 325
Amniocentesis, midtrimester, report of safety and accuracy of, at Medical College of Georgia: Eight and one half years' experience (Manganiello et al.), 911
Amnion in surgery, past and present (Trelford and Trelford-Sauder), 833 (Current developments)
Amniotic fluid bilirubin, spurious elevation of, in acute hydramnios with fetal intestinal obstruction (Wynn and Schreiner), 105 (Comm. in brief)
foam stability–50 percent test, performance of (Sher et al.), 705
test for surfactant, antenatal prediction of graduated risk of hyaline membrane disease by (Schlueter et al.), 761
human plasma and, 13,14-dihydro-15-keto-prostaglandin $F_{2\alpha}$ concentrations in (Ghodgaonkar et al.), 265
steroids, maternal and, throughout human pregnancy (Nagamani et al.), 674
studies on reliability of hexosaminidase levels in: Prenatal diagnosis of Tay-Sachs disease (Grebner and Jackson), 547
thyrotropin-releasing hormone and thyroid hormones in (Morley et al.), 581 (Current investigation)
uric acid, study of: Pregnancy in women with xanthinuria (Curiel and Bandinelli), 721 (Comm. in brief)
Anomalies, congenital, ultrasound in diagnosis of (Hobbins et al.), 331 (Current developments)
Antenatal prediction of graduated risk of hyaline membrane disease by amniotic fluid foam test for surfactant (Schlueter et al.), 761
screening program, results of: Thalassemia and pregnancy (Alger, Golbus, and Laros), 662
Antepartum assessment of fetal reserve, nonstress test for (Lee and Drukker), 460
fetal testing. I. Oxytocin challenge test (Barrada, Edwards, and Hakanson), 538
II. Acceleration/constant ratio: Nonstress test (Barrada, Edwards, and Hakanson), 538
Antibiotics, prophylactic, efficacy of, in cesarean section (Gall), 506
Antiprogesterone, induction of preterm labor in rat by (Csapo and Resch), 823 (Current investigation)
Artery ligation, bilateral internal iliac, in cervical pregnancy: Conservation of reproductive function (Nelson), 145
Aspiration, menstrual, office termination of pregnancy by (Hale et al.), 213
Assay, radioreceptor, for human chorionic gonadotropin in normal and abnormal pregnancies: Clinical evaluation (Lorenz, Work, and Menon), 471
Atraumatic delivery, glucocorticoids, and unstressful labor, role of, in prevention of respiratory distress syndrome (Quirk et al.), 768
Atresia, partial, of fallopian tube, and bicornuate uterus (Farber and Mitchell), 881
Autologous fetal blood, collection and use of (Paxson), 708
Automated assessment, approach to: Fetal heart rate variability (Huey et al.), 691
Autonomic hyperreflexia in pregnancy and labor: Case report (Nath, Vivian, and Cherny), 390

B

Bed rest in twin pregnancy: Identification of critical period and its cost implications (Powers and Miller), 23
Behavior, sexual, and response in relation to complications of pregnancy (Perkins), 498
Benign blue nevus of uterine cervix (Majmudar, Ross, and Gorelkin), 609 (Comm. in brief)
cystic teratoma, twisted, of ovary, identical twins with (Brown), 879
obstructive myxometra: Report of case (Honoré), 847 (Comm. in brief)
Beta, 17-, estradiol-, progesterone and, suppression of mixed lymphocyte reaction by (Kobayashi et al.), 255
-1 glycoprotein, "pregnancy-specific," human fibroblasts produce, in vitro (Rosen et al.), 734
lipotropin, endorphin residues of, in hormone, do reinforce reproductive functions (Kimball), 127
-subunit–like immunoreactive material, human chorionic gonadotropin, in plasma of women wearing intrauterine progesterone contraceptive system (Orloff et al.), 632
Betamethasone and magnesium sulfate administration, pulmonary edema associated with (Elliott et al.), 717 (Comm. in brief)
Bicornuate uterus and partial atresia of fallopian tube (Farber and Mitchell), 881
Big renin concentrations, renin and, maternal and fetal renin activity and, in second-trimester pregnancy (Franks and Hayashi), 20
Bilirubin, amniotic fluid, spurious elevation of, in acute hydramnios with fetal intestinal obstruction (Wynn and Schreiner), 105 (Comm. in brief)
Blood, autologous fetal, collection and use of (Paxson), 708
coagulation factors, effect of chlorotrianisene as postpartum lactation suppression on (Niebyl et al.), 518
and plasma fibrinolytic enzyme function, influence of pregnancy upon (Fletcher, Alkjaersig, and Burstein), 743
flow, reduced uterine, and fetal hypoxemia with acute maternal stress: Experimental observation in pregnant baboon (Morishima, Yeh, and James), 270

*May 1, 1-114; May 15, 115-234; June 1, 235-354; June 15, 355-492; July 1, 493-610; July 15, 611-728; August 1, 729-850; August 15, 851-964.

Blue nevus, benign, of uterine cervix (Majmudar, Ross, and Gorelkin), 600 (Comm. in brief)
Books received, 234
Bradycardia, fetal, relationship of, to maternal administration of lidocaine in sheep (Morishima et al.), 289
Breast cancer, metastatic, study of secretory component in patients with (Puleo et al.), 899
Breathing, fetal: Review (Lewis and Boylan), 587 (Current developments)
movements, fetal, in uncomplicated pregnancies. I. Relationship to gestational age (Fox, Inglis, and Steinbrecher), 544
Breech delivery, modern management of (Mann and Gallant), 611 (Clinical opinion)
vaginal, or cesarean section (Lewis and Seneviratne), 615 (Clinical opinion)

C

Calcium metabolism, perinatal, effects of magnesium sulfate treatment on. I. Maternal and fetal responses (Cruikshank et al.), 243
Cancer, metastatic breast, study of secretory component in patients with (Puleo et al.), 899
Stage I squamous cell, of vulva (Magrina et al.), 453
Candida vaginitis, chronic, cellular and humoral immune status in women with (Syverson et al.), 624
Carcinoma of cervix, pretreatment lymphangiography and operative evaluation in (Lagasse et al.), 219
endometrial, study of endocrine and metabolic variables in postmenopausal women with (Lucas and Yen), 180
ovarian: Improved survival following abdominopelvic irradiation in patients with completed pelvic operation (Dembo et al.), 793
in situ, severe dysplasia and, of vagina (Oliver), 133
squamous, of vulva: Results of treatment, 1938 to 1976 (Benedet et al.), 201
Cardioversion, attempted pharmacologic—Fetal tachycardia prior to development of hydrops: Case report (Klein, Holzman, and Austin), 347 (Comm. in brief)
Care, health: Enigma (Nichols), 187
Catheterized fetal sheep, chronically, continuous variability of fetal Po_2 in (Jansen et al.), 776
Cell cancer, Stage I squamous, of vulva (Magrina et al.), 453
disease patients, pregnant sickle, transfusion therapy in, 851 (Editorial)
Cellular and humoral immune status in women with chronic *Candida* vaginitis (Syverson et al.), 624
Central Association of Obstetricians and Gynecologists, transactions, forty-sixth annual meeting, 355-492
Cephalosporin prophylaxis, perioperative, in cesarean section: Effect of endometritis in high-risk patient (Kreutner et al.), 925
Cervical cytology, abnormal, evaluation of, during pregnancy, with colposcopy (Ostergard and Nieberg), 756
mucus, early studies on rheology of (Clift), 829 (Classic pages)
pregnancy, bilateral internal iliac artery ligation in: Conservation of reproductive function (Nelson), 145
squamocolumnar junction, effect of pregnancy on, in patients with abnormal cervical cytology (Ostergard), 759
Cervicovaginal shedding, asymptomatic, of herpes simplex virus (Ekwo, Wong, and Myers), 102 (Comm. in brief)
Cervix, carcinoma of, pretreatment lymphangiography and operative evaluation in (Lagasse et al.), 219
unripe, preinduction use of laminaria for (Lackritz, Gibson, and Frigoletto), 349 (Comm. in brief)
uterine, benign blue nevus of (Majmudar, Ross, and Gorelkin), 600 (Comm. in brief)
Cesarean hysterectomy: Twenty-five–year review (Haynes and Martin), 393
section, efficacy of prophylactic antibiotics in (Gall), 506
perioperative cephalosporin prophylaxis in: Effect on endometritis in high-risk patient (Kreutner et al.), 925
post–, endomyometritis, comparison of clindamycin-gentamicin and penicillin-gentamicin in treatment of (diZerega et al.), 238
vaginal breech delivery or (Lewis and Seneviratne), 615 (Clinical opinion)
Challenge test, oxytocin, I. Antepartum fetal testing (Barrada, Edwards, and Hakanson), 532
Chlorotrianisene, effect of, as postpartum lactation suppression on blood coagulation factors (Niebyl et al.), 518
Cholesterol, decreased high-density lipoprotein, increased platelet aggregation and, in women on oral contraceptives (Bierenbaum et al.), 638
Chorioamniotic sac, human, deformation and creep in (Lavery and Miller), 366
Chorionic gonadotropin, human, β-subunit–like immunoreactive material in plasma of women wearing intrauterine progesterone contraceptive system (Orloff et al.), 632
–like material: Presence in normal human tissues (Yoshimoto et al.), 729
in normal and abnormal pregnancies, radioreceptor assay for: Clinical evaluation (Lorenz, Work, and Menon), 471
Chromosomal mosaicism 45,X/46,XX/47,XXX, sex, induction of ovulation and pregnancy in woman with (Gemzell and Solish), 599 (Comm. in brief)
Chronically catheterized fetal sheep, continuous variability of fetal Po_2 in (Jansen et al.), 776
Classic pages, 81-82, 225-226, 329-330, 585-586, 715-716, 828-832
Clerkship, obstetrics and gynecology, evaluating student performance in (Stenchever, O'Toole, and Irby), 235
Clindamycin-gentamicin and penicillin-gentamicin, comparison of, in treatment of post–cesarean section endomyometritis (diZerega et al.), 238
Clinic, outpatient obstetric-gynecologic, screening for alcohol-related problems in (Russell and Bigler), 4
private obstetrics and gynecology, social problems of women patients in (Barton, Harvey, and Barton), 477
Clinical evaluation: Radioreceptor assay for human chorionic gonadotropin in normal and abnormal pregnancies (Lorenz, Work, and Menon), 471
opinion, 611-618
practice, female sex hormone receptors and their importance in (Taylor), 385
trends, current: Ectopic pregnancy (Kitchin et al.), 870
Clinically diagnosed premature menopause, identification of differing etiologies of (Board et al.), 936
Clomiphene, luteinizing hormone–releasing hormone and, effect of dexamethasone on gonadotropin responsiveness to, in women with secondary amenorrhea (Sowers and Fayez), 325
Coagulation, blood, and plasma fibrinolytic enzyme function, influence of pregnancy upon (Fletcher, Alkjaersig, and Burstein), 743
factors, blood, effect of chlorotrianisene as postpartum lactation suppression on (Niebyl et al.), 518
parameters, changes in, evaluation of placental endocrine function and: Induction of labor following intrauterine death with intra-amniotic hyperosmolar urea and prostaglandin $F_{2\alpha}$ (Sher), 493
Collection and use of autologous fetal blood (Paxson), 708
Colposcopy, evaluation of abnormal cervical cytology during pregnancy with (Ostergard and Nieberg), 756
Colpotomy incision, tubal ligation by (Whitaker), 885
Combined pregnancies, ultrasonic detection of (Kurzel), 100 (Comm. in brief)
Communications in brief, 100-106, 227-230, 346-350, 599-603, 717-722, 846-849
Compass, Osler's, points of (Lippard), 854
Complicated, pregnancy, by diabetes mellitus in private practice: Review of ten years (Corwin), 156
Complications of pregnancy, sexual behavior and response in relation to (Perkins), 498
Concentration(s) of cortisol and estriol in maternal plasma, effect of stress during labor on (Maltau, Eielsen, and Stokke), 681
13,14-dihydro-15-keto-prostaglandin $F_{2\alpha}$, in human plasma and amniotic fluid (Ghodgaonkar et al.), 265
elevated plasma prolactin, in cholestasis of pregnancy (Ranta et al.), 1
high, of gonadal steroids, hypothalamic-pituitary responses to, in three-month-old infant with feminizing gonadal stromal tumor (Buchanan et al.), 648
renin and big renin, maternal and fetal renin activity and, in second-trimester pregnancy (Franks and Hayashi), 20
Congenital anomalies, ultrasound in diagnosis of (Hobbins et al.), 331 (Current developments)
Constant, acceleration/ratio: Nonstress test, II. Antepartum fetal testing (Barrada, Edwards, and Hakanson), 538
Contraceptive(s) device, Copper T intrauterine, comparison of three different models of (Roy et al.), 568

Contraceptive(s) device—Cont'd
insertion, intrauterine, naproxen sodium in uterine pain following (Buttram, Izu, and Henzl), 575
oral, increased platelet aggregation and decreased high-density lipoprotein cholesterol in women on (Bierenbaum et al.), 638
optimun dosage of (Lawson et al.), 315
steroids, oral, effects of, on serum hexosaminidase activity, IV. Human hexosaminidase isozymes (Nitowsky et al.), 642
system, intrauterine progesterone, human chorionic gonadotropin β-subunit–like immunoreactive material in plasma of women wearing (Orloff et al.), 632
users, oral and nonoral, abnormalities among offspring of (Ortiz-Pérez et al.), 512
Copper T intrauterine contraceptive device, comparison of three different models of (Roy et al.), 568
Correspondence, 231-233, 723-728
Cortisol and estriol in maternal plasma, effect of stress during labor on concentration of (Maltau, Eielsen, and Stokke), 681
Cost implications, its, identification of critical period and: Bed rest in twin pregnancy (Powers and Miller), 23
Creep, deformation and, in human chorioamniotic sac (Lavery and Miller), 366
Current developments, 83-99, 331-345, 587-598, 833-845
investigation, 579-584, 819-827
Cycle(s), normal menstrual, lower esophageal sphincter pressure during (Van Thiel, Gavaler, and Stremple), 64
short-term, in human fetal activity. I. Normal pregnancies (Granat et al.), 696
Cystic teratoma, twisted benign, of ovary, identical twins with (Brown), 879
Cysts, ovarian, recurrent symptomatic functional, syndrome characterized by, in young women (Stone and Swartz), 310
Cytodynamics of human endometrial regeneration, studies on. III. In vitro short-term incubation historadioautography (Ferenczy, Bertrand, and Gelfand), 297
Cytology, abnormal cervical, effect of pregnancy on cervical squamocolumnar junction in patients with (Ostergard), 759
evaluation of, during pregnancy, with colposcopy (Ostergard and Nieberg), 756

D

Death(s), fetal, at term due to lightning (Guha-Ray), 103 (Comm. in brief)
intrauterine, induction of labor following, with intra-amniotic hyperosmolar urea and prostaglandin $F_{2\alpha}$: Evaluation of placental endocrine function and changes in coagulation parameters (Sher), 493
maternal, associated with postpartum vulvar edema (Ewing, Smale, and Elliott), 173
perinatal, in twin pregnancy (Medearis et al.), 413
Decidua, villi and, in early pregnancy, demonstration of immunoreactive somatostatin-like substance in (Kumasaka et al.), 39
Deformation and creep in human chorioamniotic sac (Lavery and Miller), 366
Dehydroepiandrosterone loading test. III. Possible placental function test (Pupkin et al.), 281
Delivery, atraumatic, glucocorticoids, and unstressful labor, role of, in prevention of respiratory distress syndrome (Quirk et al.), 768
breech, modern management of (Mann and Gallant), 611 (Clinical opinion)
of tiny newborn (Haesslein and Goodlin), 192
vaginal breech, or cesarean section (Lewis and Seneviratne), 615 (Clinical opinion)
Density, high-, lipoprotein cholesterol, decreased, increased platelet aggregation and, in women on oral contraceptives (Bierenbaum et al.), 638
optical, at 400 and 650 nm, tests of, comparison of lecithin/sphingomyelin ratio and: Assessment of fetal lung maturity (Spellacy et al.), 528
Device, Copper T intrauterine contraceptive, comparison of three different models of (Roy et al.), 568
insertion, intrauterine contraceptive, naproxen sodium in uterine pain following (Buttram, Izu, and Henzl), 575
Dexamethasone, effect of, on gonadotropin responsiveness to luteinizing hormone–releasing hormone and clomiphene in women with secondary amenorrhea (Sowers and Fayez), 325
on prolactin secretion in late pregnancy (Kauppila, Puukka, and Tuimala), 752
Diabetes mellitus, pregnancy complicated by, in private practice: Review of ten years (Corwin), 156
value of lecithin/sphingomyelin ratios in: Critical review (Lowensohn and Gabbe), 702
Diabetic pregnancies complicated by nephropathy, estriol determinations in (Rothchild et al.), 772
Diagnosed premature menopause, identification of differing etiologies of (Board et al.), 936
Diagnosis of congenital anomalies, ultrasound in (Hobbins et al.), 331 (Current developments)
and management, enigmas in: Urinary tract endometriosis (Moore et al.), 162
prenatal, of sacrococcygeal teratoma (Horger and McCarter), 228 (Comm. in brief)
of Tay-Sachs disease: Studies on reliability of hexosaminidase levels in amniotic fluid (Grebner and Jackson), 547
Diagnostic significance of double-stimulation tests with luteinizing hormone–releasing hormone and peripheral steroid-gonadotropin interactions in polycystic ovarian disease (Moltz et al.), 813
ultrasound, value of, as screening test for intrauterine growth retardation: Comparison of nine parameters (Wittmann et al.), 30
Diethylstilbestrol-exposed population, six years' experience with screening of (Mangan et al.), 860
13,14-Dihydro-15-keto-prostaglandin $F_{2\alpha}$ concentrations in human plasma and amniotic fluid (Ghodgaonkar et al.), 265
Disease, bilateral Paget's, of nipple: Case report (Anderson), 877
gynecologic, value of intravenous urography prior to abdominal hysterectomy for (Sack), 208
hyaline membrane, antenatal prediction of graduated risk of, by amniotic fluid foam test for surfactant (Schlueter et al.), 761
Legionnaires', and pregnancy, association of (Baker and Philips), 227 (Comm. in brief)
patients, pregnant sickle cell, transfusion therapy in, 851 (Editorial)
polycystic ovarian, peripheral steroid-gonadotropin interactions and diagnostic significance of double-stimulation tests with luteinizing hormone–releasing hormone in (Moltz et al.), 813
Tay-Sachs, prenatal diagnosis of: Studies on reliability of hexosaminidase levels in amniotic fluid (Grebner and Jackson), 547
vulvar, further observations on effect of topical progesterone on (Jasionowski and Jasionowski), 565
Distress syndrome, respiratory, role of glucocorticoids, unstressful labor, and atraumatic delivery in prevention of (Quirk et al.), 768
Dosage, optimum, of oral contraceptive (Lawson et al.), 315
Dysplasia, severe, and carcinoma in situ of vagina (Oliver), 133

E

E_2, prostaglandin, suppositories, vaginal, uterine rupture with use of (Sandler et al.), 348 (Comm. in brief)
Ectopic pregnancy: Current clinical trends (Kitchin et al.), 870
Edema, postpartum vulvar, maternal deaths associated with (Ewing, Smale, and Elliott), 173
pulmonary, associated with magnesium sulfate and betamethasone administration (Elliott et al.), 717 (Comm. in brief)
Editorial, 851
Endocrine function, placental, evaluation of, and changes in coagulation parameters: Induction of labor following intrauterine death with intra-amniotic hyperosmolar urea and prostaglandin $F_{2\alpha}$ (Sher), 493
and metabolic variables in postmenopausal women with endometrial carcinoma, study of (Lucas and Yen), 180
studies of normal and polycystic ovarian tissues in vitro (Wilson et al.), 56
Endometrial carcinoma, study of endocrine and metabolic variables in postmenopausal women with (Lucas and Yen), 180
regeneration, human, studies on cytodynamics of. III. In vitro short-term incubation historadioautography (Ferenczy, Bertrand, and Gelfand), 297

Endometriosis, extensive abdominal, case of (Cantor, Fenoglio, and Richart), 846 (Comm. in brief)
urinary tract: Enigmas in diagnosis and management (Moore et al.), 162
Endometritis in high-risk patient, effect on: Perioperative cephalosporin prophylaxis in cesarean section (Kreutner et al.), 925
and peritonitis, tuberculous, mimicking "frozen pelvis" (Freedman, Coleman, and Blasco), 719 (Comm. in brief)
Endometrium, baboon as primate model for study of (Dollar et al.), 305
Endomyometritis, post-cesarean section, comparison of clindamycin-gentamicin and penicillin-gentamicin in treatment of (di-Zerega et al.), 238
Endorphin residues of beta lipotropin in hormone, do reinforce reproductive functions (Kimball), 127
Endotoxin shock in beagle dog (Morris et al.), 120
Enzyme function, plasma fibrinolytic, and blood coagulation, influence of pregnancy upon (Fletcher, Alkjaersig, and Burstein), 743
Epinephrine, ^{3}H-, metabolic fate of, in central and peripheral regions during late pregnancy, influence of hypophysectomy, adrenalectomy, progesterone, oxytocin, and estradiol on (Parvez, Raza-Bukhari, and Ismahan), 13
methergine-induced uterine tetany treated with: Case report (Wong and Paul), 602 (Comm. in brief)
Ergonovine, methyl, ovum transport in women treated with (Guiloff et al.), 321
Esophageal sphincter pressure, lower, during normal menstrual cycle (Van Thiel, Gavaler, and Stremple), 64
Estradiol-17β, progesterone and, suppression of mixed lymphocyte reaction by (Kobayashi et al.), 255
hypophysectomy, adrenalectomy, progesterone, and oxytocin, influence of, on metabolic fate of ^{3}H-epinephrine in central and peripheral regions during late pregnancy (Parvez, Raza-Bukhari, and Ismahan), 13
Estriol, cortisol and, in maternal plasma, effect of stress during labor on concentration of (Maltau, Eielsen, and Stokke), 681
determination in diabetic pregnancies complicated by nephropathy (Rothchild et al.), 772
Etiology(ies), differing, of clinically diagnosed premature menopause, identification of (Board et al.), 936
microbiologic, of acute salpingitis, use of laparoscopy to determine (Sweet et al.), 68
Experimental observation in pregnant baboon: Reduced uterine blood flow and fetal hypoxemia with acute maternal stress (Morishima, Yeh, and James), 270
Exposed population, diethylstilbestrol-, six years' experience with screening of (Mangan et al.), 860

F

$F_{2\alpha}$, prostaglandin, 13,14-dihydro-15-keto-, concentrations in human plasma and amniotic fluid (Ghodgaonkar et al.), 265
intra-amniotic hyperosmolar urea and, induction of labor following intrauterine death with: Evaluation of placental endocrine function and changes in coagulation parameters (Sher), 493
with urea and intravenous oxytocin, laminaria use in midtrimester abortions induced by (Strauss et al.), 260
Factors, blood coagulation, effect of chlorotrianisene as postpartum lactation suppression on (Niebyl et al.), 518
Fallopian tube, leiomyoma of: Cause of tubal pregnancy (Moore, Waxman, and Udoffia), 101 (Comm. in brief)
partial atresia of, and bicornuate uterus (Farber and Mitchell), 881
Family planning, natural, randomized prospective study of use-effectiveness of two methods of: Interim report (Wade et al.), 628
Female sex hormone receptors and their importance in clinical practice (Taylor), 385
Feminizing gonadal stromal tumor, hypothalamic-pituitary responses to high concentrations of gonadal steroids in three-month-old infant with (Buchanan et al.), 648
Fertility, subsequent, does adoption affect (Lamb and Leurgans), 138
Fetal activity, effect of maternal glucose load on (Aladjem et al.), 276
blood, autologous, collection and use of (Paxson), 708
bradycardia, relationship of, to maternal administration of lidocaine in sheep (Morishima et al.), 289
breathing movements in uncomplicated pregnancies. I. Relationship to gestational age (Fox, Inglis, and Steinbrecher), 544
human, short-term cycles in. I. Normal pregnancies (Granat et al.), 696
Fetal breathing—Cont'd
Review (Lewis and Boylan), 587 (Current developments)
death at term due to lightning (Guha-Ray), 103 (Comm. in brief)
heart rate, acceleration of (Wood, Walker, and Yardley), 523
in labor: Excellent prognostic indicator (Powell, Melville, and MacKenna), 36
variability: Approach to automated assessment (Huey et al.), 691
ultrasonic evaluation of (Yamaguchi and Lee), 422
hypoxemia, reduced uterine blood flow and, with acute maternal stress: Experimental observation in pregnant baboon (Morishima, Yeh, and James), 270
immunoglobulin production and prematurely ruptured membranes, relationship between (Cederqvist et al.), 784
intestinal obstruction, spurious elevation of amniotic fluid bilirubin in acute hydramnios with (Wynn and Schreiner), 105 (Comm. in brief)
lung maturity, assessment of: Comparison of lecithin/sphingomyelin ratio and tests of optical density at 400 and 650 nm (Spellacy et al.), 528
monitoring, intrapartum, controlled trial of differential effects of (Haverkamp et al.), 399
Po_2, continuous variability of, in chronically catheterized fetal sheep (Jansen et al.), 776
rabbit, effects of prolactin on pulmonary maturation in (Van Petten and Bridges), 711
renin activity and renin and big renin concentrations, maternal and, in second-trimester pregnancy (Franks and Hayashi), 20
reserve, nonstress test for antepartum assessment of (Lee and Drukker), 460
responses, maternal and, I. Effects of magnesium sulfate treatment on perinatal calcium metabolism (Cruikshank et al.), 254
sheep, chronically catheterized, continuous variability of fetal Po_2 in (Jansen et al.), 776
tachycardia prior to development of hydrops—Attempted pharmacologic cardioversion: Case report (Klein, Holzman, and Austin), 347 (Comm. in brief)
testing, antepartum. I. Oxytocin challenge test (Barrada, Edwards, and Hakanson), 538
II. Acceleration/constant ratio: Nonstress test (Barrada, Edwards, and Hakanson), 538
Fetus, human, relationship of heart rate patterns and tissue pH in (Young, Katz, and Klein), 685
Fibrinolytic enzyme function, plasma, and blood coagulation, influence of pregnancy upon (Fletcher, Alkjaersig, and Burstein), 743
Fibroblasts, human, produce "pregnancy-specific" beta-1 glycoprotein in vitro (Rosen et al.), 734
Flow, reduced uterine blood, and fetal hypoxemia with acute maternal stress: Experimental observation in pregnant baboon (Morishima, Yeh, and James), 270
Fluid, amniotic, human plasma and, 13,14-dihydro-15-keto-prostaglandin $F_{2\alpha}$ concentrations in (Ghodgaonkar et al.), 265
studies on reliability of hexosaminidase levels in: Prenatal diagnosis of Tay-Sachs disease (Grebner and Jackson), 547
thyrotropin-releasing hormone and thyroid hormones in (Morley et al.), 581 (Current investigation)
bilirubin, amniotic, spurious elevation of, in acute hydramnios with fetal intestinal obstruction (Wynn and Schreiner), 105 (Comm. in brief)
foam stability, amniotic, –50 percent test, performance of (Sher et al.), 705
test, amniotic, for surfactant, antenatal prediction of graduated risk of hyaline membrane disease by (Schlueter et al.), 761
steroids, amniotic, maternal and, throughout human pregnancy (Nagamani et al.), 674
uric acid, amniotic, study of: Pregnancy in woman with xanthinuria (Curiel and Bandinelli), 721 (Comm. in brief)
Foam stability, amniotic fluid, –50 percent test, performance of (Sher et al.), 705
test, amniotic fluid, for surfactant, antenatal prediction of graduated risk of hyaline membrane disease by (Schlueter et al.), 761
"Frozen pelvis," tuberculous peritonitis and endometritis mimicking (Freedman, Coleman, and Blasco), 719 (Comm. in brief)
Function, hypothalamic-ppituitary, and radiographic evaluation of women with hyperprolactinemia and "empty" sella turcica (Haney et al.), 917
plasma fibrinolytic enzyme, and blood coagulation, influence of pregnancy upon (Fletcher, Alkjaersig, and Burstein), 743

G

Galactorrhea and pituitary tumors in postpill and non-postpill secondary amenorrhea (March et al.), 45
Genetics, medical, legal and social issues in (Turner, Hayashi, and Pogoloff), 83
Gentamicin, clindamycin-, and penicillin-gentamicin, comparison of, in treatment of post–cesarean section endomyometritis (diZerega et al.), 238
Georgia, Medical College of, report of safety and accuracy of midtrimester amniocentesis at: Eight and one half years' experience (Manganiello et al.), 911
Gestational age infants, small–for–, platelet life span in pregnancies resulting in (Wallenburg and van Kessel), 739
relationship to, I. Fetal breathing movements in uncomplicated pregnancies (Fox, Inglis, and Steinbrecher), 544
Glucocorticoids, unstressful labor, and atraumatic delivery, role of, in prevention of respiratory distress syndrome (Quirk et al.), 768
Glucose load, maternal, effect of, on fetal activity (Aladjem et al.), 276
Glycoprotein, "pregnancy-specific" beta-1, human fibroblasts produce, in vitro (Rosen et al.), 734
Gonadal steroids, hypothalamic-pituitary responses to high concentrations of, in three-month-old infant with feminizing gonadal stromal tumor (Buchanan et al.), 648
Gonadotropin, human chorionic, β-subunit–like immunoreactive material in plasma of women wearing intrauterine progesterone contraceptive system (Orloff et al.), 632
–like material: Presence in normal human tissues (Yoshimoto et al.), 729
in normal and abnormal pregnancies, radioreceptor assay for: Clinical evaluation (Lorenz, Work, and Menon), 471
pregnancy-associated ovarian refractoriness to: Myth (diZerega and Hodgen), 819 (Current investigation)
responsiveness to luteinizing hormone–releasing hormone and clomiphene, effect of dexamethasone on, in women with secondary amenorrhea (Sowers and Fayez), 325
-steroid interactions, peripheral, and diagnostic significance of double-stimulation tests with luteinizing hormone–releasing hormone in polycystic ovarian disease (Moltz et al.), 813
Growth retardation, intrauterine, value of diagnostic ultrasound as screening test for: Comparison of nine parameters (Wittmann et al.), 30
Gynecologic disease, value of intravenous urography prior to abdominal hysterectomy for (Sack), 208
malignancy, determinant factor in patients undergoing pelvic irradiation for: Correlation between retinal and pelvic vascular status (van Nagell et al.), 551
obstetric-, clinic, outpatient, screening for alcohol-related problems in (Russell and Bigler), 4
oncology patient, quality of life for (Newton), 866
Gynecology clerkship, obstetrics and, evaluating student performance in (Stenchever, O'Toole, and Irby), 235
obstetrics and, clinic, private, social problems of women patients in (Barton, Harvey, and Barton), 477

H

^{3}H-epinephrine, metabolic fate of, in central and peripheral regions during late pregnancy, influence of hypophysectomy, adrenalectomy, progesterone, oxytocin, and estradiol on (Parvez, Baza-Bukhari, and Ismahan), 13
Health care: Enigma (Nichols), 187
Heart, fetal, ultrasonic evaluation of (Yamaguchi and Lee), 422
rate acceleration, fetal, in labor: Excellent prognostic indicator (Powell, Melville, and MacKenna), 36
fetal, acceleration of (Wood, Walker, and Yardley), 523
patterns and tissue pH, relationship of, in human fetus (Young, Katz, and Klein), 685
variability, fetal: Approach to automated assessment (Huey et al.), 691
Herpes simplex virus, asymptomatic cervicovaginal shedding of (Ekwo, Wong, and Myers), 102 (Comm. in brief)
Hexosaminidase isozymes, human. IV. Effects of oral contraceptive steroids on serum hexosaminidase activity (Nitowsky et al.), 642
levels in amniotic fluid, studies on reliability of: Prenatal diagnosis of Tay-Sachs disease (Grebner and Jackson), 547
Histologic findings, normal and abnormal, of ovaries, ovarian hyperandrogenism with (Kim et al.), 445
Historadioautography, in vitro short-term incubation, III. Studies on cytodynamics of human endometrial regeneration (Ferenczy, Bertrand, and Gelfand), 297
Hormone(s), endorphin residues of beta lipotropin in, do reinforce reproductive functions (Kimball), 127
luteinizing, –releasing hormone and clomiphene, effect of dexamethasone on gonadotropin responsiveness to, in women with secondary amenorrhea (Sowers and Fayez), 325
levels in human plasma: Radioimmunoassay method (Aksel and Glass), 619
receptors, female sex, and their importance in clinical practice (Taylor), 385
–releasing hormone, luteinizing, diagnostic significance of double-stimulation tests with, and peripheral steroid-gonadotropin interactions in polycystic ovarian disease (Moltz et al.), 813
thyroid, thyrotropin-releasing hormone and, in amniotic fluid (Morley et al.), 581 (Current investigation)
thyrotropin-releasing, and thyroid hormones in amniotic fluid (Morley et al.), 581 (Current investigation)
Human chorionic gonadotropin β-subunit–like immunoreactive material in plasma of women wearing intrauterine progesterone contraceptive system (Orloff et al.), 632
–like material: Presence in normal human tissues (Yoshimoto et al.), 729
in normal and abnormal pregnancies, radioreceptor assay for: Clinical evaluation (Lorenz, Work, and Menon), 471
Humoral immune status, cellular and, in women with chronic *Canaida* vaginitis (Syverson et al.), 624
Hyaline membrane disease, antenatal prediction of graduated risk of, by amniotic fluid foam test for surfactant (Schlueter et al.), 761
Hydramnios, acute, spurious elevation of amniotic fluid bilirubin in, with fetal intestinal obstruction (Wynn and Schreiner), 105 (Comm. in brief)
Hydrops, fetal tachycardia prior to development of—Attempted pharmacologic cardioversion: Case report (Klein, Holzman, and Austin), 347 (Comm. in brief)
Hydrostatic pressure, intravaginal, correction of postpartum uterine inversion by application of (Sher), 601 (Comm. in brief)
Hyperandrogenism, ovarian, with normal and abnormal histologic findings of ovaries (Kim et al.), 445
Hyperosmolar urea, intra-amniotic, and prostaglandin $F_{2\alpha}$, induction of labor following intrauterine death with: Evaluation of placental endocrine function and changes in coagulation parameters (Sher), 493
Hyperprolactinemia and "empty" sella turcica, hypothalamic-pituitary function and radiographic evaluation of women with (Haney et al.), 917
Hyperreflexia, autonomic, in pregnancy and labor: Case report (Nath, Vivian, and Cherny), 390
Hypophysectomy, adrenalectomy, progesterone, oxytocin, and estradiol, influence of, on metabolic fate of ^{3}H-epinephrine in central and peripheral regions during late pregnancy (Parvez, Raza-Bukhari, and Ismahan), 13
Hypothalamic-pituitary function and radiographic evaluation of women with hyperprolactinemia and "empty" sella turcica (Haney et al.), 917
responses to high concentrations of gonadal steroids in three-month-old infant with feminizing gonadal stromal tumor (Buchanan et al.), 648
Hypoxemia, fetal, reduced uterine blood flow and, with acute maternal stress: Experimental observation in pregnant baboon (Morishima, Yeh, and James), 270
Hysterectomy(ies), abdominal, for gynecologic disease, value of intravenous urography prior to (Sack), 208
cesarean: Twenty-five–year review (Haynes and Martin), 393
radical: Critical review of twenty-two years' experience (Underwood et al.), 889
ten-year review of: Trends, indications, and risks (Amirikia and Evans), 431

I

Identification of differing etiologies of clinically diagnosed premature menopause (Board et al.), 936
Iliac artery ligation, bilateral internal, in cervical pregnancy: Conservation of reproductive function (Nelson), 145
Immune status, cellular and humoral, in women with chronic *Candida* vaginitis (Syverson et al.), 624

Immunoglobulin production, fetal, and prematurely ruptured membranes, relationship between (Cederqvist et al.), 784
Immunoreactive material, human chorionic gonadotropin β-subunit–like, in plasma of women wearing intrauterine progesterone contraceptive system (Orloff et al.), 632
somatostatin-like substance in villi and decidua, demonstration of, in early pregnancy (Kumasaka et al.), 39
Incision, colpotomy, tubal ligation by (Whitaker), 885
Incontinence symptoms, urinary, in women, urodynamic analysis of (Drutz and Mandel), 789
Incubation historadioautography, in vitro short-term, III. Studies on cytodynamics of human endometrial regeneration (Ferenczy, Bertrand, and Gelfand), 297
Induced, methergine-, uterine tetany treated with epinephrine: Case report (Wong and Paul), 602 (Comm. in brief)
midtrimester abortions, by intra-amniotic prostaglandin $F_{2\alpha}$ with urea and intravenous oxytocin, laminaria use in (Strauss et al.), 260
Induction of labor following intrauterine death with intra-amniotic hyperosmolar urea and prostaglandin $F_{2\alpha}$: Evaluation of placental endocrine function and changes in coagulation parameters (Sher), 493
of ovulation and pregnancy in woman with sex chromosomal mosaicism 45,X/46,XX/47,XXX (Gemzell and Solish), 599 (Comm. in brief)
Infant(s), small–for–gestational age, platelet life span in pregnancies resulting in (Wallenburg and van Kessel), 739
three-month-old, with feminizing gonadal stromal tumor, hypothalamic-pituitary responses to high concentrations of gonadal steroids in (Buchanan et al.), 648
Interactions, peripheral steroid-gonadotropin, and diagnostic significance of double-stimulation tests with luteinizing hormone–releasing hormone in polycystic ovarian disease (Moltz et al.), 813
Intestinal obstruction, fetal, spurious elevation of amniotic fluid bilirubin in acute hydramnios with (Wynn and Schreiner), 105 (Comm. in brief)
polypeptide, vasoactive, in tissues of human female reproductive tract (Goodnough et al.), 579 (Current investigation)
Intra-amniotic hyperosmolar urea and prostaglandin $F_{2\alpha}$, induction of labor following intrauterine death with: Evaluation of placental endocrine function and changes in coagulation parameters (Sher), 493
prostaglandin $F_{2\alpha}$ with urea and intravenous oxytocin, laminaria use in midtrimester abortions induced by (Strauss et al.), 260
Intramural versus transcervical recording: Motility of human myometrium in vivo (Coutinho et al.), 801
Intrapartum fetal monitoring, controlled trial of differential effects of (Haverkamp et al.), 399
Intrauterine contraceptive device, Copper T, comparison of three different models of (Roy et al.), 568
insertion, naproxen sodium in uterine pain following (Buttram, Izu, and Henzl), 575
death, induction of labor following, with intra-amniotic hyperosmolar urea and prostaglandin $F_{2\alpha}$: Evaluation of placental endocrine function and changes in coagulation parameters (Sher), 493
growth retardation, value of diagnostic ultrasound as screening test for: Comparison of nine parameters (Wittmann et al.), 30
progesterone contraceptive system, human chorionic gonadotropin β-subunit–like immunoreactive material in plasma of women wearing (Orloff et al.), 632
Intravaginal hydrostatic pressure, correction of postpartum uterine inversion by application of (Sher), 601 (Comm. in brief)
Intravenous oxytocin, urea and, laminaria use in midtrimester abortions induced by intra-amniotic prostaglandin $F_{2\alpha}$ with (Strauss et al.), 260
urography prior to abdominal hysterectomy for gynecologic disease, value of (Sack), 208
Inversion, postpartum uterine, correction of, by application of intravaginal hydrostatic pressure (Sher), 601 (Comm. in brief)
Irradiation, abdominopelvic, improved survival following, in patients with completed pelvic operation: Ovarian carcinoma (Dembo et al.), 793
pelvic, for gynecologic malignancy, determinant factor in patients undergoing: Correlation between retinal and pelvic vascular status (van Nagell et al.), 551
Isozymes, human hexosaminidase. IV. Effects of oral contraceptive steroids on serum hexosaminidase activity (Nitowsky et al.), 642
Items, 107-114, 351-354, 604-610, 850

J

Junction, cervical squamocolumnar, effect of pregnancy on, in patients with abnormal cervical cytology (Ostergard), 759

L

Labor, effect of stress during, on concentration of cortisol and estriol in maternal plasma (Maltau, Eielsen, and Stokke), 681
fetal heart rate acceleration in: Excellent prognostic indicator (Powell, Melville, and MacKenna), 36
induction of, following intrauterine death with intra-amniotic hyperosmolar urea and prostaglandin $F_{2\alpha}$: Evaluation of placental endocrine function and changes in coagulation parameters (Sher), 493
pregnancy and, autonomic hyperreflexia in: Case report (Nath, Vivian, and Cherny), 390
preterm, induction of, in rat by antiprogesterone (Csapo and Resch), 823 (Current investigation)
unstressful, glucocorticoids, and atraumatic delivery, role of, in prevention of respiratory distress syndrome (Quirk et al.), 768
Lactation suppression, postpartum, effect of chlorotrianisene as, on blood coagulation factors (Niebyl et al.), 518
Laminaria, preinduction use of, for unripe cervix (Lackritz, Gibson, and Frigoletto), 349 (Comm. in brief)
use in midtrimester abortions induced by intra-amniotic prostaglandin $F_{2\alpha}$ with urea and intravenous oxytocin (Strauss et al.), 260
Laparoscopy, use of, to determine microbiologic etiology of acute salpingitis (Sweet et al.), 68
Lecithin/sphingomyelin ratio(s), lidocaine interference in (Clague and McGeary), 229 (Comm. in brief)
and tests of optical density at 400 and 650 nm, comparison of: Assessment of fetal lung maturity (Spellacy et al.), 528
value of, in diabetes: Critical review (Lowensohn and Gabbe), 702
Legal and social issues in medical genetics (Turner, Hayashi, and Pogoloff), 83 (Current developments)
Legionnaires' disease and pregnancy, association of (Baker and Philips), 227 (Comm. in brief)
Leiomyoma of fallopian tube: Cause of tubal pregnancy (Moore, Waxman, and Udoffia), 101 (Comm. in brief)
Leiomyosarcoma, uterine (Hannigan and Gomez), 557
Leukocyte phagocytosis, human polymorphonuclear, in pregnancy (Persellin and Thoi), 250
Lidocaine interference in lecithin/sphingomyelin ratios (Clague and McGeary), 229 (Comm. in brief)
relationship of fetal bradycardia to maternal administration of, in sheep (Morishima et al.), 289
Life, quality of, for gynecologic oncology patient (Newton), 866
span, platelet, in pregnancies resulting in small–for–gestational age infants (Wallenburg and van Kessel), 739
Ligation, bilateral internal iliac artery, in cervical pregnancy: Conservation of reproductive function (Nelson), 145
tubal, by colpotomy incision (Whitaker), 885
Lightning, fetal death at term due to (Guha-Ray), 103 (Comm. in brief)
Lipotropin, beta, endorphin residues of, in hormone, do reinforce reproductive functions (Kimball), 127
cholesterol, decreased high-density, increased platelet aggregation and, in women on oral contraceptives (Bierenbaum et al.), 638
Load, maternal glucose, effect of, on fetal activity (Aladjem et al.), 276
Loading test, dehydroepiandrosterone. III. Possible placental function test (Pupkin et al.), 281
Lung maturity, fetal, assessment of: Comparison of lecithin/sphingomyelin ratio and tests of optical density at 400 and 650 nm (Spellacy et al.), 528
Luteal phase defects, unsuspected subclinical pregnancies in patients with (Cline), 438
Luteinizing hormone–releasing hormone and clomiphene, effect of dexamethasone on gonadotropin responsiveness to, in women with secondary amenorrhea (Sowers and Fayez), 325
diagnostic significance of double-stimulation tests with, and peripheral steroid-gonadotropin interactions in polycystic ovarian disease (Moltz et al.), 813
levels in human plasma: Radioimmunoassay method (Aksel and Glass), 619
Lymphangiography, pretreatment, and operative evaluation in carcinoma of cervix (Lagasse et al.), 219

Lymphocyte reaction, mixed, suppression of, by progesterone and estradiol-17β (Kobayashi et al.), 255

M

Magnesium sulfate and betamethasone administration, pulmonary edema associated with (Elliott et al.), 717 (Comm. in brief)
treatment, effects of, on perinatal calcium metabolism. I. Maternal and fetal responses (Cruikshank et al.), 243
Malignancy, gynecologic, determinant factor in patients undergoing pelvic irradiation for: Correlation between retinal and pelvic vascular status (van Nagell et al.), 551
Maternal administration of lidocaine, relationship of fetal bradycardia to, in sheep (Morishima et al.), 289
and amniotic fluid steroids throughout human pregnancy (Nagamani et al.), 674
deaths associated with postpartum vulvar edema (Ewing, Smale, and Elliott), 173
and fetal renin activity and renin and big renin concentrations in second-trimester pregnancy (Franks and Hayashi), 20
responses, I. Effects of magnesium sulfate treatment on perinatal calcium metabolism (Cruikshank et al.), 243
glucose load, effect of, on fetal activity (Aladjem et al.), 276
plasma, effect of stress during labor on concentration of cortisol and estriol in (Maltau, Eielsen, and Stokke), 681
stress, acute, reduced uterine blood flow and fetal hypoxemia with: Experimental observation in pregnant baboon (Morishima, Yeh, and James), 270
transport: Behind drama (Souma), 904
one-way: Evolving concept (Boehm and Haire), 484
Maturation, pulmonary, in fetal rabbit, effects of prolactin on (van Petten and Bridges), 711
Maturity, fetal lung, assessment of: Comparison of lecithin/sphingomyelin ratio and tests of optical density at 400 and 650 nm (Spellacy et al.), 528
Medical College of Georgia, report of safety and accuracy of midtrimester amniocentesis at: Eight and one half years' experience (Manganiello et al.), 911
genetics, legal and social issues in (Turner, Hayashi, and Pogoloff), 83
Mellitus, diabetes, pregnancy complicated by, in private practice: Review of ten years (Corwin), 156
Membrane(s) disease, hyaline, antenatal prediction of graduated risk of, by amniotic fluid foam test for surfactant (Schlueter et al.), 761
premature rupture of: Conservative approach (Kappy et al.), 655
prematurely ruptured, and fetal immunoglobulin production, relationship between (Cederqvist et al.), 784
Menopause, clinically diagnosed premature, identification of differing etiologies of (Board et al.), 936
Menstrual aspiration, office termination of pregnancy by (Hale et al.), 213
cycle, normal, lower esophageal sphincter pressure during (Van Thiel, Gavaler, and Stremple), 64
function, pituitary reserves, and prolactin production following microsurgical removal, II. Prolactin-secreting pituitary adenomas in women (Keye et al.), 360
Metabolic fate of ^{3}H-epinephrine in central and peripheral regions during late pregnancy, influence of hypophysectomy, adrenalectomy, progesterone, oxytocin, and estradiol on (Parvez, Raza-Bukhari, and Ismahan), 13
variables, endocrine and, in postmenopausal women with endometrial carcinoma, study of (Lucas and Yen), 180
Metabolism, perinatal calcium, effects of magnesium sulfate treatment on. I. Maternal and fetal responses (Cruikshank et al.), 243
Metastatic breast cancer, study of secretory component in patients with (Puleo et al.), 899
Methergine-induced uterine tetany treated with epinephrine: Case report (Wong and Paul), 602 (Comm. in brief)
Methyl ergonovine, ovum transport in women treated with (Guiloff et al.), 321
Microadenomas, prolactin-secreting, surgical treatment of (Wiebe, Kramer, and Hammond), 49
Microbiologic etiology of acute salpingitis, use of laparoscopy to determine (Sweet et al.), 68
Microsurgical removal, menstrual function, pituitary reserves, and prolactin production following, II. Prolactin-secreting pituitary adenomas in women (Keye et al.), 360
Midtrimester abortions induced by intra-amniotic prostaglandin $F_{2\alpha}$ with urea and intravenous oxytocin, laminaria use in (Strauss et al.), 260
Midtrimester—Cont'd
amniocentesis, report of safety and accuracy of, at Medical College of Georgia: Eight and one half years' experience (Manganiello et al.), 911
Mixed lymphocyte reaction, suppression of, by progesterone and estradiol-17β (Kobayashi et al.), 255
Model, primate, for study of endometrium, baboon as (Dollar et al.), 305
Monitoring intrapartum fetal, controlled trial of differential effects of (Haverkamp et al.), 399
Mosaicism 45,X/46,XX/47,XXX, sex chromosomal, induction of ovulation and pregnancy in woman with (Gemzell and Solisa), 599 (Comm. in brief)
Motility of human myometrium in vivo: Intramural versus transcervical recording (Coutinho et al.), 801
Movements, fetal breathing, in uncomplicated pregnancies. I. Relationship to gestational age (Fox, Inglis, and Steinbrecher), 544
Mucus, cervical, early studies on rheology of (Clift), 829 (Classic pages)
Myometrium, human, motility of, in vivo: Intramural versus transcervical recording (Coutinho et al.), 801
Myxometra, benign obstructive: Report of case (Honoré), 847 (Comm. in brief)

N

Naproxen sodium in uterine pain following intrauterine contraceptive device insertion (Buttram, Izu, and Henzl), 575
Natural family planning, randomized prospective study of use-effectiveness of two methods of: Interim report (Wade et al.), 628
Nephropathy, estriol determinations in diabetic pregnancies complicated by (Rothchild et al.), 772
Nevus, benign blue, of uterine cervix (Majmudar, Ross, and Gorelkin), 600 (Comm. in brief)
Newborn, tiny, delivery of (Haesslein and Goodlin), 192
Nipple, bilateral Paget's disease of: Case report (Anderson), 877
Nonoral contraceptive users, oral and, abnormalities among offspring of (Ortiz-Pérez et al.), 512
Nonstress test: Acceleration/constant ratio, II. Antepartum fetal testing (Barrada, Edwards, and Hakanson), 538
for antepartum assessment of fetal reserve (Lee and Drukker), 460

O

Obstetric(s)-gynecologic clinic, outpatient, screening for alcohol-related problems in (Russell and Bigler), 4
and gynecology clerkship, evaluating student performance in (Stenchever, O'Toole, and Irby), 235
clinic, private, social problems of women patients in (Barton, Harvey, and Barton), 477
Obstruction, fetal intestinal, spurious elevation of amniotic fluid bilirubin in acute hydramnios with (Wynn and Schreiner), 105 (Comm. in brief
Obstructive myxometra, benign: Report of case (Honoré), 847 (Comm. in brief)
Office termination of pregnancy by "menstrual aspiration" (Hale et al.), 213
Offspring of oral and nonoral contraceptive users, abnormalities among (Ortiz-Pérez et al.), 512
Oncology patient, gynecologic, quality of life for (Newton), 866
Operation, completed pelvic, improved survival following abdominopelvic irradiation in patients with: Ovarian carcinoma (Dembo et al.), 793
Operative evaluation, pretreatment lymphangiography and, in carcinoma of cervix (Lagasse et al.), 219
Optical density at 400 and 650 nm, tests of, comparison of lecithin/sphingomyelin ratio and: Assessment of fetal lung maturity (Spellacy et al.), 528
Oral contraceptive(s), increased platelet aggregation and decreased high-density lipoprotein cholesterol in women on (Bierenbaum et al.), 638
optimum dosage of (Lawson et al.), 315
steroids, effects of, on serum hexosaminidase activity, IV. Human hexosaminidase isozymes (Nitowsky et al.), 642
and nonoral contraceptive users, abnormalities among offspring of (Ortiz-Pérez et al.), 512
Osler's compass, points of (Lippard), 854
Outpatient obstetric-gynecologic clinic, screening for alcohol-related problems in (Russell and Bigler), 4

Ovarian carcinoma: Improved survival following abdominopelvic irradiation in patients with completed pelvic operation (Dembo et al.), 793
cysts, recurrent symptomatic functional, syndrome characterized by, in young women (Stone and Swartz), 310
disease, polycystic, peripheral steroid-gonadotropin interactions and diagnostic significance of double-stimulation tests with luteinizing hormone–releasing hormone in (Moltz et al.), 813
hyperandrogenism with normal and abnormal histologic findings of ovaries (Kim et al.), 445
refractoriness to gonadotropin, pregnancy-associated: Myth (diZerega and Hodgen), 819 (Current investigation)
tissues, normal and polycystic, endocrine studies of, in vitro (Wilson et al.), 56
tumor, unusual case of (Bambirra and Tafuri), 346 (Comm. in brief)
Ovary(ies), identical twins with twisted benign cystic teratoma of ovary (Brown), 879
ovarian hyperandrogenism with normal and abnormal histologic findings of (Kim et al.), 445
Ovulation, induction of, and pregnancy in woman with sex chromosomal mosaicism 45,X/46,XX/47,XXX (Gemzell and Solish), 599 (Comm. in brief)
Ovum transport in women treated with methyl ergonovine (Guiloff et al.), 321
Oxytocin challenge test, I. Antepartum fetal testing (Barrada, Edwards, and Hakanson), 532
estradiol, hypophysectomy, adrenalectomy, and progesterone, influence of, on metabolic fate of ^{3}H-epinephrine in central and peripheral regions during late pregnancy (Parvez, Raza-Bukhari, and Ismahan), 13
intravenous, urea and, laminaria use in midtrimester abortions induced by intra-amniotic prostaglandin $F_{2\alpha}$ with (Strauss et al.), 260

P

Pacific Coast Obstetrical and Gynecological Society, transactions, forty-fifth annual meeting, 115-224
Paget's disease, bilateral, of nipple: Case report (Anderson), 877
Pain, chronic pelvic, psychological aspects of, in women (Renaer et al.), 75
uterine, following intrauterine contraceptive device insertion, naproxen sodium in (Buttram, Izu, and Henzl), 575
Patterns, heart rate, and tissue pH, relationship of, in human fetus (Young, Katz, and Klein), 685
Pelvic operation, completed, improved survival following abdominopelvic irradiation in patients with: Ovarian carcinoma (Dembo et al.), 793
pain, chronic, psychological aspects of, in women (Renaer et al.), 75
vascular status, retinal and, correlation between: Determinant factor in patients undergoing pelvic irradiation for gynecologic malignancy (van Nagell et al.), 551
"Pelvis, frozen," tuberculous peritonitis and endometritis mimicking (Freedman, Coleman, and Blasco), 719 (Comm. in brief)
Penicillin-gentamicin, comparison of clindamycin-gentamicin and, in treatment of post–cesarean section endomyometritis (diZerega et al.), 238
Perinatal calcium metabolism, effects of magnesium sulfate treatment on, I. Maternal and fetal responses (Cruikshank et al.), 243
deaths in twin pregnancy (Medearis et al.), 413
Peritonitis and endometritis, tuberculosis, mimicking "frozen pelvis" (Freedman, Coleman, and Blasco), 719 (Comm. in brief)
pH, tissue, heart rate patterns and, relationship of, in human fetus (Young, Katz, and Klein), 685
Phagocytosis, human polymorphonuclear leukocyte, in pregnancy (Persellin and Thoi), 250
Pharmacologic cardioversion, attempted—Fetal tachycardia prior to development of hydrops: Case report (Klein, Holzman, and Austin), 347 (Comm. in brief)
Pituitary adenomas, prolactin-secreting, in women. II. Menstrual function, pituitary reserves, and prolactin production following microsurgical removal (Keye et al.), 360
-hypothalamic function and radiographic evaluation of women with hyperprolactinemia and "empty" sella turcica (Haney et al.), 917
responses to high concentrations of gonadal steroids in three-month-old infant with feminizing gonadal stromal tumor (Buchanan et al.), 648
Pituitary—Cont'd
tumors, galactorrhea and, in postpill and non-postpill secondary amenorrhea (March et al.), 45
Placental endocrine function, evaluation of, and changes in coagulation parameters: Induction of labor following intrauterine death with intra-amniotic hyperosmolar urea and prostaglandin $F_{2\alpha}$ (Sher), 493
function test, possible, III. Dehydroepiandrosterone loading test (Pupkin et al.), 281
Planning, natural family, randomized prospective study of use-effectiveness of two methods of: Interim report (Wade et al.), 628
Plasma fibrinolytic enzyme function and blood coagulation, influence of pregnancy upon (Fletcher, Alkjaersig, and Burstein), 743
human, and amniotic fluid, 13,14-dihydro-15-keto-prostaglandin $F_{2\alpha}$ concentrations in (Ghodgaonkar et al.), 265
luteinizing hormone–releasing hormone levels in: Radioimmunoassay method (Aksel and Glass), 619
maternal, effect of stress during labor on concentration of cortisol and estriol in (Maltau, Eielsen, and Stokke), 681
prolactin concentration, elevated, in cholestasis of pregnancy (Ranta et al.), 1
of women wearing intrauterine progesterone contraceptive system, human chorionic gonadotropin β-subunit–like immunoreactive material in (Orloff et al.), 632
Platelet aggregation, increased, and decreased high-density lipoprotein cholesterol in women on oral contraceptives (Bierenbaum et al.), 638
life span in pregnancies resulting in small–for–gestational age infants (Wallenburg and van Kessel), 739
Po_2, fetal, continuous variability of, in chronically catheterized fetal sheep (Jansen et al.), 776
Points of Osler's compass (Lippard), 854
Polycystic ovarian disease, peripheral steroid-gonadotropin interactions and diagnostic significance of double-stimulation tests with luteinizing hormone–releasing hormone in (Moltz et al.), 813
tissues, normal and, endocrine studies of, in vitro (Wilson et al.), 56
Polymorphonuclear leukocyte phagocytosis, human, in pregnancy (Persellin and Thoi), 250
Polypeptide, vasoactive intestinal, in tissues of human female reproductive tract (Goodnough et al.), 579 (Current investigation)
Postmenopausal women with endometrial carcinoma, study of endocrine and metabolic variables in (Lucas and Yen), 180
Postpartum lactation suppression, effect of chlorotrianisene as, on blood coagulation factors (Niebyl et al.), 518
uterine inversion, correction of, by application of intravaginal hydrostatic pressure (Sher), 601 (Comm. in brief)
vulvar edema, maternal deaths associated with (Ewing, Smale, and Elliott), 173
Postpill and non-postpill secondary amenorrhea, galactorrhea and pituitary tumors in (March et al.), 45
Prediction, antenatal, of graduated risk of hyaline membrane disease by amniotic fluid foam test for surfactant (Schlueter et al.), 761
Pregnancy(ies)-associated ovarian refractoriness to gonadotropin: Myth (diZerega and Hodgen), 819 (Current investigation)
association of Legionnaires' disease and (Baker and Philips), 227 (Comm. in brief)
cervical, bilateral internal iliac artery ligation in: Conservation of reproductive function (Nelson), 145
combined, ultrasonic detection of (Kurzel), 100 (Comm. in brief)
complicated by diabetes mellitus in private practice: Review of ten years (Corwin), 156
complications of, sexual behavior and response in relation to (Perkins), 498
diabetic, complicated by nephropathy, estriol determinations in Rothchild et al.), 772
early, demonstration of immunoreactive somatostatin-like substance in villi and decidua in (Kumasaka et al.), 39
ectopic: Current clinical trends (Kitchin et al.), 870
effect of, on cervical squamocolumnar junction in patients with abnormal cervical cytology (Ostergard), 759
evaluation of abnormal cervical cytology during, with colposcopy (Ostergard and Nieberg), 756
human, maternal and amniotic fluid steroids throughout (Nagamani et al.), 674

Pregnancy (pregnancies)—Cont'd
polymorphonuclear leukocyte phagocytosis in (Persellin and Thoi), 250
induction of ovulation and, in woman with sex chromosomal mosaicism 45,X/46,XX/47,XXX (Gemzell and Solish), 599 (Comm. in brief)
influence of, upon blood coagulation and plasma fibrinolytic enzyme function (Fletcher, Alkjaersig, and Burstein), 743
and labor, autonomic hyperreflexia in: Case report (Nath, Vivian, and Cherny), 390
late, effect of dexamethasone on prolactin secretion in (Kauppila, Puukka, and Tuimala), 752
influence of hypophysectomy, adrenalectomy, progesterone, oxytocin, and estradiol on metabolic fate of ^{3}H-epinephrine in central and peripheral regions during (Parvez, Raza-Bukhari, and Ismahan), 13
normal and abnormal, radioreceptor assay for human chorionic gonadotropin in: Clinical evaluation (Lorenz, Work, and Menon), 471
I. Short-term cycles in human fetal activity (Granat et al.), 696
office termination of, by "menstrual aspiration" (Hale et al.), 213
prolonged, management of: Results of prospective randomized trial (Knox, Huddleston, and Flowers), 376
resulting in small-for-gestational age infants, platelet life span in (Wallenburg and van Kessel), 739
second-trimester, maternal and fetal renin activity and renin and big renin concentrations in (Franks and Hayashi), 20
-specific" beta-1 glycoprotein, human fibroblasts produce, in vitro (Rosen et al.), 734
thalassemia and: Results of antenatal screening program (Alger, Golbus, and Laros), 662
tubal, cause of: Leiomyoma of fallopian tube (Moore, Waxman, and Udoffia), 101 (Comm. in brief)
twin, bed rest in: Identification of critical period and its cost implications (Powers and Miller), 23
perinatal deaths in (Medearis et al.), 413
uncomplicated, fetal breathing movements in. I. Relationship to gestational age (Fox, Inglis, and Steinbrecher), 544
unsuspected subclinical, in patients with luteal phase defects (Cline), 438
in woman with xanthinuria: Study of amniotic fluid uric acid (Curiel and Bandinelli), 721 (Comm. in brief)
Pregnant baboon, experimental observation in: Reduced uterine blood flow and fetal hypoxemia with acute maternal stress (Morishima, Yeh, and James), 270
sickle cell disease patients, transfusion therapy in, 851 (Editorial)
Preinduction use of laminaria for unripe cervix (Lackritz, Gibson, and Frigoletto), 349 (Comm. in brief)
Premature menopause, clinically diagnosed, identification of differing etiologies of (Board et al.), 936
rupture of membranes: Conservative approach (Kappy et al.), 655
Prematurely ruptured membranes and fetal immunoglobulin production, relationship between (Cederqvist et al.), 784
Prenatal diagnosis of sacrococcygeal teratoma (Horger and McCarter), 228 (Comm. in brief)
of Tay-Sachs disease: Studies on reliability of hexosaminidase levels in amniotic fluid (Grebner and Jackson), 547
Pressure, intravaginal hydrostatic, correction of postpartum uterine inversion by application of (Sher), 601 (Communication in brief)
lower esophageal sphincter, during normal menstrual cycle (Van Thiel, Gavaler, and Stremple), 64
Preterm labor, induction of, in rat by antiprogesterone (Csapo and Resch), 823 (Current investigation)
Pretreatment lymphangiography and operative evaluation in carcinoma of cervix (Lagasse et al.), 219
Prevention of respiratory distress syndrome, role of glucocorticoids, unstressful labor, and atraumatic delivery in (Quirk et al.), 768
Previa, vasa (Pent), 151
Private obstetrics and gynecology clinic, social problems of women patients in (Barton, Harvey, and Barton), 477
practice, pregnancy complicated by diabetes mellitus in: Review of ten years (Corwin), 156
Progesterone contraceptive system, intrauterine, human chorionic gonadotropin β-subunit–like immunoreactive material in plasma of women wearing (Orloff et al.), 532
and estradiol-17β, suppression of mixed lymphocyte reaction by (Kobayashi et al.), 255
Progesterone—Cont'd
oxytocin, estradiol, hypophysectomy, and adrenalectomy, influence of, on metabolic fate of ^{3}H-epinephrine in central and peripheral regions during late pregnancy (Parvez, Raza-Bukhari, and Ismahan), 13
topical, further observations on effect of, on vulvar disease (Jasionowski and Jasionowski), 565
Prolactin concentration, elevated plasma, in cholestasis of pregnancy (Ranta et al.), 1
effects of, on pulmonary maturation in fetal rabbit (Van Petten and Bridges), 711
-secreting microadenomas, surgical treatment of (Wiebe, Kramer, and Hammond), 49
pituitary adenomas in women. II. Menstrual function, pituitary reserves, and prolactin production following microsurgical removal (Keye et al.), 360
secretion in late pregnancy, effect of dexamethasone on (Kauppila, Puukka, and Tuimala), 752
Prolonged pregnancy, management of: Results of prospective randomized trial (Knox, Huddleston, and Flowers), 376
Prophylactic antibiotics, efficacy of, in cesarean section (Gall), 506
Prophylaxis, perioperative cephalosporin, in cesarean section: Effect of endometritis in high-risk patient (Kreutner et al.), 925
Prostaglandin E_2 suppositories, vaginal, uterine rupture with use of (Sandler et al.), 348 (Comm. in brief)
$F_{2\alpha}$, 13,14-dihydro-15-keto-, concentrations in human plasma and amniotic fluid (Ghodgaonkar et al.), 265
intra-amniotic hyperosmolar urea and, induction of labor following intrauterine death with: Evaluation of placental endocrine function and changes in coagulation parameters (Sher), 493
with urea and intravenous oxytocin, laminaria use in midtrimester abortions induced by (Strauss et al.), 260
Psychological aspects of chronic pelvic pain in women (Renaer et al.), 75
Pulmonary edema associated with magnesium sulfate and betamethasone administration (Elliott et al.), 717 (Comm. in brief)
maturation in fetal rabbit, effects of prolactin on (Van Petten and Bridges), 711

Q

Quality of life for gynecologic oncology patient (Newton), 865

R

Radical hysterectomy: Critical review of twenty-two years' experience (Underwood et al.), 889
Radiographic evaluation and hypothalamic-pituitary function of women with hyperprolactinemia and "empty" sella turcica (Haney et al.), 917
Radioimmunoassay method: Luteinizing hormone–releasing hormone levels in human plasma (Aksel and Glass), 619
Radioreceptor assay for human chorionic gonadotropin in normal and abnormal pregnancies: Clinical evaluation (Lorenz, Work, and Menon), 471
Rate acceleration, fetal heart, in labor: Excellent prognostic indicator (Powell, Melville, and MacKenna), 36
fetal heart, acceleration of (Wood, Walker, and Yardley), 523
patterns, heart, and tissue pH, relationship of, in human fetus (Young, Katz, and Klein), 685
variability, fetal heart: Approach to automated assessment (Huey et al.), 691
Ratio(s), acceleration/constant: Nonstress test, II. Antepartum fetal testing (Barrada, Edwards, and Hakanson), 538
lecithin/sphingomyelin, lidocaine interference in (Clague and McGeary), 229 (Comm. in brief)
and tests of optical density at 400 and 650 nm, comparison of: Assessment of fetal lung maturity (Spellacy et al.), 528
value of, in diabetes: Critical review (Lowensohn and Gabbe), 702
Receptors, female sex hormone, and their importance in clinical practice (Taylor), 385
Recording, intramural versus transcervical: Motility of human myometrium in vivo (Coutinho et al.), 801
Recurrent symptomatic functional ovarian cysts, syndrome characterized by, in young women (Stone and Swartz), 310
Refractoriness, ovarian, to gonadotropin, pregnancy-associated: Myth (diZerega and Hodgen), 819 (Current investigation)

Regeneration, human endometrial, studies on cytodynamics of. III. In vitro short-term incubation historadioautography (Ferenczy, Bertrand, and Gelfand), 297
Releasing hormone, luteinizing hormone–, and clomiphene, effect of dexamethasone on gonadotropin responsiveness to, in women with secondary amenorrhea (Sowers and Fayez), 325
diagnostic significance of double-stimulation tests with, and peripheral steroid-gonadotropin interactions in polycystic ovarian disease (Moltz et al.), 813
levels in human plasma: Radioimmunoassay method (Aksel and Glass), 619
thyrotropin-, and thyroid hormones in amniotic fluid (Morley et al.), 581 (Current investigation)
Renin activity and renin and big renin concentrations, maternal and fetal, in second-trimester pregnancy (Franks and Hayashi), 20
Reproductive function(s), conservation of: Bilateral internal iliac artery ligation in cervical pregnancy (Nelson), 145
do endorphin residues of beta lipotropin in hormone reinforce (Kimball), 127
tract, human female, vasoactive intestinal polypeptide in tissues of (Goodnough et al.), 579 (Current investigation)
Reserve, fetal, nonstress test for antepartum assessment of (Lee and Drukker), 460
Respiratory distress syndrome, role of glucocorticoids, unstressful labor, and atraumatic delivery in prevention of (Quirk et al.), 768
Retardation, intrauterine growth, value of diagnostic ultrasound as screening test for: Comparison of nine parameters (Wittmann et al.), 30
Retinal and pelvic vascular status, correlation between: Determinant factor in patients undergoing pelvic irradiation for gynecologic malignancy (van Nagell et al.), 551
Rheology of cervical mucus, early studies on (Clift), 829 (Classic pages)
Risk(s), graduated, of hyaline membrane disease, antenatal prediction of, by amniotic fluid foam test for surfactant (Schlueter et al.), 761
high-, patient, effect of endometritis in: Perioperative cephalosporin prophylaxis in cesarean section (Kreutner et al.), 925
trends, and indications: Ten-year review of hysterectomies (Amirikia and Evans), 431
Rupture, premature, of membranes: Conservative approach (Kappy et al.), 655
uterine, with use of vaginal prostaglandin E_2 suppositories (Sandler et al.), 348 (Comm. in brief)
Ruptured membranes, prematurely, and fetal immunoglobulin production, relationship between (Cederqvist et al.), 784

S

Sac, human chorioamniotic, deformation and creep in (Lavery and Miller), 366
Sachs, Tay-, disease, prenatal diagnosis of: Studies on reliability of hexosaminidase levels in amniotic fluid (Grebner and Jackson), 547
Sacrococcygeal teratoma, prenatal diagnosis of (Horger and McCarter), 228 (Comm. in brief)
Safety and accuracy of midtrimester amniocentesis, report of, at Medical College of Georgia: Eight and one half years' experience (Manganiello et al.), 911
Salpingitis, acute, use of laparoscopy to determine microbiologic etiology of (Sweet et al.), 68
Screening for alcohol-related problems in outpatient obstetric-gynecologic clinic (Russell and Bigler), 4
of diethylstilbestrol-exposed population, six years' experience with (Mangan et al.), 860
program, antenatal, results of: Thalassemia and pregnancy (Alger, Golbus, and Laros), 662
test for intrauterine growth retardation, value of diagnostic ultrasound as: Comparison of nine parameters (Wittmann et al.), 30
Second-trimester pregnancy, maternal and fetal renin activity and renin and big renin concentrations in (Franks and Hayashi), 20
Secondary amenorrhea, effect of dexamethasone on gonadotropin responsiveness to luteinizing hormone–releasing hormone and clomiphene in women with (Sowers and Fayez), 325
postpill and non-postpill, galactorrhea and pituitary tumors in (March et al.), 45
Secreting, prolactin-, microadenomas, surgical treatment of (Wiebe, Kramer, and Hammond), 49
pituitary adenomas in women. II. Menstrual function, pituitary reserves, and prolactin production following microsurgical removal (Keye et al.), 360
Secretion, prolactin, in late pregnancy, effect of dexamethasone on (Kauppila, Puukka, and Tuimala), 752
Secretory component, study of, in patients with metastatic breast cancer (Puleo et al.), 899
Section, cesarean, efficacy of prophylactic antibiotics in (Gall), 506
perioperative cephalosporin prophylaxis in: Effect on endometritis in high-risk patient (Kreutner et al.), 925
vaginal breech delivery or (Lewis and Seneviratne), 615 (Clinical opinion)
post–cesarean, endomyometritis, comparison of clindamycin-gentamicin and penicillin-gentamicin in treatment of (diZerega et al.), 238
Sella turcica, "empty," and hyperprolactinemia, hypothalamic-pituitary function and radiographic evaluation of women with (Haney et al.), 917
Serum hexosaminidase activity, effects of oral contraceptive steroids on, IV. Human hexosaminidase isozymes (Nitowsky et al.), 642
Sex chromosomal mosaicism 45,X/46,XX/47,XXX, induction of ovulation and pregnancy in women with (Gemzell and Solish), 599 (Comm. in brief)
hormone receptors, female, and their importance in clinical practice (Taylor), 385
Sexual behavior and response in relation to complications of pregnancy (Perkins), 498
Shedding, asymptomatic cervicovaginal, of herpes simplex virus (Ekwo, Wong, and Myers), 102 (Comm. in brief)
Shock, endotoxin, in beagle dog (Morris et al.) 120
Sickle cell disease patients, pregnant, transfusion therapy in, 851 (Editorial)
Simplex virus, herpes, asymptomatic cervicovaginal shedding of (Ekwo, Wong, and Myers), 102 (Comm. in brief)
Situ, carcinoma in, severe dysplasia and, of vagina (Oliver), 133
Small–for–gestational age infants, platelet life span in pregnancies resulting in (Wallenburg and van Kessel), 739
Social issues, legal and, in medical genetics (Turner, Hayashi, and Pogoloff), 83 (Current developments)
problems of women patients in private obstetrics and gynecology clinic (Barton, Harvey, and Barton), 477
Sodium, naproxen, in uterine pain following intrauterine contraceptive device insertion (Buttram, Izu, and Henzl), 575
Somatostatin-like substance, immunoreactive, in villi and decidua, demonstration of, in early pregnancy (Kumasaka et al.), 39
Sphincter pressure, lower esophageal, during normal menstrual cycle (Van Thiel, Gavaler, and Stremple), 64
Sphingomyelin, lecithin/, ratio(s), lidocaine interference in (Clague and McGeary), 229 (Comm. in brief)
and tests of optical density at 400 and 650 nm, comparison of: Assessment of fetal lung maturity (Spellacy et al.), 528
value of, in diabetes: Critical review (Lowensohn and Gabbe), 702
Squamocolumnar junction, cervical, effect of pregnancy on, in patients with abnormal cervical cytology (Ostergard), 759
Squamous carcinoma of vulva: Results of treatment, 1938 to 1976 (Benedet et al.), 201
cell cancer, Stage I, of vulva (Magrina et al.), 453
Stability, amniotic fluid foam, –50 percent test, performance of (Sher et al.), 705
Stage I squamous cell cancer of vulva (Magrina et al.), 453
Steroid(s), gonadal, hypothalamic-pituitary responses to high concentrations of, in three-month-old infant with feminizing gonadal stromal tumor (Buchanan et al.), 648
-gonadotropin interactions, peripheral, and diagnostic significance of double-stimulation tests with luteinizing hormone–releasing hormone in polycystic ovarian disease (Moltz et al.), 813
maternal and amniotic fluid, throughout human pregnancy (Nagamani et al.), 674
oral contraceptive, effects of, on serum hexosaminidase activity, IV. Human hexosaminidase isozymes (Nitowsky et al.), 642
Stimulation tests, double-, with luteinizing hormone–releasing hormone, diagnostic significance of, and peripheral steroid-gonadotropin interactions in polycystic ovarian disease (Moltz et al.), 813

Stress, acute maternal, reduced uterine blood flow and fetal hypoxemia with: Experimental observation in pregnant baboon (Morishima, Yeh. and James), 270
during labor, effect of, on concentration of cortisol and estriol in maternal plasma (Maltau, Eielsen, and Stokke), 681
Stromal tumor, feminizing gonadal, hypothalamic-pituitary responses to high concentrations of gonadal steroids in three-month-old infant with (Buchanan et al.), 648
Student performance in obstetrics and gynecology clerkship, evaluating (Stenchever, O'Toole, and Irby), 235
Subclinical pregnancies, unsuspected, in patients with luteal phase defects (Cline), 438
Subunit, β-, –like immunoreactive material, human chorionic gonadotropin, in plasma of women wearing intrauterine progesterone contraceptive system (Orloff et al.), 632
Successors, our (Dignam), 115
Sulfate, magnesium, and betamethasone administration, pulmonary edema associated with (Elliott et al.), 717 (Comm. in brief)
treatment, effects of, on perinatal calcium metabolism. I. Maternal and fetal responses (Cruikshank et al.), 243
Suppositories, vaginal prostaglandin E_2, uterine rupture with use of (Sandler et al.), 348 (Comm. in brief)
Surfactant, amniotic fluid foam test for, antenatal prediction of graduated risk of hyaline membrane disease by (Schlueter et al.), 761
Surgery, amnion in, past and present (Trelford and Trelford-Sauder), 833 (Current developments)
Surgical treatment of prolactin-secreting microadenomas (Wiebe, Kramer, and Hammond), 49
Survival, improved, following abdominopelvic irradiation in patients with completed pelvic operation: Ovarian carcinoma (Dembo et al.), 793
Symptoms, urinary incontinence, in women, urodynamic analysis of (Drutz and Mandel), 789
Syndrome characterized by recurrent symptomatic functional ovarian cysts in young women (Stone and Swartz), 310
respiratory distress, role of glucocorticoids, unstressful labor, and atraumatic delivery in prevention of (Quirk et al.), 768

T

T, Copper, intrauterine contraceptive device, comparison of three different models of (Roy et al.), 568
Tachycardia, fetal, prior to development of hydrops—Attempted pharmacologic cardioversion: Case report (Klein, Holzman, and Austin), 347 (Comm. in brief)
Tay-Sachs disease, prenatal diagnosis of: Studies on reliability of hexosaminidase levels in amniotic fluid (Grebner and Jackson), 547
Teratoma, sacrococcygeal, prenatal diagnosis of (Horger and McCarter), 228 (Comm. in brief)
twisted benign cystic, of ovary, identical twins with (Brown), 879
Term, fetal death at, due to lightning (Guha-Ray), 103 (Comm. in brief)
Termination, office, of pregnancy by "menstrual aspiration" (Hale et al.), 213
Test(s), amniotic fluid foam stability–50 percent, performance of (Sher et al.), 705
for surfactant, antenatal prediction of graduated risk of hyaline membrane disease by (Schlueter et al.), 761
dehydroepiandrosterone loading. III. Possible placental function test (Pupkin et al.), 281
double-stimulation, with luteinizing hormone–releasing hormone, diagnostic significance of, and peripheral steroid-gonadotropin interactions in polycystic ovarian disease (Moltz et al.), 813
nonstress: Acceleration/constant ratio, II. Antepartum fetal testing (Barrada, Edwards, and Hakanson), 538
for antepartum assessment of fetal reserve (Lee and Drukker), 460
of optical density at 400 and 650 nm, comparison of lecithin/sphingomyelin ratio and: Assessment of fetal lung maturity (Spellacy et al.), 528
oxytocin challenge, I. Antepartum fetal testing (Barrada, Edwards, and Hakanson), 532
screening, for intrauterine growth retardation, value of diagnostic ultrasound as: Comparison of nine parameters (Wittmann et al.), 30
Testing, antepartum fetal. I. Oxytocin challenge test (Barrada, Edwards, and Hakanson), 538
Testing, antepartum fetal—Cont'd
II. Acceleration/constant ratio: Nonstress test (Barrada, Edwards, and Hakanson), 538
Tetany, methergine-induced uterine, treated with epinephrine: Case report (Wong and Paul), 602 (Comm. in brief)
Thalassemia and pregnancy: Results of antenatal screening program (Alger, Golbus, and Laros), 662
Therapy, transfusion, in pregnant sickle cell disease patients, 851 (Editorial)
Thyroid hormones, thyrotropin-releasing hormone and, in amniotic fluid (Morley et al.), 581 (Current investigation)
Thyrotropin-releasing hormone and thyroid hormones in amniotic fluid (Morley et al.), 581 (Current investigation)
Time (Goddard), 355
Tiny newborn, delivery of (Haesslein and Goodlin), 192
Tissue(s) of human female reproductive tract, vasoactive intestinal polypeptide in (Goodnough et al.), 579 (Current investigation)
normal human, presence in: Human chorionic gonadotropin–like material (Yoshimoto et al.), 729
and polycystic ovarian, endocrine studies of, in vitro (Wilson et al.), 56
pH, heart rate patterns and, relationship of, in human fetus (Young, Katz, and Klein), 685
Topical progesterone, further observations on effect of, on vulvar disease (Jasionowski and Jasionowski), 565
Transactions, forty-fifth annual meeting, Pacific Coast Obstetrical and Gynecological Society, 115-224
forty-sixth annual meeting, Central Association of Obstetricians and Gynecologists, 355-492
Transcervical versus intramural recording: Motility of human myometrium in vivo (Coutinho et al.), 801
Transfusion therapy in pregnant sickle cell disease patients, 851 (Editorial)
Transport, maternal: Behind drama (Souma), 904
one-way maternal: Evolving concept (Boehm and Haire), 484
Treated with epinephrine, methergine-induced uterine tetany: Case report (Wong and Paul), 602 (Comm. in brief)
with methyl ergonovine, ovum transport in women (Guiloff et al.), 321
Treatment, magnesium sulfate, effects of, on perinatal calcium metabolism. I. Maternal and fetal responses (Cruikshank et al.), 243
of post–cesarean section endomyometritis, comparison of clindamycin-gentamicin and penicillin-gentamicin in (diZerega et al.), 238
results of, 1938 to 1976: Squamous carcinoma of vulva (Benedet et al.), 201
surgical, of prolactin-secreting microadenomas (Wiebe, Kramer, and Hammond), 49
Trends, current clinical: Ectopic pregnancy (Kitchin et al.), 870
Trimester, second-, pregnancy, maternal and fetal renin activity and renin and big renin concentrations in (Franks and Hayashi), 20
Tubal ligation by colpotomy incision (Whitaker), 885
pregnancy, cause of: Leiomyoma of fallopian tube (Moore, Waxman, and Udoffia), 101 (Comm. in brief)
Tube, fallopian, leiomyoma of: Cause of tubal pregnancy (Moore, Waxman, and Udoffia), 101 (Comm. in brief)
partial atresia of, and bicornuate uterus (Farber and Mitchell), 881
Tuberculous peritonitis and endometritis mimicking "frozen pelvis" (Freedman, Coleman, and Blasco), 719 (Comm. in brief)
Tumor(s), feminizing gonadal stromal, hypothalamic-pituitary responses to high concentrations of gonadal steroids in three-month-old infant with (Buchanan et al.), 648
ovarian, unusual case of (Bambirra and Tafuri), 345 (Comm. in brief)
pituitary, galactorrhea and, in postpill and non-postpill secondary amenorrhea (March et al.), 45
Twin(s), identical, with twisted benign cystic teratoma of ovary (Brown), 879
pregnancy, bed rest in: Identification of critical period and its cost implications (Powers and Miller), 23
perinatal deaths in (Medearis et al.), 413

U

Ultrasonic detection of combined pregnancies (Kurzel), 100 (Comm. in brief)
evaluation of fetal heart (Yamaguchi and Lee), 422

Ultrasound in diagnosis of congenital anomalies (Hobbins et al.), 331 (Current developments)
diagnostic, value of, as screening test for intrauterine growth retardation: Comparison of nine parameters (Wittmann et al.), 30
Unripe cervix, preinduction use of laminaria for (Lackritz, Gibson, and Frigoletto), 349 (Comm. in brief)
Urea, intra-amniotic hyperosmolar, and prostaglandin $F_{2\alpha}$, induction of labor following intrauterine death with: Evaluation of placental endocrine function and changes in coagulation parameters (Sher), 493
and intravenous oxytocin, laminaria use in midtrimester abortions induced by intra-amniotic prostaglandin $F_{2\alpha}$ with (Strauss et al.), 260
Uric acid, amniotic fluid, study of: Pregnancy in women with xanthinuria (Curiel and Bandinelli), 721 (Comm. in brief)
Urinary incontinence symptoms in women, urodynamic analysis of (Drutz and Mandel), 789
tract endometriosis: Enigmas in diagnosis and management (Moore et al.), 162
Urodynamic analysis of urinary incontinence symptoms in women (Drutz and Mandel), 789
Urography, intravenous, prior to abdominal hysterectomy for gynecologic disease, value of (Sack), 208
Uterine blood flow, reduced, and fetal hypoxemia with acute maternal stress: Experimental observation in pregnant baboon (Morishima, Yeh, and James), 270
cervix, benign blue nevus of (Majmudar, Ross, and Gorelkin), 600 (Comm. in brief)
inversion, postpartum, correction of, by application of intravaginal hydrostatic pressure (Sher), 601 (Comm. in brief)
leiomyosarcoma (Hannigan and Gomez), 557
pain following intrauterine contraceptive device insertion, naproxen sodium in (Buttram, Izu, and Henzl), 575
rupture with use of vaginal prostaglandin E_2 suppositories (Sandler et al.), 348 (Comm. in brief)
tetany, methergine-induced, treated with epinephrine: Case report (Wong and Paul), 602 (Comm. in brief)
Uterus, bicornuate, and partial atresia of fallopian tube (Farber and Mitchell), 881

V

Vagina, severe dysplasia and carcinoma in situ of (Oliver), 133
Vaginal breech delivery or cesarean section (Lewis and Seneviratne), 615 (Clinical opinion)
prostaglandin E_2 suppositories, uterine rupture with use of (Sandler et al.), 348 (Comm. in brief)

Sure as a new day will dawn, Peri-Colace® works with gentle, proven predictability

ERI-COLACE combines the gentle xative and effective stool softener often needed when bowel motility depressed. PERI-COLACE acts gently induce peristalsis, while the stool-ftening agent lets natural intestinal ter permeate stools.

PERI-COLACE is predictable—gentle evacuation usually occurs within 8 to 12 hours. It is useful in obstetrical patients, as well as in geriatrics, pre- and postoperative patients, the convalescent, in patients with medication-related suppression of bowel motility and children.

PERI-COLACE—gentle, proven, pre dictable. In capsule and liquid forms

PERI-COLACE

casanthranol and dioctyl sodium sulfosuccinat

Gentle laxative plus stool softene
